(Received August 29, 1955)

The energy spectrum and the angular distribution of the neutrons from the $N^{14}(d,n)O^{15}$ reaction were investigated by the photographic plate method. The energy of the bombarding deuterons was 1.85 MeV, and the $Q$-value corresponding to the ground state of $O^{15}$ nucleus was obtained to be $(5.21 \pm 0.07)$ MeV. The low energy neutron group corresponding to the first excited state of $O^{15}$ nucleus was also observed, but it overlapped with the contaminated $C^{12}(d,n)N^{13}$ neutrons and the accurate $Q$-value could not be determined. The estimated rough value was about $-0.1$ MeV.

The angular distribution of the high energy neutron group has a maximum at about 20 degrees (c.m.s.) and decreases considerably beyond this maximum, indicating the stripping process corresponding to $l_p=1$.

This reaction may be a good source of neutrons of about 7 MeV at the bombarding energies of deuterons below 2 MeV.

## § 1. Introduction

The neutrons from the $N^{14}(d, n)O^{15}$ reaction were investigated quantitatively first by Stephens et al.[1]. They bombarded a $NaNO_2$ thick target by an unanalysed deuteron beam of 0.93 MeV and found two groups of neutrons corresponding to the $Q$-value of $Q_0=(5.1 \pm 0.2)$ and $Q_1=(1.1 \pm 0.2)$ MeV respectively. Afterwards, Gibson and Livesey[2] also investigated this reaction at the same bombarding energy and found that there existed only one group of neutrons of which $Q$-value was $Q_0=(5.15 \pm 0.10)$ MeV, and the angular distribution of this group was almost isotropic in the centre-of-mass system.

Hudspeth and Swann[3] observed initially two groups of neutrons at the bombarding energy of 1.2 MeV of deuterons, but it was reported afterwards[4] that the observed low energy group was that from the alminium contained in the target material. Rose et al.[4] observed two groups of neutrons at the bombarding energy of 1.7 MeV of deuterons, and their $Q$-values were $Q_0=5.1$ and $Q_1=0.2$ MeV respectively.

At the bombarding energy of 7.69 MeV of deuterons, Evans et al[5]. observed seven groups of neutrons, and they measured the angular distributions of each group and estimated the $l_p$-values according to Butler's stripping theory.

Considering the above mentioned results obtained hitherto, the neutrons from this reaction are thought to consist of single group at the bombarding energies of deuterons below 1 MeV, and the low energy group corresponding to the first excited state of $O^{15}$ nucleus may begin to appear at a bombarding energy between 1 and 2 MeV, but the intensity of this group is expected to be not so strong. At these bombarding energies the energy of this group is estimated to have a value between 1 and 1.5 MeV from the $Q$-value of $Q_1=(-0.14 \pm 0.11)$ MeV obtained by Evans et al.[4] and is far below than that of the high energy group (about 7 MeV). So this reaction may be a good source of neutrons of about 7 MeV.[6]

On the other hand, the stripping process of deuterons of energy between 1 and 2 MeV contains many problems, i.e., competition with the compound process, the effect of Coulomb barrier, and the interaction between the emitted particle (neutron) and the residual nucleus.

---

* Now at Rigakudenki Ltd., Kichijōji, Tokyo.

On the above standpoint we investigated the energy spectrum and the angular distribution of the neutrons emitted by this reaction at the bombarding energy of 1.85 MeV of deuterons.

## § 2. Experimental Arrangements and Procedures

The deuteron bombardment was performed with the Van de Graaff accelerator at the Kyushu University and its voltage used in this experiment was 2.20 MV. The accelerating voltage was simply stabilized by controlling the spray voltage automatically with the corona current from the high voltage electrode to a corona point, and the voltage fluctuation of the electrode was less than one per cent..

Nitrogen gas was used as the target material. The target chamber, as shown in Fig. 1, consists of two coaxial cylinders, their bottoms being placed 4 cm apart, of which the outer one is of brass 3.5 cm in inside diameter and 0.15 cm in thickness, and the inner one is of steel 3.3 cm in outside diameter and 0.1 cm in thickness. The entrance to the target chamber is an aperture of 1.0 cm in diameter drilled in the bottom of the inner cylinder and sealed with a silver foil of 2.4 mg/cm$^2$ thick, prepared by the vacuum evaporation method. Any portion of the target assembly exposed to the deuteron beam is covered with silver plates as perfectly as possible in order to reduce the neutron background. The nitrogen gas used is commercial one and gas pressure of the chamber is 20 cm Hg.

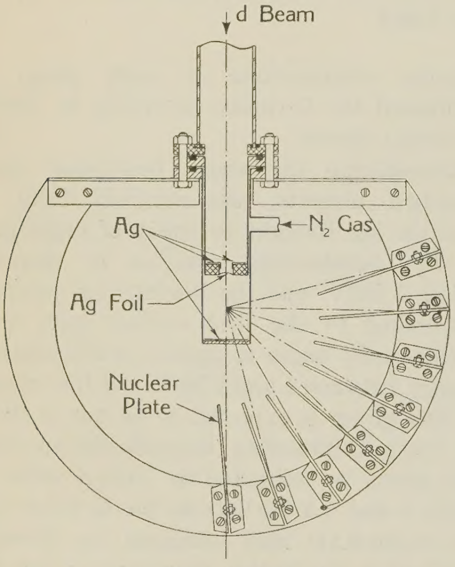

Fig. 1. Arrangements of the target chamber and photographic plates.

Nuclear photo-emulsion were used to detect the neutrons. Each nuclear plate was wraped completely in a thin black paper, after being covered with an alminium foil of about 0.1 cm in thickness to absorb protons produced in the black paper. These plates were placed on an alminium frame, surrounding the centre of the target chamber circularly at eight angles of 0.8, 14.2, 29.2, 44.2, 59.2, 74.2, 89.2 and 104.2 degrees* respectively with respect to the incident deuteron beam. The glancing angle of each plate was chosen to be 5 degrees.

The effective energy of the bombarding deuteron was taken as 1.85 MeV, considering the thickness of the silver foil window of the target chamber, 210 keV, and that of the nitrogen gas, 280 keV, respectively.

Since the target assembly itself was insulated from the ground, it was able to be used conveniently as a collector cup for the deuteron beam and was connected to both a current integrator7) and micro-ammeter in series. The analysed ion beam employed was $0.3\,\mu A$ in average during the bombardment time. The ion beam which entered into the target assembly was found to be utilized almost completely, but the available quantity of the deuterons was somewhat uncertain, since some molecular hydrogen ions were contained in the ion beam and their content was not known accurately.

The bombardment was performed in the two cases; one was the case in which the nitrogen gas was present in the target chamber and the other no gas present. Both runs were carried out similarly for about two hours in such a way that the total integrated ion currents used in both runs were equal.

The plates used were 150 micron Sakura NR-Ml nuclear plates. After the exposure the plates were processed by the two-bath development method according to the procedure recommended by the manufacturer. The original plate size was $8.2\times10.7\,\mathrm{cm}^2$, and each plate was divided into six parts for the exposure. To measure the emulsion thickness, a small piece was again cut off from the each divided plate, and the thickness of the glass backing plus emulsion and that of the glass backing alone were measured with a screw micrometer. The emulsion thickness was obtained as the difference of these two values. The thickness of the processed emulsion was measured with the fine-focus screw of a microscope, and the ratio of the thickness of the unprocessed emulsion to that of the processed one gave the shrinkage factor, the mean value of which was 2.2±0.1.

---

* The values of these angles are referred to the centres of the scanned area of each plate.

The scanning was performed throughout with Tiyoda L.C.M. binocular microscopes with ×7 eye pieces and ×135 oil immersion objectives. In each plate the region was scanned which had rectangular shape, 2 cm long and 0.6 cm wide, centred about the line connecting the centres of the target and the plate. The centre of the scanning region was about 3 cm distant from the inner edge of the plate, and 9.5 cm from the centre of the target chamber. Those recoil proton tracks were recorded which had horizontal angles of less than or equal to 15 degrees with the central line and dip angles of less than or equal to 15 degrees in the unprocessed emulsion, and originated and ended in the emulsion.

In the present experiment, for the sake of simplicity, we merely measured the projected length to the emulsion surface of the available tracks selected with the above criteria. From this measured quantity alone, the corresponding energy of the neutron is obtained with the following procedures.

The projected length $R_p$ of a recoil proton track is related to the absolute range $L_p$ of the proton in the unprocessed emulsion by the formula[8],

$$L_p = R_p/\overline{\cos\psi}\ , \qquad (1)$$

where $\overline{\cos\psi}$ is the average value of the cosine of the angle $\psi$ between $R_p$ and $L_p$, as shown in Fig. 2. With the slightly approximate calculations, it is easily found that $\overline{\cos\psi}$ is the function of the angles $\theta_{\max}$ and $\phi_{\max}$, which are the maximum values of the half angles $\theta$ and $\phi$ respectively of the rectangular pyramid formed by the recoil proton track. In the present case both $\theta_{\max}$ and $\phi_{\max}$ are 15 degrees.

The energy of the recoil proton, the absolute range of which is calculated by the above formula, is obtained directly from the range-energy relation. But the range-energy relation in the emulsion used was not known, so the relation calculated by Webb's method[9] taking into account the air humidity was used. It has been reported[9)10)11] that the relations calculated by this method of the several emulsions generally used were in good agreement with the experimental results. For the proton energies higher than 1 MeV, our calculated curve agreed well with the experimental proton range-energy curve for NTA emulsion in the air[10], as shown in Fig. 3. It was also found that the mean range of the alpha-particles in our emulsion obtained by contacting the Po-alpha source to the emulsion surface in the air was (21.5±0.5) microns, which fell within the error on the experimental curves

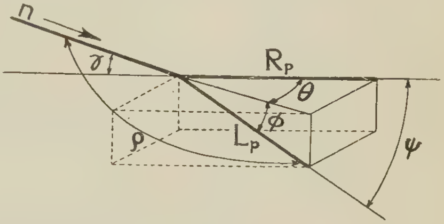

Fig. 2. Relation between the incident neutron and the recoil proton. $L_p$ is the absolute range of the proton in the unprocessed emulsion and $R_p$ is the projected length to the emulsion surface of the recoil proton track.

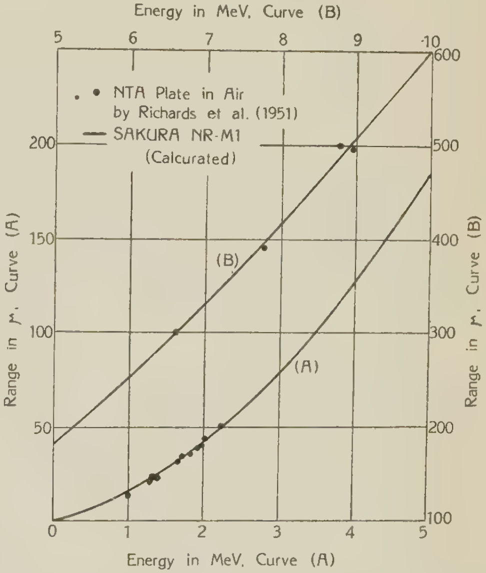

Fig. 3. Proton range-energy curve for Sakura NR-M1 emulsion, calculated by Webb's method. The circles are the experimental points by Richards et al. for NTA emulsion.

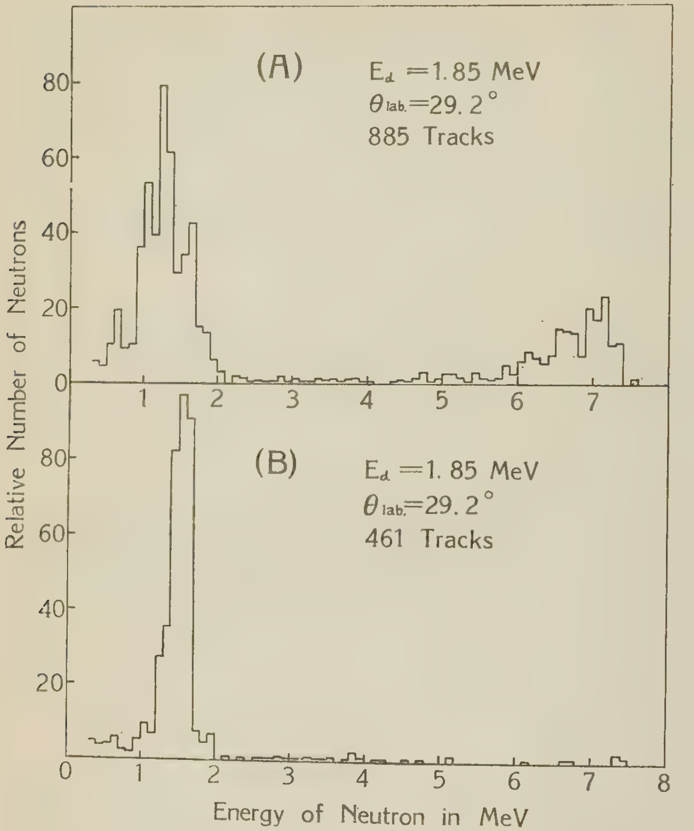

Fig. 4. Energy spectra of neutrons from $(d, n)$ reactions on $N^{14}$ at a laboratory angle of 29.2 degrees. The histogram (A) was obtained with the target chamber filled with nitrogen gas and (B), obtained with the evacuated target chamber, shows the background.

for Ilford B1[12)] and C2[13)] emulsions whose range-energy relations are supposed to differ not appreciably from NTA emulsion.

Next, the neutron energy $E_n$, corresponding to the recoil proton energy $E_p$, is given by the following relation[8)],

$$E_n = E_p / \overline{\cos^2 \rho} \qquad (2)$$

where $\overline{\cos^2 \rho}$ is the average value of the cosine squared of the angle $\rho$ between the incident neutron and the recoil proton directions and is also given as the function of $\theta_{max}$, $\phi_{max}$ and $\gamma_{max}$. $\gamma_{max}$ is the maximum value of the angle $\gamma$ that the incident neutron makes with the axis along which the projected lengths of tracks are measured.

The above described approximations lead to errors of less than one per cent. in the neutron energy $E_n$ for $\theta_{max}$, $\phi_{max}$ and $\gamma_{max} \leqq 15$ degrees[8)], which is just the present case.

Finally, in order to transform the proton energy distribution obtained by the above procedures into the neutron energy distribution, it must be still taken into account the variation of the neutron-proton scattering cross section and the escape probabilities of recoil protons from the emulsion surface. For the neutron-proton scattering cross sections, we have used the recent experimental results of several authors[14-17)]. As for the escape correction of recoil protons, it is sufficient to divide the results obtained above by the following factor $P$, so long as the tracks are rectilinear,

$$P = 1 - (L_p \sin\phi_{max} / 2t) \, , \qquad (3)$$

where $t$ is the thickness of the unprocessed emulsion[8)].

Following the above mentioned procedures, the neutron energy distributions per 0.1 MeV energy interval were obtained for each angle respectively, after being normalized with the scanned volumes.

In our experimental arrangement, the nitrogen gas target is 4 cm in length and so is considerably long. Hence, some part of neutrons emerging from the target into directions of more than 30 degrees will enter the emulsion from the backside of the photographic plates. These neutrons naturally penetrate the glasses of the plates and some of them, therefore, are taken off from the neutron beam by scattering. The correction for the presence of such neutrons was carried out rather simply for the angular distribution of the high energy group. It was found graphically that the average distances which were passed by the above described neutrons in the glass varied from 2 to 3 cm for each plate respectively. The proportions of these lost neutrons were calculated easily considering the total cross section of neutrons for the elements constituting the glass. The correction to be added to the results was found to have a maximum value of 6.2 per cent. for the plate placed at 104.2 degrees. The above mentioned correction, however, is supposed to be over-correction, because all the scattered neutrons are assumed to be lost entirely, but this is not the case as the forward scattering is predominant in general. But, as the correction itself is a small one compared with the statistical error, it is thought to have scarcely any meaning to consider the correction more accurately.

## § 3. Results and Discussions

The typical histograms of the energy spectra of neutrons are shown in Fig. 4, which were observed at an angle of 29.2 degrees in the laboratory system. The histogram (A) in Fig. 4 was obtained with the target chamber filled with nitrogen gas, while the histogram (B) of the background neutrons was obtained with the evacuated target chamber.

From these energy spectra, one can easily find the high energy group of neutrons from nitrogen with the peak at about 7 MeV.

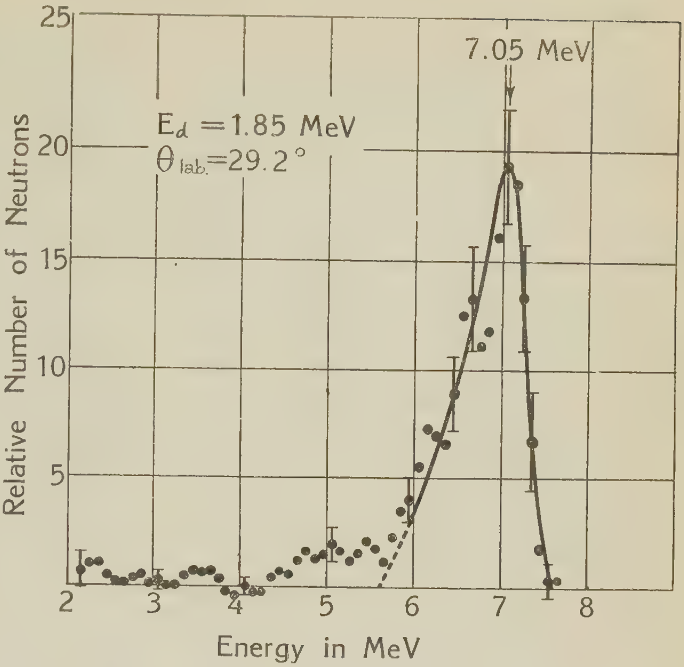

Fig. 5. Energy spectrum of neutrons of greater than 2 MeV from $(d, n)$ reactions on $N^{14}$ at a laboratory angle of 29.2 degrees, obtained by eliminating the background and smoothing up the histogram shown in Fig. 4 (A).

The interpretation of the lower energy region, below 2 MeV, of these spectra is much more complex. It is expected that the background neutrons in this region will be due to the carbon contaminant deposited on the silver foil and plate of the target chamber, because the Ag $(d, n)$ reaction has not been observed. The $Q$-value of $(-0.281 \pm 0.003)$ MeV has been reported for the $C^{12}(d, n)$ reaction by Bonner et al.[18] We have three carbon layers deposited on i) the forward surface of the silver foil of the target chamber, ii) the backward surface of this foil, and iii) the bottom surface of the target chamber. When the energy of the deuteron beam from the accelerating tube is 2.20 MeV, these three carbon layers are bombarded with the deuterons of 2.20, 1.99 and 1.71 MeV, respectively. Accordingly, the energy of neutrons observed at an angle of 29.2 degrees in the laboratory system must be 1.81, 1.61 and 1.34 MeV, respectively. The last one of these three groups will coincide in energy with the second one in case of the evacuated target chamber. And the relative intensities of these three neutron groups will depend on the thickness of the carbon layers, which are quite unknown and, moreover, may change with the bombarding time. Owing to these ambiguities, it was abandoned to treat this low energy region accurately, but some evidence of the existence of the low energy group was seen in the histograms at angles greater than 44.2 degrees. The $Q$-value was estimated roughly to be about $-0.1$ MeV which is consistent with the value obtained by Evans et al.[5]

In order to determine the energy of neutrons of high energy group, the histograms, after the background being subtracted, were smoothed up by plotting the sum of the neutron intensity in each energy interval and the halves of the neutron intensities in the both neighbouring intervals. In this way, we obtained the curve shown in Fig. 5 as an example. From these curves corresponding to each angles, we obtained the energies of neutrons at the peaks and calculated the $Q$-value for this reaction as shown in Table I, and obtained the mean value of $(5.21 \pm 0.04)$ MeV. But the absolute value of the energy of the bombarding deuterons may have an error of about 3 per cent., so the absolute value of $Q$-

Table I. $Q$-value of the high energy neutron group

| Plate number | $\theta$ in lab. system in degree | Neutron energy in MeV | $Q$ in MeV |
|---|---|---|---|
| $l$-1 | 0.8 | 7.00 | 5.19 |
| $l$-2 | 14.2 | 6.88 | 5.08 |
| $l$-3 | 29.2 | 7.05 | 5.32 |
| $l$-4 | 44.2 | 6.80 | 5.17 |
| $l$-5 | 59.2 | 6.85 | 5.36 |
| $l$-6 | 74.2 | 6.50 | 5.16 |
| $l$-7 | 89.2 | 6.50 | 5.33 |
| $l$-8 | 104.2 | 6.10 | 5.06 |
| mean value (5.21±0.04) MeV | | | |

Table II. Comparison of the $Q$-values by several investigators.

| $Q$ in MeV | Method | Investigator |
|---|---|---|
| 5.1 ±0.2 | cloud chamber | Stephens et al. (1937) [1] |
| 5.15±0.10 | nuclear plate | Gibson and Livesey (1948) [2] |
| 5.11±0.04 | nuclear plate | Mandeville et al. (1952) [19] |
| 5.1 | nuclear plate | Rose et al. (1952) [4] |

| 5.21±0.07 | nuclear plate | Present authors |

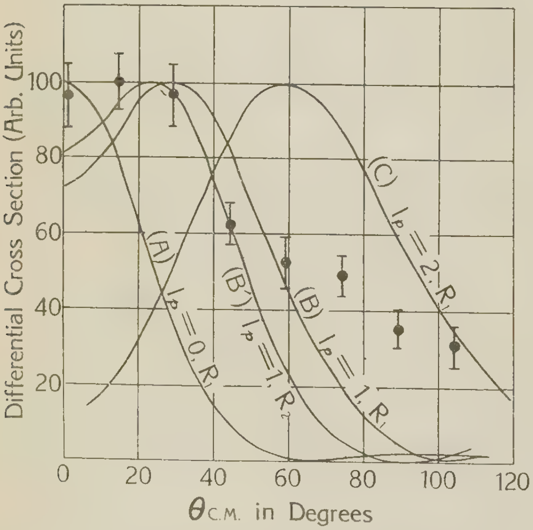

Fig. 6. Angular distribution of neutrons associated with the ground state of $O^{15}$ in the reaction $N^{14}(d, n)O^{15}$ for a deuteron energy of 1.85 MeV. Solid and broken curves were calculated from Butler's theory with $R=R_1=4.6\times10^{-13}$ cm for curves (A), (B) and (C) and $R=R_2=5.5\times10^{-13}$ cm for curve (B′), respectively. The curves (A) and (C) correspond to $l_p=0$ and 2 and the curves (B) and (B′) to $l_p=1$, respectively.

value is estimated to be (5.21±0.07) MeV, which is compared in Table II with the results previously obtained by other investigators. The agreement between the present result and the others is quite satisfactory.

In order to estimate the intensity of the high energy group of neutrons, we extrapolated the slope of lower energy side of the peak, as shown in Fig. 5 for example, and obtained the energy value of the intercept with the abscissa as 5.65 MeV, which was twenty per cent. lower than the value at the peak. As it was found that the value of twenty per cent. was almost common for all the other energy spectra obtained at other angles, we considered the neutrons of energy higher than this intercept as the ones associated with the reaction leading to the ground state of $O^{15}$ and thus we obtained the angular distribution in the centre-of-mass system, which is shown in Fig. 6. The errors indicated are statistical ones based on the number of tracks observed. The curves shown in Fig. 6 are theoretical angular distributions calculated from Butler's theory with $R=4.6\times10^{-13}$ cm for curves (A), (B) and (C) and $R=5.5\times10^{-13}$ cm for curve (B′), respectively. The curves (A) and (C) correspond to $l_p=0$ and 2 and the curves (B) and (B′) correspond to $l_p=1$, respectively. The experimental points agree with the theoretical curves for $l_p=1$ in reaching the maximum at about 20 degrees and decreasing considerably beyond this maximum, and this result agrees with that of Evans et al.[5] at 7.69 MeV of deuteron energy. As the ground state of $N^{14}$ has been measured to have the spin of unity and even parity, the result shows that the ground state of $O^{15}$ has the spin of 5/2, 3/2 or 1/2 and odd parity. According to the shell model of nuclei, the ground state of $O^{15}$ must be $P_{1/2}$ and is consistent with our present result. The experimental points lie considerably above the theoretical curves at angles greater than 60 degrees. These deviations would possibly be caused by i) the compound nucleus process, ii) the effect of the Coulomb barrier, and iii) the interaction between the emitted neutron and the residual nucleus. But it is impossible to analyse these discrepancies in the present state.

As a conclusion, we would like to make some mention on the availability of the $N^{14}$

$(d, n)O^{15}$ reaction as a neutron source. Although the low energy group of neutrons, not greater than 2 MeV, can be seen with some intensity, it is considerably apart from the high energy group. So it will not be impossible to use the high energy group as a neutron source of about 7 MeV, with some improvement on the measuring devices, but large yield will not be expected. In our present experiment, only a trace of neuterons from *d-d* reaction by deuterium contamination could be found.

The authors wish to express their cordial thanks to Mr. Y. Wakabayashi of the Chemical Research Laboratory of Konishi-Roku Photographic Industry for his kind preparation of nuclear plates. This work has been supported by the Scientific Research Expenditure of the Ministry of Education.

# A Lattice Theory of Quantum Fluids

By Shoichiro KOIDE

*Institute of Physics, College of General Education,*
*University of Tokyo*

(Received August 29, 1955)

Using the procedure of 'lattice space quantization', the cell method for liquids is developed quantum mechanically so as to include the inter-cellular motion of the molecules. It is shown that the statistics plays its essential roles in this inter-cellular motion just as in the case of ideal gases. The ground state of the Bose liquid and the lambda-transition of liquid helium are discussed on this stand point.

## §1. Introduction

The cell method or free volume theory is one of the most promising methods for the description of the liquid states[1]. The relation of this intuitive method to the rigorous one is discussed by Kirkwook[2], and, so far as the classical liquids are concerned, its approximation is now of established character.

However, the cell method is rather like the theory of solids than of liquids, if we take the number of cells equal to that of the molecules and neglect the probability of multiple occupations. In this respect improvements are made by the hole theory[3], and, more recently, by the cell-cluster models proposed by de Boer[4].

In most of these theories, starting point is the classical partition function $Z_c$, and the kinetic energy is included only in the factor $(2\pi mkT/\hbar)^{3N/2}$ multiplied to the 'configurational integral' $Q_N$: $Z_c=(2\pi mkT/\hbar)^{3N/2}Q_N$. In the case of quantum liquids, however, the partition function cannot be factorized in this way. Since the zero point motion of a light particle increases when confined in a small cage because of the uncertainty principle, the kinetic energy is not a small correction to the lattice potential energy even at extremely low temperatures. The above mentioned $Z_c$ cannot describe this situation.

In the calculation of the zero-point energy of helium, Pekeris[5] estimated this kinetic energy by solving the Schrödinger equation of a molecule confined in a cage of the potential by its neighbor molecules. It is, however, impossible for this kind of calculation to consider another important quantum effect, i.e. the effect of statistics. Prigogine and Philippot considered the multiply occupied cells and tried to take account of the effect of statistics[6]. They treated the molecules as rigid spheres moving freely in each cell, because the detailed shape of the cage potential is not so important. According to their theory, all molecules in a multiply occupied cell can occupy the lowest energy level if they obey the Bose statistics, but it is not the case for Fermi paticles. Their treatment still seems to be insufficient if we think about the essential role of the statistics in the case of ideal gases.

In gases, the molecules move about the whole vessels, and, if we imaginarily divide the entire volume of the vessel into cells, they migrate from cell to cell and exchange their positions with each other all the time. The statistics displays its feature in this 'inter-cellular' motion.

As is well known, liquid helium has a small density and in some respects behaves like gases. Many of its properties can be explained by the gas models, and Bose statistics is essential for the interpretation of its peculiarity. It is, therefore, highly desirable to construct a cell model, in which the inter-cellular migration of the molecules are considered quantum mechanically. This model must also be able to be connected with the usual quantum mechanical treatment of the gases, i.e. it must tend to the ideal gas in the limit of vanishing interaction and of infinitely small cell size.

According to the above considerations, most of the contribution to the inter-cellular motion should be attributed to the kinetic part of the Hamiltonian, though the potential part may affect to some extent. This inter-cellular motion is represented by the non-diagonal elements of the Hamiltonian in the cofiguration representation. Any configuration obtained by arranging the molecules among cells cannot be by itself an eigenstate of the Hamiltonian. It has an undeservedly high energy, because every molecule is locked in a small cell in an artificial way. This increase of the kinetic energy is relieved by taking linear combination of the configurations. In other words, the molecules wander about in order to relax the excessive kinetic energy. Therefore, it is essential to take account of the non-diagonal elements of the Hamiltonian, especially of its kinetic part, which are completely disregarded in previous works on the lattice theory of fluids.

If we think about the analogy between the lambda-transition of liquid helium and the Bose-Einstein condensation of the ideal gas, it may be probable that the lambda-transition arises from the inter-cellular motion of the helium atoms rather than from their intra-cellular motion, which plays an essential role in Prigogine and Philippot's theory[6].

## § 2. Lattice Hamiltonian

In this section, applying a procedure 'lattice space quantization' introduced by Wentzel and Schiff[7], we will translate the Hamiltonian of the fluid into an approximate one which is convenient to be connected with the cell method.

Using the formalism of the second quantization, the Hamiltonian of an assembly of $N$ interacting particles can be expressed as

$$H=\int dv\frac{\hbar^2}{2m}(\nabla\psi^*,\nabla\psi)+\tfrac{1}{2}\iint dvdv'\psi^*(\boldsymbol{r})\psi^*(\boldsymbol{r}')U(\boldsymbol{r},\boldsymbol{r}')\psi(\boldsymbol{r}')\psi(\boldsymbol{r}), \tag{1}$$

where $m$ represents the mass of a particle and $U(\boldsymbol{r}, \boldsymbol{r}')$ the potential of the interaction. $\psi(\boldsymbol{r})$ is the so-called quantized wave function and satisfies the following commutation relations.

$$\begin{aligned}&\psi(\boldsymbol{r})\psi^*(\boldsymbol{r}')\pm\psi^*(\boldsymbol{r}')\psi(\boldsymbol{r})=\delta(\boldsymbol{r}-\boldsymbol{r}')\\ &\psi(\boldsymbol{r})\psi(\boldsymbol{r}')\pm\psi(\boldsymbol{r}')\psi(\boldsymbol{r})=0 \qquad (2)\\ &\psi^*(\boldsymbol{r})\psi^*(\boldsymbol{r}')\pm\psi^*(\boldsymbol{r}')\psi^*(\boldsymbol{r})=0\,.\end{aligned}$$

Here and in the following, the upper and the lower sign correspond to the case of Fermi- and Bose statistics respectively.

Let us now subdivide the geometrical volume of the fluid $V=L^3$ into $N_l$ cubic cells of volume $l^3$, and suppose that $\psi(\boldsymbol{r})$ is defined only at the centers of these cells where it is characterized by a quantum mechanical operator $\psi_s$. (For the sake of simplicity, these lattice points are taken to be of simple cubic form.)

Using the averaging function introduced by Schiff,

$$f(\boldsymbol{r}-\boldsymbol{r}_s)=L^{-3}\sum_k \exp\left[i\boldsymbol{k}(\boldsymbol{r}-\boldsymbol{r}_s)\right]\,, \qquad (3)$$

we can define the operator $\psi_s$ associated with the lattice point $\boldsymbol{r}_s$ as

$$\begin{aligned}\psi_s&=l^{3/2}\int f(\boldsymbol{r}-\boldsymbol{r}_s)\psi(\boldsymbol{r})\,dv\\ \psi_s^*&=l^{3/2}\int f(\boldsymbol{r}-\boldsymbol{r}_s)\psi^*(\boldsymbol{r})dv\,. \qquad (4)\end{aligned}$$

The summation variable $\boldsymbol{k}$ in Eq. (3) is restricted to the reciprocal lattice points; each component of $\boldsymbol{k}$ ranges from $-\pi/l$ to $\pi/l$ in steps of $2\pi/L$. Since $f$ is such a function that has unit integral over $L^3$ and has its sharp maximum (height $1/l^3$, linear dimensions of order $l$) at the $s$-th lattice point, $\psi_s$ is an average of the continuous $\psi(\boldsymbol{r})$ over a distance of order $l$ about $\boldsymbol{r}_s$, multiplied by $l^{3/2}$.

Using the relation

$$\begin{aligned}&\sum_k \exp\left[i\boldsymbol{k}(\boldsymbol{r}_s-\boldsymbol{r}_t)\right]=N\delta_{st}\\ &\sum_k \exp\left[i(\boldsymbol{k}-\boldsymbol{k}')\boldsymbol{r}_s\right]=N\delta_{kk'}\,, \qquad (5)\end{aligned}$$

the commutation relations (2) can be transcribed into the following ones:

$$\begin{aligned}&\psi_s\psi_t^*\pm\psi_t^*\psi_s=\delta_{st}\\ &\psi_s\psi_t\pm\psi_t\psi_s=\psi_s^*\psi_t^*\pm\psi_t^*\psi_s^*=0\,. \qquad (6)\end{aligned}$$

There are several ways in which the Hamiltonian can be represented in the lattice space. Following Wentzel and Schiff, we may replace the kinetic energy term $(\hbar^2/2m)\int(\nabla\psi^*, \nabla\psi)\,dv$ by

$$\sum_{s,t} K_{st}\psi_s^*\psi_t\,,$$

where

$$K_{st}=(\hbar^2/2mN_l)\sum_k \boldsymbol{k}^2 \exp\left[i\boldsymbol{k}(\boldsymbol{r}_s-\boldsymbol{r}_t)\right]. \qquad (7)$$

Properly speaking, the interaction term of Eq. (1) should be replaced by the term such as $\sum U_{rs,\,tu}\psi_r^*\psi_s^*\psi_u\psi_t$. In the following, however, we may tentatively use the approximate expression

$$\tfrac{1}{2}\sum_s\sum_t U_{st}\psi_s^*\psi_t^*\psi_t\psi_s\,, \qquad (8)$$

because this has the proper limit as $l\to 0$ and we may be unable to expect any important role of the neglected small term for our purposes.

Thus the lattice Hamiltonian can now be written:

$$\mathscr{H}=\sum_s\sum_t K_{st}\psi_s^*\psi_t+\tfrac{1}{2}\sum_s\sum_t U_{st}\psi_s^*\psi_t^*\psi_t\psi_s\,. \qquad (9)$$

## § 3. Cell Model and Lattice Hamiltonian

The commutation relations (6) show that the eigenvalues of the operator $\psi_s^*\psi_s$ are restricted to 0 and 1 for the Fermion assembly and to 0,1,2,$\cdots$for the Boson assembly. We may assert that this operator $\psi_s^*\psi_s=n_s$ expresses the number of molecules localized in the $s$-th cell. It may then be reasonable to put approximately

$$U_{st}\simeq U(\boldsymbol{r}_s, \boldsymbol{r}_t)=U(r_{st})\,. \qquad (\text{for } s\neq t) \qquad (10)$$

This approximation cannot be allowed for $U_{ss}$. In the following, however, we may tentatively put $U_{ss}=+\infty$ and exclude the possibility of multiple occupations. Namely, we consider that each lattice point is either vacant or occupied by a molecule. This assumption is resonable if we take $l$ to be equal order of magnitude to the diamerter of the hard core, and, by this procedure, we can account for the effect of the repulsion between molecules. For spinless Fermions, this condition is automatically fulfilled by the exclusion principle.

Let us now consider the kinetic part of the lattice Hamiltonian. The coefficient of the diagonal term

$$K_{ss}=\frac{\hbar^2\pi^2}{2ml^2}=\frac{3\hbar^2}{2m}\left(\frac{\pi}{\sqrt{3}\,l}\right)^2, \qquad (11)$$

being equal to the zero point energy of a mass point confined in a cube of edge length $\sqrt{3}\,l$, can be interpreted as the zero-point kinetic energy of a molecule localized about the $s$-th lattice point. This becomes large if we take small value for $l$. However, as is emphasized in § 1, this zero point energy is relieved by the inter-cellular motion caused by the non-diagonal terms. The non-vanishing element of $K_{st}$ is restricted to the case in which $\boldsymbol{r}_s-\boldsymbol{r}_t$ is parallel to one of the edges of the cube $L^3$, and is given by

$$K_{st}=\frac{\hbar^2}{ml^2}\frac{(-1)^j}{j^2}\,, \tag{12}$$

where

$$j=|\boldsymbol{r}_s-\boldsymbol{r}_t|/l\,. \tag{12a}$$

Due to the existence of these non-diagonal terms, any fixed configuration of the $N$ molecules among $N_l$ lattice points cannot by itself be an eigenstate of our lattice Hamiltonian. The eigenstates are given by the proper linear combination of these configurations, and the coefficients of these combinations correspond to the usual configurational eigenfunction of the continuum Hamiltonian (1).

## § 4. Ideal Gases

To clarify the relation between the usual theory of gases and our model, we treat here the ideal gas by using our lattice gas model. The lattice Hamiltonian of an ideal gas

$$\mathscr{H}_0=\sum_s\sum_t K_{st}\psi_s{}^*\psi_t \tag{13}$$

can be easily diagonalized by the transformation

$$\psi_k=\frac{1}{\sqrt{N_l}}\sum_s\exp[i\boldsymbol{k}\boldsymbol{r}_s]\psi_s\,,$$

$$\psi_k{}^*=\frac{1}{\sqrt{N_l}}\sum_s\exp[-i\boldsymbol{k}\boldsymbol{r}_s]\psi_s{}^* \tag{14}$$

as

$$\mathscr{H}_0=\frac{\hbar^2}{2m}\sum_k k^2\psi_k{}^*\psi_k\,. \tag{15}$$

The commutation relation for the operators $\psi_k$ and $\psi_k{}^*$ is just like Eq. (6) if we replace the indices by the wave numbers. The Hamiltonian (15) is nothing but the usual one of the plane wave representation except that each component of the wave number $\boldsymbol{k}$ is restricted between $-\pi/l$ and $\pi/l$.

Let us now consider the ideal Fermi gas. Supposing the number of cells is large enough so that the Fermi sphere does not swell out from the cube of edge length $2\pi/l$. Then, in the ground state, all the molecules fill up the Fermi sphere of radius $k_0=(6\pi^2N/V)^{1/3}$, and the total kinetic energy is given by

$$K_{\mathrm{F0}}=\frac{N\hbar^2}{2m}\frac{3}{5}k_0{}^2: \tag{16}$$

Since the exclusion principle prevents the multiple occupations in the case of spinless Fermions, repulsion between molecules is effectively included in the calculation of ideal gas. The ground state of ideal Fermi gas, therefore, may be used as a good approximation of real Fermi gas when the attraction between molecules is small enough. In this state the expectation value of $n_s$ is easily calculated as

$$\langle n_s\rangle_{F0}=N/N_l\,, \tag{17}$$

indicating the uniform distribution of the molecules. Using the approximation of replacing the summation with respect to $\boldsymbol{k}$ by the integration over the Fermi sphere, we obtain the expectation value of the potential energy in this approximation as

$$\langle U\rangle_{\mathrm{F0}}=\frac{1}{2}\sum\sum_{s\neq r}\left\{\frac{N^2}{N_l{}^2}\right.$$
$$\left.-\frac{(\sin k_0r_{st}-k_0r_{st}\cos k_0r_{st})^2}{4\pi^4(r_{st}/l)^6}\right\}U_{st}\,. \tag{18}$$

Nearest neighbor interaction

$$\begin{aligned}U_{st}&=-\varepsilon\quad\text{(if $s$ and $t$ are nearest neighbors)}\\&=0\qquad\text{(otherwise)}\end{aligned} \tag{19}$$

may be a good approximation for (18), giving

$$\langle U\rangle_{\mathrm{F0}}=-\tfrac{1}{2}Nz\varepsilon\,\frac{N}{N_l}\left\{1\right.$$
$$\left.-\frac{9(\sin k_0l-k_0l\cos k_0l)^2}{(k_0l)^6}\right\}, \tag{20}$$

where $z$ denotes the number of nearest neighbors of a lattice point and is equal to 6 in our case. The second term in the curly brackets of (18) or (20) represents the effects of exchange repulsion due to the exclusion principle, and is familiar in the electron theory of metals.

## § 5. Ground State of Bose Liquids

In usual terms (i.e. expressed as a function of the coodinates of the constituent molecules), the ground state eigenfunction of a Boson assembly has no node, and drops to zero if two atoms overlap in any part of the fluid. In our language, this situation may be stated as follows: the ground state is expressed as a linear combination of such configurations in which each lattice point is either vacant or occupied by only one molecule, and all the coefficients of the combination have the same sign.

Of course it is quite difficult to obtain these coefficients exactly. So let us first consider the combination in which all the coefficients are equal. The number of configurations mentioned above is $N_l!/N!\,(N_l-N)!$. Let us denote them by $\phi_j$. Then our trial ground state function is expressed as

$$\varPhi=(N_l!/N!(N_l-N)!)^{-1/2}\sum_j\phi_j. \tag{21}$$

If we adopt the approximation of nearest neighbor interaction (19), then the expectation value of the lattice Hamiltonian with respect to $\varPhi$ can be easily calculated in the approximation of neglecting $1/N_l$ and $1/N$ to 1 as

$$\begin{aligned}E_{B0}&=N\frac{N}{N_l}\left\{\frac{\hbar^2\pi^2}{2m^2}-\frac{z}{2}\varepsilon\right\}\\&=\frac{N}{v}\left\{\frac{h^2\pi^2}{2m}l-\frac{z}{2}\varepsilon l^3\right\},\end{aligned} \tag{22}$$

where $v=V/N$ is the specific volume per molecule. Here we can see the relaxation of the kinetic energy into $(N/N_l)$ times of the original value $NK_{ss}=N\hbar^2\pi^2/2ml^2$.

The second term of the Eq. (22), being the mean value of the potential energy, shows that each lattice point is occupied by $N/N_l$ molecules on an average.

In the case of very small density, Lenz[8] calculated the lowest energy value of the gas of hard molecules ($\varepsilon=0$) as

$$K_0=\frac{N}{v}\frac{\hbar^2\pi^2}{2m}\frac{4d}{\pi}, \tag{23}$$

where $d$ is the diameter of the molecule. This agrees with the first term of our expression (22) if we let the size of our cell $l$ be equal to $4d/\pi$. In the limit of $d\to 0$ ($l\to 0$), this zero-point kinetic energy tends to zero: the ground state eigenvalue of ideal Bose gas. So $\varPhi$ may be considered to correspond to the ground state of Bose gas in the case of small density.

For high density, London[9] considered that each molecule is roughly like a mass point locked in the interior of a hollow sphere of radius $r-d$, where $r$ is the distance between the centers of nearest neighbors; and he gives the lowest energy value as

$$K_0=\frac{N}{2m}\frac{\hbar^2\pi^2}{(r-d)^2} \tag{24}$$

Based on an analogy to the one-dimensional case, Prigogine[10] puts the lowest energy as

$$K_0=\frac{3N\hbar^2\pi^2}{2m\gamma(r-d)^2}, \tag{25}$$

and determined the parameter $\gamma$ so as to get a good agreement with experiments. In the case of liquid $^4$He, he takes $\gamma=4.5$ and gets reasonable results. Our expression corresponding to these is

$$K_0=\frac{N\hbar^2\pi^2}{2m}\frac{N}{N_l l}=\frac{N\hbar^2\pi^2}{2m}\frac{l}{R^3}, \tag{26}$$

where

$$R=(V/N)^{1/3}.$$

Since $r=1.122R$ for a close packed structure, and $d<l<2d$, our expression (26) gives much smaller value than those of (24) and (25) for high density ($r-d\ll d$). This underestimation of the lowest energy arises from the imperfect consideration for the repulsive potential. So the validity of (26) may be doubtful for extremely dense liquid.

Considering $\varepsilon$ as a function of $l$, we can determine the value of $l$ so that it minimizes the energy $E_{B0}$ of (22). The value of $l$ determined in this way is independent of the volume $V$. The lowest energy $E_{B0}$, therefore, depends on the volume $V$ only through the factor $N/v$. So we cannot determine the stable volume of the liquid at $0^0K$ by our crude model.

## § 6. Possibility of Lambda Transition

The effects of statistics is most clearly exhibited if we consider the thermodynamic properties of our lattice fluid. For the sake of brevity, here we adopt the Bragg-Williams approximation for the effect of the intermolecular attraction, i.e. we replace it by its mean value

$$\bar{U}=-\frac{z}{2}\frac{N^2}{N_l}\varepsilon, \tag{27}$$

and take account of the repulsion only through the exclusion of the configurations with multiply occupied cells.

Let us divide the kinetic energy as

$$\sum_s\sum_t K_{st}\psi_s{}^*\psi_t=k_0+k_1, \tag{28}$$

where

$$k_0=\sum_s K_{ss}n_s=NK_{ss} \tag{28a}$$

and

$$k_1=\sum\sum_{s\neq t} K_{st}\psi_s{}^*\psi_t\ . \tag{28b}$$

Then we can write the partition function of our system as

$$Z=\mathrm{Tr}'\exp-\beta(k_0+k_1+\bar{U})$$
$$=\exp[-\beta(k_0+\bar{U})]\mathrm{Tr}'(1-\beta k_1+\tfrac{1}{2}\beta^2k_1{}^2-\cdots)\ , \tag{29}$$

because $k_1$ commutes with $N=\sum_s n_s$. The prime on the Tr sign means that the trace should be taken only with respect to the configurations without multiply occupied cell. Since the number of such configurations is

$$W(N_l,N)=\frac{N_l!}{N!(N_l-N)!}\ ,$$

we can immediately obtain

$$\mathrm{Tr}'1=W(N_l,N)\ . \tag{30}$$

The first order term vanishes because of its non-diagonality:

$$\mathrm{Tr}'(-\beta k_1)=0\ . \tag{31}$$

The second order term is calculated as follows:

$$\mathrm{Tr}'(\tfrac{1}{2}\beta^2k_1{}^2)=(\beta^2/2)\sum\sum_{s\neq t}\mathrm{Tr}'K_{st}{}^2\psi_s{}^*\psi_t\psi_t{}^*\psi_s$$
$$=(\beta^2/2)\sum\sum_{s\neq t}K_{st}{}^2\mathrm{Tr}'n_s(1\mp n_t)$$
$$=(\beta^2/2)N_l(\sum_{t=2}^{\infty}K_{1t}{}^2)\{W(N_l-1,N-1)$$
$$\mp W(N_l-2,N-2)\}$$
$$=(1/30)(\beta\kappa)^2NW(N_l,N)(1\mp\gamma+O(1/N)), \tag{32}$$

where

$$\gamma=N/N_l\quad\text{and}\quad\kappa=\hbar^2\pi^2/ml^2\ . \tag{33}$$

Similarly,

$$\mathrm{Tr}'(-(1/3!)\beta^3k_1{}^3)$$
$$=-(1/945)(\beta\kappa)^3NW(N_l,N)(1\mp3\gamma+2\gamma^2)\ . \tag{34}$$

The contribution to the fourth order term comes from the terms of types

$$K_{st}{}^2K_{ur}{}^2\psi_s{}^*\psi_t\psi_t{}^*\psi_s\psi_u{}^*\psi_r\psi_r{}^*\psi_u$$
$$K_{st}{}^2K_{ur}{}^2\psi_s{}^*\psi_t\psi_u{}^*\psi_r\psi_t{}^*\psi_s\psi_r{}^*\psi_u \tag{35}$$
$$K_{st}{}^2K_{ur}{}^2\psi_s{}^*\psi_t\psi_u{}^*\psi_r\psi_r{}^*\psi_u\psi_t{}^*\psi_s\ ,$$

which give

$$\frac{1}{2}\frac{(\beta\kappa)^4}{900}W(N_l,N)N^2\{(1\mp\gamma)^2+O(1/N)\}\ . \tag{36}$$

The main term of Eq. (36) comes from the terms of (35) in which $s$, $t$, $u$ and $r$ are different from each other. Similarly we obtain

$$\frac{1}{n!}\frac{(\beta\kappa)^{2n}}{30^n}W(N_l,N)N^n(1\mp\gamma)^n \tag{37}$$

as the most predominant contribution from the $2n$-th order terms. It is, however, quite difficult to get a simple expression for the remaining terms, which may give overwhelming contribution at low temperatures. So the validity of our expansion is restricted to the case of small $\beta$.

Let us now put

$$Z=W(N_l,N)\exp\{-\beta\bar{U}$$
$$-N(a\beta\kappa+b\beta^2\kappa^2+c\beta^3\kappa^3+\cdots)\}\ . \tag{38}$$

Comparing with Eqs. (30), (31), (32), (34) and (36), we get

$$a=1/2\ ,\qquad b=(-1/30)(1\mp\gamma)\ ,$$
$$c=(1/945)(1\mp3\gamma+2\gamma^2)\ ,\cdots\ . \tag{39}$$

As is well known, when the Bose-Einstein condensation takes place, an appreciable fraction of molecules occupies the state of zero momentum or of a macroscopic de Broglie wave length. Such a situation cannot be expressed by the expansion like Eq. (38). However, it may not be so unreasonable to guess that the transition corresponding to the Bose-Einstein condensation, if it exists, occurs for our system at the temperature where the series (38) diverges, because the contribution from the motions associated with long wave lengths are considered to come from the terms of the high order powers of the operator $\psi_s{}^*\psi_t$. Then the transition temperature $T_\lambda$ may be given by $\beta_\lambda$ which satisfies

$$|a\beta_\lambda\kappa|\simeq|b\beta_\lambda{}^2\kappa^2|\simeq|c\beta_\lambda{}^3\kappa^3|\simeq\cdots$$

or

$$\beta_\lambda\kappa\simeq\frac{15}{1+\gamma}\simeq\frac{31}{1+3\gamma+2\gamma^2}\simeq10\ .$$

If we put $m=m'M_p$ and $l=l'\times10^{-8}$ cm, where $M_p$ is the proton mass, then the transition temperature $T_\lambda$ is given by

$$T_\lambda\simeq50/m'l'^2\ . \tag{40}$$

For the liquid helium ($m'=4$, $l'=2\sim2.5$), we obtain $T_\lambda=2\sim3$°K, a correct order of magnitude.

Since we do not know the exact form of the partition function, we cannot explain why such transition does not occur in the case of Fermi statistics. As is seen in (39), the magnitudes of the coefficients $b, c,\cdots$ are much smaller in this case than in the case of Bose fluid. The convergence of the series (38), therefore, would be much better and be kept even at 0°K in the case of Fermi fluid.

The Helmholtz free energy $F$ is derived from $Z$ by the formula $F=-kT\log Z$. Using the relation $V=Nl^3/\gamma$, the pressure $p$ is calculated as

$$p=-(\partial F/\partial V)_T=(\gamma/V)(\partial F/\partial\gamma)_T\ .$$

This gives the eqution of state as

$$p=\frac{1}{l^3}\left\{-\frac{z\mathcal{E}V_0^2}{2V^2}+kT\log\frac{V}{V-V_0}\right.$$
$$\left.\mp\frac{V_0^2}{30kTV^2}\kappa^2+\frac{(\mp 3+4V_0/V)V_0^2}{945k^2T^2V^2}\kappa^3+\cdots\right\}, \tag{41}$$

where

$$V_0=Nl^3\ . \tag{42}$$

If we put $\kappa=0$, Eq. (41) becomes the equation of state for the simplest classical lattice gas. It is known that the isothermal $p$-$V$ curve of this classical lattice gas has a maximum and a minimum for the temperatures lower than $T_c=\mathcal{E}z/4k$. So $T_c$ is considered to express the critical point. For helium, if we use the minimum value of the intermolecular potential $-10^{-15}$ ergs for $-\mathcal{E}$, we obtain $T_c=11$°K (experimentally 5.2°K) which is higher than $T_\lambda$. For other substances, the attraction is much stronger and the mass is heavier than helium in general. So we can always expect that $T_\lambda$ is lower than the critical point $T_c$.

The terms of (41) containing $\kappa$ express the quantum correction to this classical lattice fluid. It may, however, be unpractical to discuss such a correction in detail on the basis of our rough model. Anyway, our Bose fluid seems to have two types of transitions; one is the ordinary transition between gas and liquid and the other the quantum mechanical one which presumably corresponds to the lambda-transition of liquid helium.

## § 7. Concluding Remarks

The main purpose of the present paper is to emphasize the important roles of the inter-cellular motion in the explanation of the quantum effects by the cell model. So we have attached importance to the kinetic energy part at the sacrifice of the rigorous treatment of the interaction potentials.

Our procedure adopted in § 2 is equivalent to the number representation of the Hamiltonian with the use of basic function $\varphi_s=(N_l L^3)^{-1/2}\times\sum_k\exp[i\boldsymbol{k}(\boldsymbol{r}-\boldsymbol{r}_s)]$. Apart from the imcompleteness of this function system, it may be somewhat unreasonable to assume that $\varphi_s$ describes the state of molecule confined in the $s$-th cell, because it has fairly large amplitude in the neighboring cells. It may, therefore, be worthwhile considering another choices of the basic functions more appropriate for the description of localized molecules.

In spite of the simplifications for the potential part, the lattice Hamiltonian (9) is still unmanageable. As to the eigensolution of the lattice Hamiltonian, therefore, we have had to restrict our discussion to the ground state of the Bose fluid (§ 5). It is much more difficult to investigate the Fermi fluid in the same way because of its antisymmetric property. Concerning the lower excited states of the Bose fluid, our crude theory has nothing to add to the Feynman's excellent work about the liquid helium11), though the similar treatment is possible by our model.

The statistical mechanical treatment has been also limited to the case of high temperatures, and yet quite unsatisfactory (§ 6). It is, however, natural if we think about the difficulty which lies even in solving much more simplified problems such as the Ising model for the ferromagnetics which is proved to be equivalent to the classical lattice gas with nearest neighbor interactions12).

In conclusion, the author wishes to express his sincere thanks to Professors S. Ono and T. Usui for their valuable suggestions and discussions.

# Quantum Effects in the Theory of Surface Energy

By Akira HARASIMA and Yoshihisa SHIMURA

*Tokyo Institute of Technology, Oh-Okayama, Tokyo, Japan*

(Received September 9, 1955)

Applying Prigogine's method of calculating the cohesive energy and the volume of liquid helium at 0°K and also Prigogine's method of calculating the surface tension, we have discussed the quantum effects in the theory of surface energies of several substances at 0°K. Assuming that the intermolecular potential is of the form

$$\phi(R)=4\varepsilon\{(\sigma/R)^{12}-(\sigma/R)^{6}\}\ ,$$

we can express the reduced surface energy at 0°K, $U_0{}^*=U_0\sigma^2/\varepsilon$, as a function of the quantum mechanical parameter

$$\Lambda^*=\frac{h}{\sigma\sqrt{m\varepsilon}}\ , \quad m\text{: mass of a molecule}$$

It is shown that $U_0{}^*$ decreases with increasing $\Lambda^*$ in agreement with observed tendency.

## § 1. Introduction

The surface tension is the free energy associated with a unit area of the surface of a liquid. We consider a system composed of liquid and vapour phases with an interface whose area is $A$. The Helmholtz free energy of a system of $N$ monatomic molecules occupying a volume $V$ is given, in classical theory, by

$$F=-kT\log\frac{1}{N!}\left(\frac{2\pi mkT}{h^2}\right)^{3/2N}\times\int\cdots\int\exp\left(-\sum\phi_{ij}/kT\right)dr_1dr_2\cdots dr_N\ . \tag{1}$$

To obtain the expression of the surface tension in terms of molecular quantities, we deform the system so as to give the interface a change in area and calculate the increase in the free energy. Beside the liquid-vapour interface we must, generally, take into consideration the interfaces between the liquid and the wall of the vessel and those between the vapour and the walls of the container. But we can give a deformation by which only the area of the liquid-vapour interface is changed, areas of other interfaces remaining unchanged.[1] Namely, we assume the vessel to be a cube with edge length $a$ and the system to be composed of the liquid phase in the form of a macroscopically thin but microscopically thick membrane which is parallel to a pair of walls and the vapour phase in equilibrium with the liquid. Then we displace one of the walls which are perpendicular to the membrane an infinitesimal amount $\eta a$ outward while at the same time displace a wall which is parallel to the membrane the same amount inward. By such displacements only the area of the vapour-liquid interface is increased, other interfaces remaining unchanged as far as small quantities of higher orders are neglected. By these procedures one can obtain the expression of surface tension $\gamma$ in terms of the intermolecular force and the molecular distribution function:

$$\gamma=\frac{1}{2}\iiiint\frac{d\phi_{12}}{dR_{12}}\frac{x_{12}{}^2-z_{12}{}^2}{R_{12}}\rho^{(2)}(z_1,\boldsymbol{R}_{12})dz_1d\boldsymbol{R}_{12}\,, \tag{2}$$

where z-axis is perpendicular to the vapour-liquid interface and $\rho^{(2)}$ is the pair distribution function.

To consider the surface tension from the standpoint of corresponding states, it is not necessary to follow details of the derivation of the formula (2). We can derive the principle directly from the expression (1) of the free energy. If the area of the interface between the liquid and the vapour is $A$, we have

$$\gamma=\frac{\partial F}{\partial A}=-kT\frac{\partial}{\partial A}\log\int\cdots\int\exp\left(-\sum\phi_{ij}/kT\right)d\boldsymbol{r}_1d\boldsymbol{r}_2\cdots d\boldsymbol{r}_N\,. \tag{3}$$

We assume, further, that the form of the intermolecular potential is of the Lennard-Jones type, that is,

$$\phi(R)=4\varepsilon\left\{\left(\frac{\sigma}{R}\right)^{12}-\left(\frac{\sigma}{R}\right)^{6}\right\}. \tag{4}$$

If we use the reduced values

$$\left.\begin{aligned}&T^*=\frac{kT}{\varepsilon}\,,\quad A^*=\frac{A}{\sigma^2}\,,\quad R^*=\frac{R}{\sigma}\,,\quad \boldsymbol{r}^*=\frac{\boldsymbol{r}}{\sigma}\,,\\ &\text{and}\\ &\gamma^*=\gamma\frac{\sigma^2}{\varepsilon}\,,\end{aligned}\right\} \tag{5}$$

we have

$$\gamma^*=-T^*\frac{\partial}{\partial A^*}\log\int\cdots\int\exp\left[-\sum\frac{4}{T^*}\left\{\left(\frac{1}{R_{ij}{}^*}\right)^{12}-\left(\frac{1}{R_{ij}{}^*}\right)^{6}\right\}\right]d\boldsymbol{r}_1{}^*\cdots d\boldsymbol{r}_N{}^*\,,$$

so that we have

$$\gamma^*=f(T^*)\,, \tag{6}$$

that is, treated by classical theory, the reduced surface tension can be written as a universal function of the reduced temperature so long as the form of the intermolecular potential is given by the formula (4).

The surface energy is given, as is well known, by

$$U=\gamma-T\frac{\partial\gamma}{\partial T}\,, \tag{7}$$

in terms of the reduced variables, it can be written as

$$U^*=\gamma^*-T^*\frac{\partial\gamma^*}{\partial T^*}\,, \tag{8}$$

where

$$U^*=U\frac{\sigma^2}{\varepsilon}\,. \tag{9}$$

De Boer and Lunbeck[2)] showed that the reduced surface tension can be expressed as a function of the reduced temperature and the quantum mechanical parameter

$$\Lambda^*=\frac{h}{\sigma\sqrt{m\varepsilon}}\,, \tag{10}$$

and predicted the temperature dependence of surface tension of liquid $^3$He. The theoretical predictions which they made can be compared with the observations by Lovejoy[3)]. The agreement is seen to be exceptionally good.

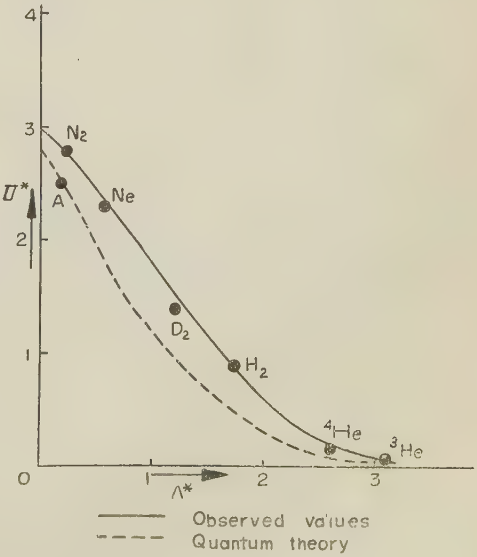

Fig. 1.

Table I.

| Substance | $U$ | Temperature Range (°K) | $\varepsilon(10^{-16}$ ergs) | $\sigma$(A.U.) | $U^*$ | $\Lambda^*$ |
|---|---|---|---|---|---|---|
| $^3$He | 0.16 | 1.5- 3.4 | 14.03 | 2.56 | 0.075 | 3.05 |
| $^4$He | 0.36 | 1.6- 4.3 | 14.03 | 2.56 | 0.168 | 2.64 |
| $H_2$ | 5.4 | 15.1-20.1 | 50.75 | 2.92 | 0.904 | 1.73 |
| $D_2$ | 8.2 | 18.7-21.1 | 50.75 | 2.92 | 1.38 | 1.22 |
| Ne | 15 | 24.8-28.3 | 48.82 | 2.74 | 2.31 | 0.591 |
| $N_2$ | 26 | 77.2-90.1 | 132.4 | 3.72 | 2.72 | 0.225 |
| A | 35 | 85.1-90.1 | 165.0 | 3.41 | 2.47 | 0.187 |

In this paper we shall show that surface energies also obey a similar law and further that we can derive a parametrical dependence of $U^*$ on $\Lambda^*$, at least qualitatively, if we resort to some approximate considerations.

Experimental data of surface energies as well as the force constants of several substances with which we are going to deal in this paper are shown in Table I.

Experimental values of $U^*$ are plotted as a function of $\Lambda^*$ in Fig. 1. The values of $U^*$ except for those of $^4$He and $^3$He are not those at 0°K, but those in the liquid region shown in Table I. Since $^4$He and $^3$He can be in the liquid state at 0°K, we have extrapolated the values at 0°K from the measurements by Allen and Misener for $^4$He[4] and by Lovejoy for $^3$He[3]. They are shown in the figure. The broken curve in the figure shows the results of computations by the theory shown in § 4.

## § 2. Prigogine's Method for Computing the Cohesive Energy

Before discussing the problem of surface energy, we shall first consider quantum effects on the volume of the condensed phase in bulk. We shall use the same method as adopted by Prigogine[5] in calculating the energies of liquid $^4$He and $^3$He at 0°K.

De Boer and Blaisse[6] showed that by quantum mechanical cell theory one can derive a relation between the reduced volume $V^*$ and the reduced energy $E^*$ which are given by

$$V_0^* = \frac{V_0}{N\sigma^3}, \quad E_0^* = \frac{E_0}{N\varepsilon}. \tag{11}$$

Their derivation consisted in expanding the pressure in a power series of the parameter $\Lambda^*$ and was valid only for small values of $\Lambda^*$. The procedure which we shall adopt in this paper is not so refined as de Boer and Blaisse's theory, but it will not be required that $\Lambda^*$ is small. Though Prigogine applied his method to liquid $^4$He and $^3$He, we shall extend the method to substances other than liquid helium. These substances are, of course, solid at 0°K except for helium. But we shall assume that we can apply the same method to these substances in the following treatment, considering the comparative crudeness of our theory which does not discriminate between liquid and solid states.

In Prigogine's theory which was applied to liquid helium, the structure of the liquid is considered to be of a lattice-like form and the energy at 0°K is assumed to be the sum of the potential energy $\Phi$ corresponding to the configuration that all the molecules are at the lattice points of a face-centred cubic lattice and the zero-point energy $E_r$ for the motion of molecules.

It is very easy to show that $\Phi$ is given by[7]

$$\Phi = 24.26N\varepsilon\left[\left(\frac{\sigma}{a}\right)^{12} - 1.191\left(\frac{\sigma}{a}\right)^{6}\right], \tag{12}$$

where $a$ is the distance between two neighbouring cell centres and it is given by

$$V = \frac{Na^3}{\sqrt{2}}.$$

Using the reduced values

$$\Phi^* = \frac{\Phi}{N\varepsilon}, \quad V^* = \frac{V}{N\sigma^3}, \tag{13}$$

we have, from (12),

$$\Phi^* = 6.065\left(\frac{1}{V^{*4}} - \frac{2.382}{V^{*2}}\right). \tag{14}$$

It is very difficult to calculate the zero-point energy. Since the substances we are treating are solid at 0°K except for $^4$He and $^3$He, it may seem most adequate to treat the problem on the line of Debye's theory of solid bodies. On the other hand, Hobbs⁸⁾ calculated the energies of solid $H_2$, HD and $D_2$ by a similar procedure as that adopted in this paper. Though it would be best to treat argon and neon by Debye's method, we shall treat them by the same method as for helium and hydrogen, since the errors would not be great considering that the quantum effect itself is rather small for these substances. In the quantum mechanical cell theory, we solve Schrödinger's equation for a molecule which is under the resulting potential field from other molecules surrounding the molecule under consideration. It is often assumed that each molecule is a hard sphere moving inside the cell in which it is locked when the density of the phase is high.

Then the zero-point energy is given by

$$E_r = \frac{Nh^2}{8m(a-\sigma)^2}\,, \tag{15}$$

where $a$ is the distance between two neighbouring cell centres and $\sigma$ is the diameter of a molecule.

If the density is small, the molecules will not be locked in cells but roam from cell to cell and the zero-point energy of a molecule will be given by the formula due to Heitler and Lenz⁹⁾:

$$E_r = \frac{Nh^2\sigma}{2\pi m R^3}\,, \qquad R^3 = \frac{V}{N}\,. \tag{16}$$

A simple interpolation formula between these two is given by the expression:

$$E_r = \frac{Nh^2\sigma}{2\pi m(R-0.891\sigma)^2(R+0.713\sigma)}\,, \tag{17}$$

which can be used for densities ranging from very small to very large values. We shall here use similar but somewhat different formula which was used by Prigogine in his theory of liquid helium, and which is written as

$$E_r = \frac{3Nh^2}{8\delta m(a-\sigma)^2}\,. \tag{18}$$

If we put $\delta=1$ in (18), $E_r$ becomes equal to the zero-point energy of a molecule in a cubic cell. We assume that by using the parameter $\delta$ we can take into consideration the type of the lattice and other modes of motion than the one in which a molecule moves in the cell it is locked, e.g. the mode in which the molecules roam from cell to cell. This idea was proposed by Prigogine and we follow him by putting

$$\delta = 4.5 \tag{19}$$

for any substance we treat in this paper, though Prigogine limited his treatment to the cases of liquid $^4$He and $^3$He.

The zero-point energy expressed in reduced variable is

$$E_r^* = \frac{E_r}{N\varepsilon} = \frac{3h^2}{8\varepsilon m\delta(a-\sigma)^2} = \frac{3}{8}\,\frac{\Lambda^{*2}}{\delta(2^{1/6}V^{*1/3}-1)^2}\,, \tag{20}$$

and adding this energy to that given by (14), we have the expression for the total energy in terms of reduced variables:

$$E^* = 6.07\left(\frac{1}{V^{*4}} - \frac{2.382}{V^{*2}}\right) + \frac{1}{12}\,\frac{\Lambda^{*2}}{(2^{1/6}V^{*1/3}-1)^2}\,. \tag{21}$$

Fig. 2 shows $\Phi^*$, $E_r^*$ and $E^*$ as functions of $V^*$ for $\Lambda^*=1$. The values of the volume $V_0^*$ and the energy $E_0^*$ for the equilibrium state are determined by the condition of minimum energy:

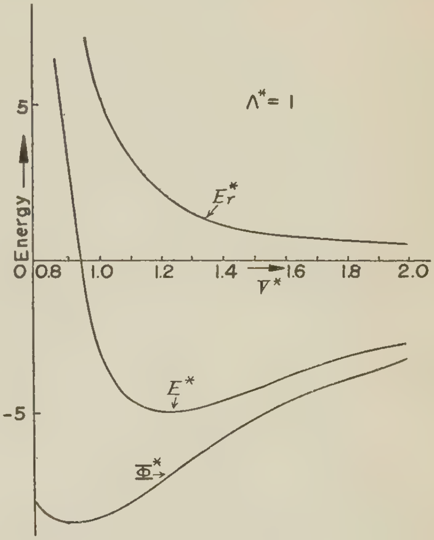

Fig. 2.

$$\left(\frac{\partial E^*}{\partial V^*}\right)_{V_0^*} = 0\,, \tag{22}$$

for each value of $\Lambda^*$. This is given by Fig. 3 together with experimental value. In Fig. 4 the values of the energy $E_0^*$ at 0°K are shown as a function of $\Lambda^*$. By these figures we may conclude that Prigogine's treatment applied to substances not limited to liquid $^4$He and $^3$He gives quantum effects in fairly good agreement with experimental values. The relation between $V_0^*$ and $\Lambda^*$ which we have obtained will be used in our theory of surface energy in § 4.

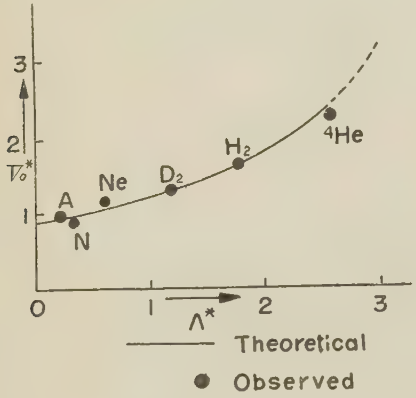

Fig. 3.

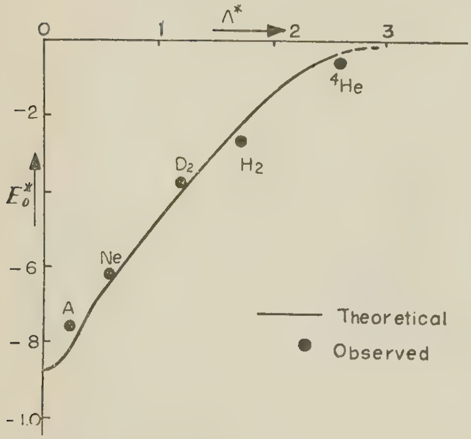

Fig. 4.

## § 3. Calculation of Surface Energy (Classical theory)

Surface energy is defined as the increase in energy per unit surface area in an isothermal change. According to the classical theory the mean value of the kinetic energy of a molecule is constant whether it is in the interior or on the surface of the liquid, so we have only to calculate the increase in the total potential energy of the system which results from an increase of the area of the surface.

The structure of the liquid near the surface is obviously different from that of the liquid in bulk. But we shall neglect this difference and assume that the molecular arrangement is kept unchanged up to the surface of the liquid.

We now divide the potential energy of the liquid into two parts, that is, the potential energy when the molecules are at the cell centres and the mean potential energy for the molecular motion around the cell centres. If the motion of a molecule is simple harmonic, the average potential energy of the molecule corresponding to motion in any direction is given by $1/2\,kT$ irrespective of the frequencies, so it is constant whether the molecule is in the interior or on the surface of the liquid. Any difference in the frequency of vibration of molecules will give rise to surface entropy, so that the difference in the frequency cannot be neglected in calculating the surface free energy, that is, the surface tension. In calculating the surface free energy one can thus neglect the difference in potential energy due to deviations of molecules from cell centres, so long as the motion of each molecule is simple harmonic. The force acting on a molecule when it deviates from the cell centre is more complicated than in the case of a harmonic oscillator and the mean potential energy due to the molecular motion when the molecule is on the surface is different from that when it is in the interior of the liquid, but it may be said that a large part of the mean potential energy will be cancelled by taking differences and the part which remains will be small compared with that which arises from the lattice energy.

By making such simplifying assumptions, we can obtain classical surface energy in the form of the increase in potential energy per unit surface area when we divide an infinite face-centred cubic lattice into two semi-infinite parts. The result depends to some extent upon the crystal plane which is to be exposed and according to the calculations by one of the writers (A.H.), the following results were obtained[10).

Exposed face: (100)-plane

$$U=\frac{8}{a^2}\varepsilon\left\{1.4\left(\frac{\sigma}{a}\right)^6-\left(\frac{\sigma}{a}\right)^{12}\right\}. \tag{23}$$

Exposed face: (110)-plane

$$U=\frac{8.8}{a^2}\varepsilon\left\{1.35\left(\frac{\sigma}{a}\right)^6-\left(\frac{\sigma}{a}\right)^{12}\right\}. \tag{24}$$

Exposed face: (111)-plane

$$U=\frac{7.2}{a^2}\varepsilon\left\{1.35\left(\frac{\sigma}{a}\right)^6-\left(\frac{\sigma}{a}\right)^{12}\right\}. \quad (25)$$

We can obtain a similar result by a somewhat different procedure due to Fowler. He obtained an expression for surface energy by assuming the molecular density to change discontinuously from the density of the bulk liquid to that of the saturated vapour. The surface energy is expressed in terms of the radial distribution function as follows:

$$U=-\frac{1}{8}\rho^{(1)}\int_0^\infty R\phi(R)\rho^{(1)}g(R)\cdot 4\pi R^2dR \quad (26)$$

where $\rho^{(1)}$ is the molecular number density and $g(R)$ is the radial distribution function. In this formula $\rho^{(1)}\cdot g(R)\cdot 4\pi R^2dR$ is the average number of molecules which are in the distance between $R$ and $R+dR$ from any specified molecule. Denoting this number by $n(R)dR$, we have

$$U=-\frac{1}{8}\rho^{(1)}\int_0^\infty Rn(R)\phi(R)dR\,.$$

This formula can be rewritten as

$$U=-\frac{1}{8}\rho^{(1)}\sum n_iR_i\phi(R_i)\,, \quad (27)$$

where $n_i$ is the number of molecules at the distance $r_i$ from a specified molecule. Assuming face-centred cubic structure, we have

$$U=\frac{8}{a^2}\phi_0\left\{1.5\left(\frac{\sigma}{a}\right)^6-1.08\left(\frac{\sigma}{a}\right)^{12}\right\}. \quad (28)$$

Since the formulas (23), (24), (25) and (28) are derived by approximate treatment it would be insignificant to discuss which one is the most accurate, but we shall use the formula (25) as it gives the smallest value for the surface energy. By writing it in the reduced form, we have

$$U^*=\frac{1.43}{V^{*2/3}}\left(\frac{2.70}{V^{*2}}-\frac{1}{V^{*4}}\right). \quad (29)$$

We see by this formula that $U^*$ can be expressed as a function of $V^*$ which is a function of the reduced temperature $T^*$ if the pressure is zero. Hence in classical theory the reduced values of the surface energy is the same for all substances if the intermolecular potential is given by the expression (4).

## § 4. Calculation of Surface Energy (Quantum theory)

We shall now consider the surface energy at 0°K taking into consideration the zero-point energy. Among substances we are to deal with, $^4$He and $^3$He are only subustances whose experimental values of surface energy can be obtained by extrapolation. But since the model which we adopt does not, strictly speaking, discriminate between solid and liquid states, we shall call them generally as condensed phases and deal with the surface tension at 0°K. In comparing theoretical values with experimental ones, we shall use the values of the latter at temperatures in the liquid region, so the comparison will be merely qualitative.

Let a molecule in the condensed phase execute simple harmonic motion under molecular forces resulting from surrounding molecules with the frequency $\nu$ when the molecule is in the interior of the phase and with the frequency $\nu_s$ when it is in the surface layer. The difference in the zero-point energies is

$$\frac{1}{2}h(\nu-\nu_s)$$

per one degree of freedom. The difference in frequencies means difference in the free volume in the cell theory of liquid. But the concept of small vibrations is not valid in some cases, so we shall not restrict ourselves to the case where molecules execute simple harmonic motion, and treat the problem in a more general though somewhat simplified way.

Prigogine[11)] treated the problem of surface tension in the following way. His treatment was limited to classical theory and it was assumed that in the surface layer the motion of any molecule parallel to the surface of the liquid is the same as it is in the interior of the liquid, while in the direction perpendicular to the surface the motion of the molecule in the surface layer is such that we obtain the expression for free volume by replacing $a-\sigma$ in the expression for a molecule in the interior of the liquid by $a-\sigma/2$. Here $a$ is the distance between nearest neighbours and $\sigma$ is the diameter of a molecule. Though this idea was proposed by Prigogine in the classical theory of surface tension, we shall adopt the same idea in discussing the zero-point energy concerning the surface energy of a liquid. Then the decrease in the zero-point energy of a molecule when it emerges from the interior to the surface of a liquid is

$$\frac{h^2}{8\delta m}\left\{\frac{1}{(a-\sigma)^2}-\frac{1}{(a-\sigma/2)^2}\right\}.$$

If we assume that the surface is the (111)-plane of the lattice the area per molecule is $(\sqrt{3}/2)a^2$ and the decrease in the zero-point energy per unit area is

$$\varDelta E_{\mathrm{r}}=\frac{h^2}{4\sqrt{3}\,\delta m a^2}\left\{\frac{1}{(a-\sigma)^2}-\frac{1}{(a-\sigma/2)^2}\right\},$$

which can be written in the reduced values

$$\begin{aligned}\varDelta E_{\mathrm{r}}^*&=\frac{\sigma^2}{\varepsilon}\varDelta E_{\mathrm{r}}\\&=\frac{\varLambda^{*2}}{4\sqrt{3}\cdot 2^{1/3}\delta\cdot V^{*2/3}}\left\{\frac{1}{(2^{1/6}V^{*1/3}-1)^2}\right.\\&\qquad\left.-\frac{1}{(2^{1/6}V^{*1/3}-1/2)^2}\right\}. \qquad (30)\end{aligned}$$

Subtracting this value from that given by (29), we obtain the surface energy of the condensed phase at 0°K, and putting $V^*=V_0^*$, we have

$$\begin{aligned}U_0^*&=\frac{1.43}{V_0^{*2/3}}\left(\frac{2.70}{V_0^{*2}}-\frac{1}{V_0^{*4}}\right)\\&\quad-\frac{\varLambda^{*2}}{39.3V_0^{*2/3}}\left\{\frac{1}{(2^{1/6}V_0^{*1/3}-1)^2}\right.\\&\quad\left.-\frac{1}{(2^{1/6}V_0^{*1/3}-1/2)^2}\right\}. \qquad (31)\end{aligned}$$

Since the values of $V_0^*$ as a function of $\varLambda^*$ are given by the equation (22) expressing equilibrium at 0°K, we can calculate the surface energy $U_0^*$ as a function of $\varLambda^*$, that is

$$U_0^*=U_0^*(\varLambda^*)\,. \qquad (32)$$

The dotted curve in Fig. 1 shows the calculated relation between $U_0^*$ and $\varLambda^*$. Since the experimental values are those obtained from experimental data of surface tension in the liquid region, the comparison between the theory and experiments is rather qualitative than quantitative. But we see from the figure, quantum effects concerning surface energy can be deduced from free volume theory at least in a qualitative way, considering that we cannot expect on the basis of such a crude simplified theory as ours to obtain satisfactory numerical values.

## § 5. More Precise Calculation for Liquid $^4$He

Keesom and Taconis[12)] made an x-ray analysis of liquid helium. It is not easy to draw a definite conclusion from their analysis, but they showed that the structure of liquid helium is such as we will obtain if we remove from a face-centred cubic lattice half of the atoms so that each atom is surrounded by six atoms and six empty sites. F. London[13)] estimated the cohesion energy of liquid helium assuming the structure to be as proposed by Keesom and Taconis.

We now show the estimation of surface energy calculated by the same method as shown in § 3. We adopt two types of inter-atomic potential, the one is the Lennard-Jones type potential given by (4) with the constants $\varepsilon=14.03\times10^{-16}$ ergs, $\sigma=2.56$ Å and the other that given by Yntema and Schneider

$$\begin{aligned}\phi(R)=[&1200\exp(-R/0.212)\\&-1.24/R^6-1.89/R^8]\cdot10^{-12}\,\text{erg}. \qquad (33)\end{aligned}$$

The results are:

| | |
|---|---|
| Exposed face: (100)-plane | |
| Using L.-J. potential | 0.69 ergs/cm$^2$ |
| Using Y. and S. potential | 1.06 ergs/cm$^2$ |
| Exposed face: (110)-plane | |
| Using L.-J. potential | 0.72 ergs/cm$^2$ |
| Using Y. and S. potential | 1.10 ergs/cm$^2$ |
| Exposed face: (111)-plane | |
| Using L.-J. potential | 0.55 ergs/cm$^2$ |
| Using Y. and S. potential | 0.74 ergs/cm$^2$ |

If we resort to the method which we used in deriving the formula (28) which is valid in the case of face-centred cubic structure, we can calculate the increase in the potential energy when the liquid is divided into two semi-infinite halves. The result is:

| | |
|---|---|
| Using L.-J. potential | 0.41 ergs/cm$^2$ |
| Using Y. and S. potential | 0.71 ergs/cm$^2$ |

These values are near those for the case where the exposed face is the (111)-plane.

As shown above there are some differences in the values according to the face to be exposed. The smallest values are those for the exposed face (111). So it would be reasonable to assume the values 0.5∼0.7 ergs/cm$^2$ to be the increase in the potential energy due to the formation of the surface. This corresponds to the reduced value of about 0.3 ergs/cm$^2$. The term due to the zero-point energy has, from the second term of (31), the value 0.27 ergs/cm$^2$, so that if we subtract this from 0.3 ergs/cm$^2$ the result will be very close to zero. The experimental value is $U_0^*=0.17$ (see Table I). Though this might seem to show the discrepancy between theory and experiment we may be satisfied with the result that our calculations show that the surface energy of liquid helium is very small, considering that we have calculated the surface energy by taking the difference between two comparatively large quantities of the same order each of which was estimated independently.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 11, No. 1, JANUARY, 1956

# Magnetic Properties of Nickel Telluride

By Enji UCHIDA and Hisamoto KONDOH
*Department of Physics, Naniwa University, Osaka*

(Received September 7, 1955)

Experimental results are reported of the magnetic properties of $NiTe_x$, where $x$ is the molal content of tellurium. When $0.1 \leq x \leq 0.65$, this substance is found to be ferromagnetic; the variations with composition of the saturation magnetization and of the Curie temperature show evidences of a transition at $x=0.33$ (27 atomic percent Te) from a heterogeneous phase begining at pure metallic nickel to a certain ferromagnetic homogeneous phase. A paramagnetic phase appears above $x=0.7$ (41 atomic percent Te), although its paramagnetic behaviour is not truely paramagnetic in the Curie-Weiss sense, especially at high temperatures, namely, a considerable temperature dependence of the susceptibility is observed at low temperatures and a temperature-independent susceptibility of a small value less than 0.5 emu/g at high temperatures. These behaviours of the susceptibility are apparently similar to those of Cu-rich Cu-Ni alloys studied by Kaufmann and Starr, though a marked dissimilarity is also found between their characters. Namely, an antiferromagnetic character is present in $NiTe_x$ at the paramagnetic compositions.

## § 1. Introduction

The magnetic properties of NiAs-type compounds in which one component is a transition metal and the other is a metalloid element, e.g. FeS¹⁾, MnAs²⁾, etc., are, as far as they have been studied, very peculiar and particular in each case. The antiferromagnetic properties of some of these NiAs type compounds seem to be determined on the one hand by the degree of the metallic character which is generally present in such compounds and, on the other hand, by the superexchange effect via the intermediary of the metalloid ions in the lattice. The present work has been done as one of the series of experimental investigations on tellurides in order to clarify these points. Investigations on other tellurides, FeTe[3], CoTe[4], MnTe[5] and CrTe[6], have been already reported.

There exist no through measurements of the magnetic properties of NiTe$_x$. The only data, which are due to Gal'perin and Perkallina[7], are concerned with the stoichiometric composition and the temperature range from liquid air temperature to room temperature. The present work extends the temperature range to 1150°C and the composition range to $0.10 \leq x \leq 2.00$.

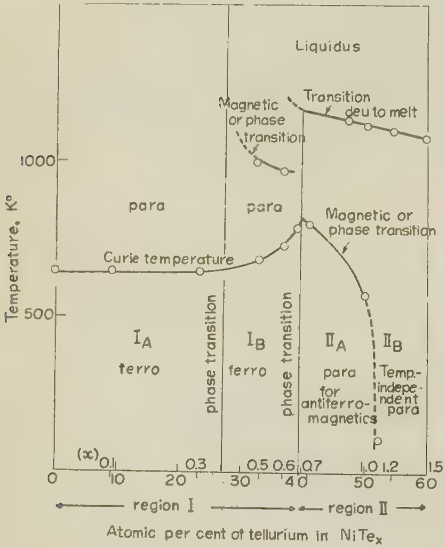

Fig. 1. The magnetic phase diagram of NiTe$_x$.
Region I: ferromagnetic composition region.
Region II: paramagnetic composition region.

## § 2. Experimental

The procedure of the preparation of the specimens is as follows: mixed powder of nickel and tellurium, both 99.9 percent pure, with a desired proportion was sealed in an evacuated silica tube ($10^{-6}$ mmHg), and this was heated in a furnace at 1200°C for 10 hours. The product was a solid material with a silvery appearance. The X-ray Debye-Scherrer diffraction pattern was compatible with the NiAs structure with lattice spacings $a_0=3.96$ A and $c_0=5.35$ A, which are in good agreement with the published data.

The same technique and the same magnetic balance as those described in previous papers[3],[4] were used for the magnetization measurements. In the present experiment, we had sometimes to observe very small values of the magnetization at paramagnetic compositions, and in such cases a relatively large quantity of the mass of the specimen, i.e. a few grams, was required for the measurements, in order to obtain sufficient deflections of the magnetic balance. However, increase in mass and thus increase in volume of the specimen introduced errors in keeping a constant field gradient over the working volume of the specimen. In such cases, the accuracy of determinig the absolute value of the magnetization was estimated to be three times less than that of the usual cases, but the errors remained within 10 percent. The accuracy of the relative values was as good as usual, since great cares were taken regarding the position of the specimen and also the blank condition of the apparatus.

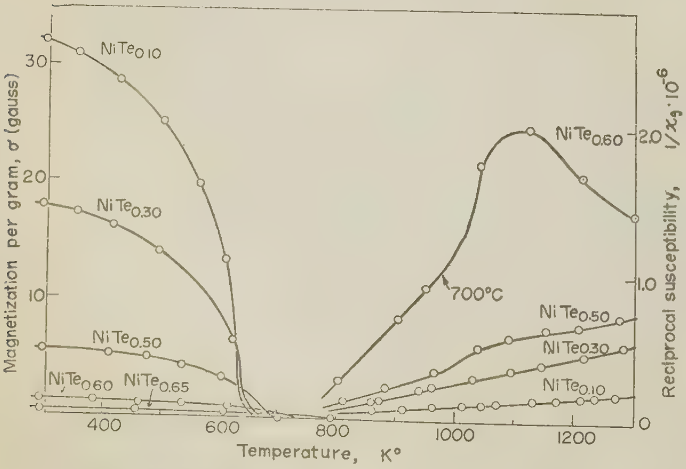

Fig. 2. Temperature dependences of the magnetization and the reciprocal susceptibility of NiTe$_x$ of ferromagnetic composition.

## § 3. Results

First some obtained data of the magnetic character of NiTe$_x$ are summarized in Fig. 1. It is found that NiTe$_x$ is definitely ferromagnetic in the range $0 < x \leq 0.65$, but paramagnetic, though not in the Curie-Weiss sense, in the range $0.7 \leq x \leq 2.00$. The ferromagnetic region, denoted as region I in Fig. 1, is divided into two sub-regions $I_A$ and $I_B$, and the paramagnetic composition region, denoted as region II, into sub-regions $II_A$ and $II_B$. These divisions have the following meanings.

a) *Ferromagnetic composition range* (*region I*)

Curves in Fig. 2 represent the magnetization and reciprocal susceptibility of $NiTe_x$ in range I as functions of temperature. Fig. 3 shows the magnetization as a function of applied field intensity at room temperature. As seen in these figures, every curve shows essentially the ferromagnetic behaviour. The molal saturation magnetization is a linear function of the atomic percentage of tellurium in region $I_A$ and another linear function in region $I_B$, as shown in Fig. 4. On the other hand, we see, in the same figure, that the Curie temperture shows little variation with composition in region $I_A$, while it rises strikingly in region $I_B$. Such a rapid rise of the Curie point with increasing composition is known in few other cases. According to Marian[9], the Curie point of Ni–Mn alloy rises rapidly and the saturation moment drops linearly with increasing Mn content in the range of composition over 17 atomic percent of Mn. In $NiTe_x$, we have found this strange type of dependence of Curie point on composition, and for this dependence no convincing explanation can be given at present.

The values of the reciprocal susceptibility above the Curie temperature are plotted against temperature in Fig. 2. They lie on a straight line for specimens in region $I_A$. For sprcimens in region $I_B$ they lie on a straight line only below 700°C and an anomalous behaviour is observed above 700°C. From these straight lines, the effective Bohr magneton numbers for a Ni atom are estimated for several compositions and given, together with the corresponding values of the Curie temperature, in Table I.

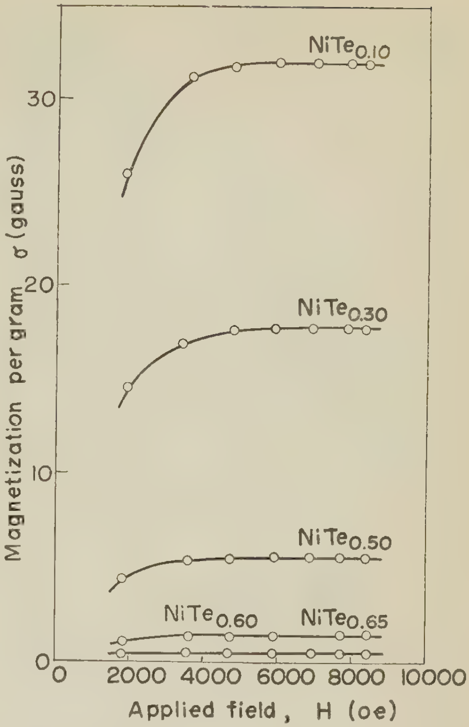

Fig. 3. Dependence on applied field of the magnetization of $NiTe_x$ of ferromagnetic composition.

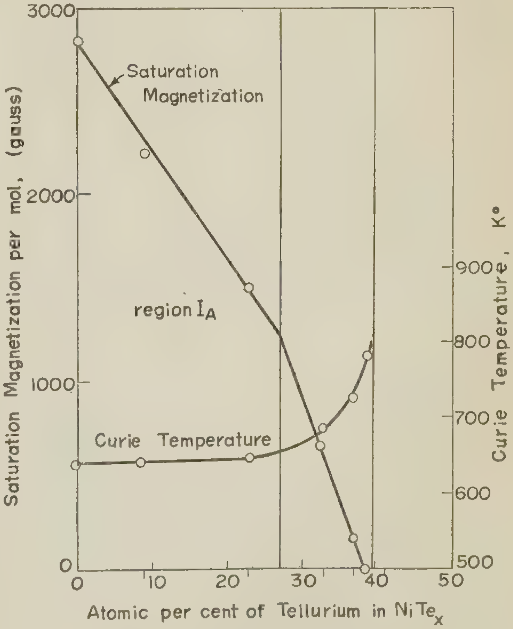

Fig. 4. Variation with composition of the molal saturation magnetization and the Curie point of $NiTe_x$ of ferromagnetic composition.

The Debye-Scherrer patterns obtained for specimens of compositions in region $I_A$, show lines due to metallic nickel beside several lines which are difficult to analyse, while the patterns for region $I_B$ are different both from those of region $I_A$ and the NiAs type pattern of NiTe in region II. Thus a heterogeneous phase whose one componet is metallic nickel is probably realized in region $I_A$. In fact,

the Curie temperature in region I$_A$ remains, as shown in Fig. 4, almost constant, and is close to the Curie point of the pure nickel, i.e., 640°K. The discontinuous change of slope of the saturation magnetization curve and the change in the Curie temperature curve in Fig. 4 for $x>0.33$ indicate a phase change at $x=0.33$. That an anomalous behaviour of $1/x-T$ curve in Fig. 2 is not observed in sub-region I$_A$ but is observed in I$_B$ is also suggestive of the phase transition.

b) *Paramagnetic composition range (region II)*

It is shown in Fig. 5 that the magnetization

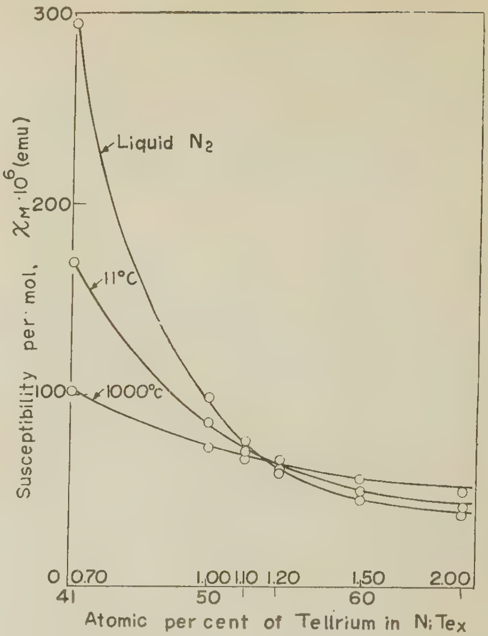

Fig. 6. Variation with composition of the susceptibility of NiTe$_x$ of paramagnetic composition.

in the region $0.7 \leq x \leq 2.00$ varies linearly with field up to about 9000 oe. This composition range is thus paramagnetic. The values of the susceptibility which are determined by taking the slopes of these straight lines are plotted against temperature in Fig. 8 and also against tellurium content in Fig. 6. In the latter curves, we see that the points fall on a smooth curve for each temperature and that the curves rise as the ferromagnetic compositions are approached.

The reciprocals of the susceptibility at various compositions in region II are plotted against absolute temperature in Fig. 7. As can be seen in this figure, plots of the reciprocal susceptibility for stoichiometric composition lie, below 300°C, on a straight line, the extrapolation of this straight line crossing the temperature axis at −1110°K. The absolute value of the temperature of this cross point appears to decrease as Te content decreases. The fact that the paramagnetic Curie point of NiTe is found in the negative region of temperature indicates an antiferromagnetic character of this compound. But this is not conclusive because the observed values of the susceptibility are too small compared with those of ordinary antiferromagnetic substances and also no Néel

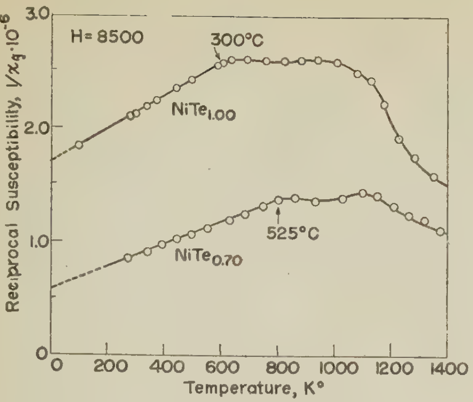

Fig. 7. Temperature dependence of the reciprocal susceptibility of $NiTe_x$ of paramagnetic composition.

point was yet found in the temperature range of the present experiment. It is to be noted, that similar phenomena have been found in other intermetallic compounds. A manganese nitride $Mn_5N_2$ recently studied by Yousef[10)] and others shows no evidence of the Néel point and yet shows an antiferromagnetic character in its $1/\chi - T$ relation. The data in the case of FeTe obtained by the present authors are another similar example in this respect. The molal susceptibility $\chi_M$ corresponding to the linear part in Fig. 7 can be represented by the formula $\chi_M = C/(T+\theta)$, with values of the Curie constant $C$, the characteristic temperature $\theta$ and the effective Bohr magneton numbers $p$ per nikel atom given by

$C=0.122$, $\theta=1110°\mathrm{K}$, $p=0.99\,\mu^B$
and for $x=1.00$,

$C=0.155$, $\theta=630°\mathrm{K}$, $p=1.12\,\mu_B$
for $x=0.70$.

The reciprocal susceptibility in the temperature region above 300°C for stoichiometric compound is independent of temperature up to 1000°K and then drops. This behaviour will be discussed later. The dissimilarity in behaviour in two temperature regions separated by 300°C might indicate a magnetic transition or a change in crystal structure at 300°C. It is to be noted that the similar break of the reciprocal susceptibility curve in FeTe was correlated with a specific heat anomaly. The same circumstance can be expected for NiTe.

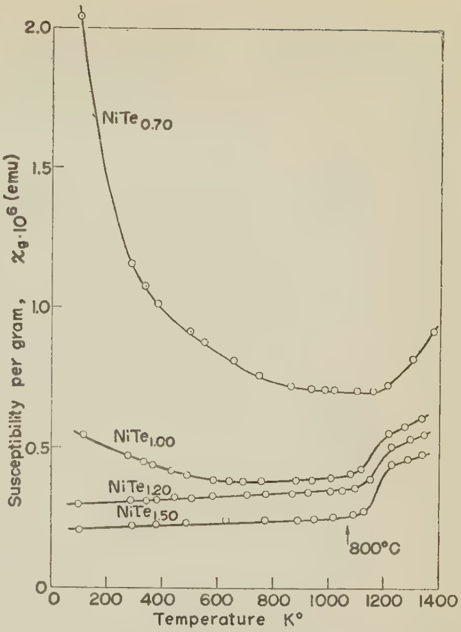

Fig. 8. Temperature dependence of the susceptibility of $NiTe_x$ of paramagnetic composition.

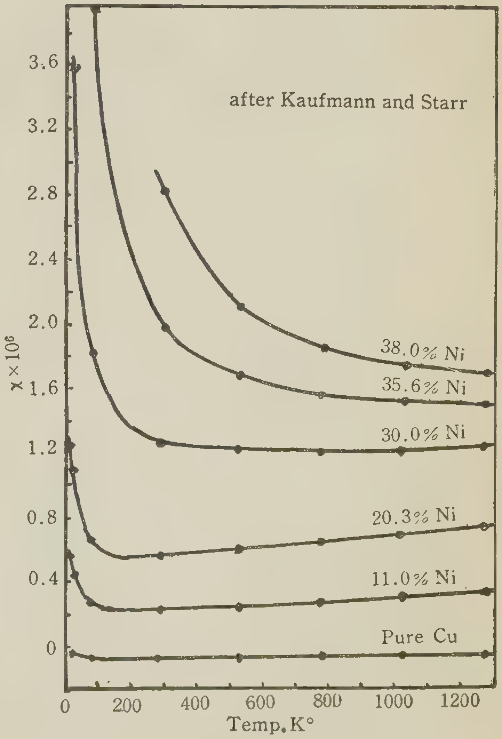

Fig. 9. Temperature dependence of the susceptibility of nickel-copper alloys of various composition (after Kaufmann and Starr).

We now mention the temperature dependence of the magnetic susceptibility shown in Fig. 8. This temperature dependence of the paramagnetic susceptibility has a close similarity in its appearance to that found by

Kaufmann and Starr[11] for Cu-rich Cu-Ni alloys. Their measurements are reproduced in Fig. 9 for the purpose of comparison. Discussions concerning this resemblance will be given later.

With regard to Fig. 8 we can point out the following characteristics of the curves. A large temperature dependence of the susceptibility exists at lower temperatures, which disappears gradually as the tellurium content is increased. At higher temperatures the susceptibility is almost temperature-independent and takes small values. Similar behaviours were found in FeTe and CoTe and were discussed previously[3]. This almost temperature-independent susceptibility exhibits, however, a slight increase with increasing temperature for Te-rich compounds. A further feature of the curves is a sudden rise of the susceptibility in the region between 800°C and 900°C, which is followed by a gradual increase with increasing temperature. This anomaly must be due to the melting of the specimens, because the specimens show different appearences at temperatures higher and lower than this temperature region. A similar anomalous behaviour due to melting has been found in FeTe and in pure Te.

We note finally that all the data obtained in the present experiment are generally reproducible and also reversible with temperature.

## §4. Discussions of the Results

Comparing the results for the paramagnetic nickel telluride obtained in the present experiment with those of the paramagnetic Cu-Ni alloys studied by Karfmann and Starr, we find similar features between them. But there are also distinctly different features.

Those found in common in both cases are the followings: a characteristic variation of the susceptibility with composition (see Fig. 6), the temperature-independent susceptibility of small values, and a tendncy to increase with increasing temperature of this susceptibility (see Fig. 8 and Fig. 9). It may be reasonable to consider that in nickel telluride these magnetic properties arise from an alloyic character present in this compound, since the similar magnetic properties pertain to paramagnetic Cu-Ni alloys. In fact, it has been shown by Schönberg[12] that tellurides of transition metals are more metallic than sulphides or selenides of the same metals.

On the other head, the low temperature susceptibility behaviours of nickel telluride (Fig. 8) are distinctly different from the corresponding behaviours of paramagnetic Cu-Ni, in spite of their apparent similarity (Fig. 8 and Fig. 9). An antiferromagnetic character of the reciprocal susceptibility pertains to the low temperature behaviours of nickel telluride, whereas the low temperature susceptibility of paramagnetic Cu-Ni shows nothing like that. It is natural to expect such a difference to exist between them since a superexchange effect via the intermediary of each negative ion must exist in the case of telluride. This consideration is supported by the fact that MnTe and FeTe are antiferromagnetic substances possessing NiAs lattice just like NiTe.

### Conclusion

It is found that NiTe is a substance of an antiferromagnetic character, although the present measurements down to liquid nitrogen temperature show no evidence of the Néel point, which might be at a lower temperature. The detection of the Néel point would deserve a further investigation.

It is also to be noted that a temperature-independent paramagnetism is commonly found in tellurides of Fe, Co and Ni, especially for Te-rich compositions in each case.

The authors wish to thank Professor T. Nagamiya of Osaka University for kind discussions, Professor Y. Mashiyama of Naniwa University for his warm encouragement and Professor Y. Shimomura for kind permission to work with his X-ray equipments. The authors would also like to thank Mr. Fukuoka for his helpful assistance in measurements. This work has been supported in part by the research expenditure of the group 'Research of Ferromagnetic Oxides' organized by Professor Kaya.

# Magnetic and Electrical Properties of Manganese Telluride

By Enji UCHIDA, Hisamoto KONDOH and Nobuo FUKUOKA

*Department of Physics, Naniwa University, Osaka*

(Received September 7, 1955)

The temperature dependence of the susceptibility of the antiferromagnetic compound MnTe was measured over a range of temperature between liquid nitrogen temperature and 720°C. An abrupt change in slope and a maximum of the susceptibility curve were found at 37°C and at 55°C respectively. These results are compared with the observed Néel temperatures previously reported by Squire and by Serre. A thermal hysteresis was also found above the Néel temperature, relating to the heat history of the specimen. It is shown that the susceptibility of $MnTe_{1+x}$ ($0 \leq x \leq 1$), where $x$ is the excess content of tellurium, is explicable in terms of two phases, MnTe and $MnTe_2$ which possess different susceptibilities. The electrical properties, i.e., the resistivity, the thermo-emf and the Hall emf, were measured as functions of temperature. Evidence was found of anomalous behaviours at the Néel temperature for them. A large thermal hysteresis of the resistivity is also found above the Néel temperature, which suggests a change of the crystal structure at about 130°C.

## §1. Introduction

According to the previously published data[1], the crystal structure of the compound MnTe is the NiAs type with lattice spacings $a_0=4.12$ A and $c_0=6.70$A. The magnetic susceptibility has been investigated by Squire[2] and by Serre[3]. They found that the susceptibility showed the behaviour of an antiferromagnetic compound, the Néel temperature being reported as 37°C by Squire or 55.6°C by Serre. The heat capacity measurements of Kelley[4] have shown that MnTe exhibits a hump of the heat capacity with its maximum at 34°C (307° K). Antiferromagnetic resonance absorption measurements for MnTe have been made by Maxwell and McGuire[5], who reported the $g$ values to be 2.00. Squire[6] has also studied the electrical resistivity of this compound and found that it shows an anomalous behaviour with a maximum at about the Néel temperature (30°C).

As mentioned above, the Néel temperature reported by Squire differs so much from that by Serre that the difference seems to be too large as an error of measurements. The present experiment is concerned with the confirmation of the Néel temperature. From the fact that the resistivity dependence on temperature shows a maximum at about the Néel temperature, it is expected that the

other electrical properties, i.e., the thermo-emf and the Hall emf, behave anomalously at the same temperature. The present experiment is also concerned with the investigations of the electrical properties in order to seek for possible evidence of the correlation of the electrical properties with the magnetic properties of this compound.

## § 2. Experimental

The procedure of the preparation of the compound MnTe$_{1+x}$ is as follows: Mixed powder of manganese (99.4 percent pure) and tellurium (99.9 percent pure) with a desired proportion was sealed in an evacuated silica tube ($10^{-6}$ mm Hg), and this was heated in a furnace at 725°C for 20 hours and slowly cooled after that. The product was a solid material with a grayish appearance. The X-ray Debye-Scherrer diffraction pattern of a sample of stoichiometric composition was compatible with the NiAs structure.

The susceptibility was measured with the same technique and the same magnetic balance as those described in previous papers7),8).

The electrical properties i.e., the resistivity, the thermo-emf and the Hall emf were measured by the usual methods. The specimens used for the present electrical measurements were prepared by moulding the powder sample to a shape of 7 mm in length, 4 mm in diameter (for the resistivity and the thermo-emf measurements) or a shape of 5 mm × 7 mm × 2 mm (for the Hall effect measurements) in a press tool, and by subsequent heat treatment of the material at 725°C to convert it to the crystalline modification. The sample holder is shown in Fig. 1. After it had been held in a brass case which was serviceable to homogenize the temperature of the sample, the measurements were carried out in vacuum ($10^{-2}$ mm Hg).

## § 3. Results

### a) *Magnetic measurements*

Fig. 2 shows the molal susceptibility of MnTe$_{1+x}$ as a function of temperature. All curves in this figure are obtained in heating runs for various compositions except the one which represents the cooling curve for the stoichiometric composition. In all cases the heating curve is found reversible up to about 100°C but it ceases to be so beyond that temperature. The cooling curve, from a higher temperature than 100°C, appears to be influenced in some way by the previous temperature history of the sample. The side curves in Fig. 2 represent a typical set of the details of the heating and cooling curves in the vicinity of the Néel point. Similar curves are obtained with different specimens, when measurements are made with special regard to the question of the Néel temperature. The heating curve indicates an abrupt change in slope at 37°C (310°K) and a maximum value of the susceptibility is obtained at 55°C (328°K), while a little lower values of the susceptibility occur with a broadening of the maximum in the cooling run. We can see, in the data of reciprocal susceptibility against temperature obtained by Serre for MnTe, a point which might possibly correspond to the abrupt change in slope in question; an observed point at about 37°C in Serre's case, in fact, deviates slightly from the curve, although the deviation is found so small that it cannot be noticed without special attention to this point.

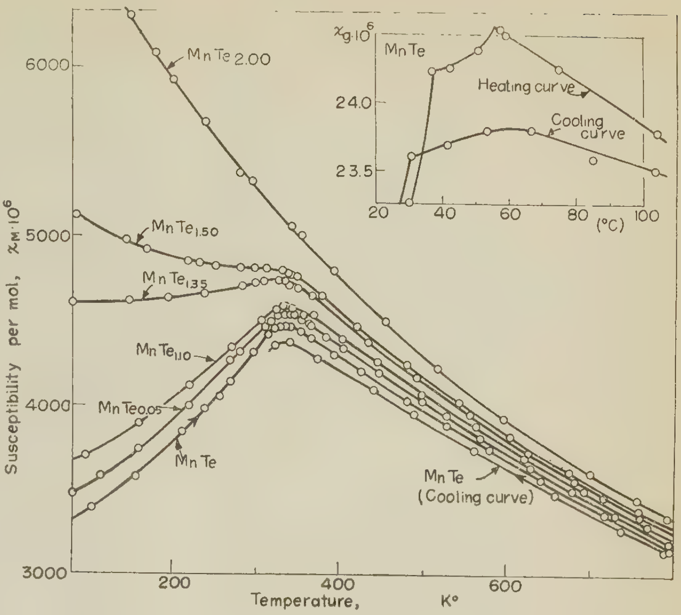

Fig. 2. Graph of molal susceptibility vs temperature for $MnTe_{1+x}$.

It is to be noted here that all the susceptibility curves of $MnTe_{1+x}$ in Fig. 2 can be understood as representing the sum of the molal susceptibilities of MnTe and $MnTe_2$, with the ratio of $(1-x)$: $x$, at corresponding temperature. Accordingly, the molal susceptibility of $MnTe_{1+x}$ is found to be a linear function of $x$ as shown in Fig. 3. This certainly indicates that $MnTe_{1+x}$ is constituted of two phases, MnTe and $MnTe_2$.

The reciprocals of the susceptibility for MnTe and $MnTe_2$ are plotted against absolute temperature in Fig. 4. As can be seen in this figure, plots for MnTe lie along a smooth curve, showing an upward concavity, which is in agreement to that previously observed by Serre. However, in the present case, the plots lie, above about 200°C, almost on a straight line, the extrapolation of this straight line crossing the temperature axis at −650°K. The molal susceptibility in the temperature range of this straight line can be written

$$\chi_M = C/(T+\theta)$$

with values of the Curie constant C, the characteristic temperature $\theta$ and the effective Bohr magneton numbers $p$ for a manganese atom given by

$$C=3.24, \quad \theta=650°\text{K}, \quad p=5.10\mu_B$$

These values of $C$, $\theta$ and $p$ are found to be a little smaller than those obtained by Serre.

From the linear relation of the reciprocal susceptibility against temperature of $MnTe_2$ (Fig. 4), the values of C, $\theta$ and $p$ for $MnTe_2$ are also estimated as follows:

$$C=4.00, \quad \theta=430°\text{K}, \quad p=5.68\,\mu_B$$

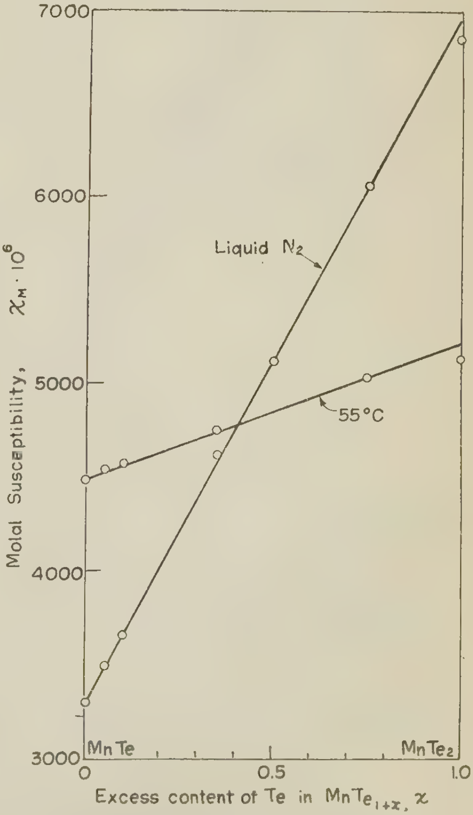

Fig. 3. Graph of molal susceptibility vs excess content of tellurium for $MnTe_{1+x}$.

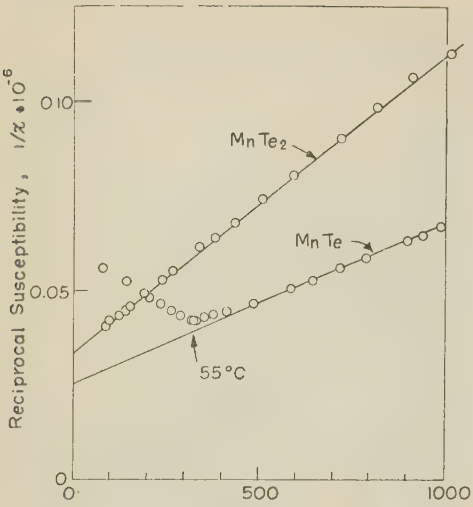

Fig. 4. Graph of reciprocal susceptibility vs temperature for MnTe and $MnTe_2$.

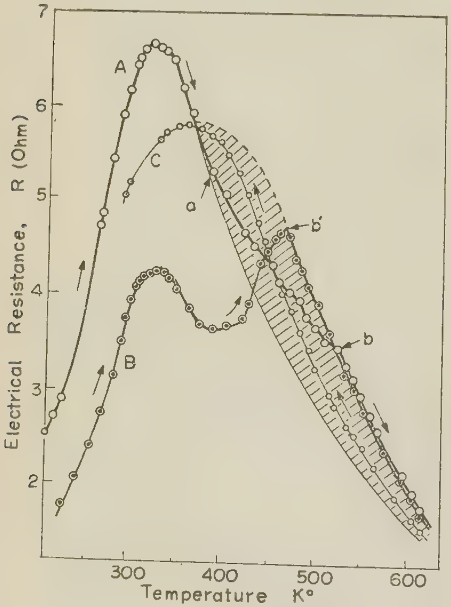

Fig. 5. Graph of electrical resistance vs temperature for MnTe.

Curve A: after 725°C heat treatment and subsequent slow cooling.

Curve B: after 725°C heat treatment and subsequent rapid cooling.

Curve C: after the runs for Curve A and for Curve B.

The fact that the paramagnetic Curie point of $MnTe_2$ is found in the negative region of temperature indicates an antiferromagnetic character of this compound, although no Néel point was yet found in the temperature range of the present experiment. It is to be noted that similar phenomena can be found in other intermetallic compounds, such as $Mn_5N_2$, FeTe or NiTe; each of them shows no evidence of the Néel point in the temperature range down to about 80°K and yet shows an antiferromagnetic character in its $1/\chi - T$ relation.

b) *Electrical properties*

The electrical properties of MnTe i.e., the resistivity, the thermo-emf and the Hall constant, are determined from liquid nitrogen temperature up to 400°C in order to see the correlation between the electrical and the magnetic properties of this compound.

The graph in Fig. 5 represents a set of typical runs in the measurements of resistivity. The data plotted on Curve A in this figure were obtained with the sample which has previously been subjected to a heat treatment at 725°C and to a subsequent slow cooling, by first cooling it to the liquid nitrogen temperature and then allowing it to warm up to the highest temperature of the measurements, usually at a rate of 2°/min. Up to the point 'a' on the curve at some ten degrees above the Néel point, Curve A shows a noticeable resemblance to the magnetic susceptibility behaviour, with a maximum at about 50°C (323°K). But, beyond this temperature, the observation generally shows a long relaxation time for the resistivity to approach its final value which is shown by the broken curve in this figure. However, after it has once reached the broken curve at the point 'b,' in the case of Curve A, this relaxation is experienced no more in the successive heating run. Curve C represents the subsequent cooling run to Curve A with a cooling rate of 2°/min. In all cases the cooling curve is a function of the interval of time during which the sample is held at the highest temperature of the run, the highest temperature itself and also the cooling rate. The hatched area in Fig. 5 represents the region in which all the cooling curves subject to different cooling conditions fall.

For the data plotted on Curve B, the heating run was started with the sample used for Curve A, which this time has previously been subjected to a heat treatment at 725°C for 20 hours and then to a rapid cooling from that temperature. The heating rate in this run is 2°/min, same as in the case of Curve

A. Compared with the case of Curve A, the lower values of the resistivity occurred up to about 100°C (373°K) and the relaxation time for the resistivity to approach to the broken line appeared to be shorter; consequently the point 'b′' on this curve, which corresponds to 'b' on Curve A, was found at a lower temperature than the latter. It is to be noted that in either cases of the run for Curve A and that for Curve B, the curve is found to be reversible up to about 100°C and it ceases to be reversible beyond, a similar phenomenon being also found in the magnetic susceptibility measurements. The hysteresis effect of the temperature dependence of resistivity above the Néel point is a good evidence of a certain change of the crystal structure at about 130°C.

The specific resistivity value of MnTe at room temperature is usually found to be of the order of 1 ohm cm. This is a very high conductivity compared with those of other antiferromagnetic manganese compounds such as MnSe, MnS or MnO.

Fig. 6 gives a typical result of the temperature dependence of the thermo-emf developed by the present specimens. For this data, a constant temperature difference of 40° is held across the specimen at every temperature of the measurements. It is found that the thermo-electric power lies between the values 0.3~0.6 mV/deg and shows a tendency to increase slowly with increasing temperature. The thermo-electric potential is always positive at the lower temperature side of the specimen, which indicates a predominanting hole conduction in MnTe.

Every plot in Fig. 7 represents the mean value of the data of ten repeated observations of the Hall voltage with a carrying current of 30 mA. The values of the Hall constant obtained by taking the slopes of the curves in this figure are plotted against temperature in Fig. 8. The sign of the Hall emf is found to be positive at all temperatures, which is consistent to the results of the thermo-emf measurements.

It is to be noted that both the thermo-emf and the Hall voltage behave anomalously at a temperature close to the Néel point (50°C), as in the resistivity; a maximum for the thermo-emf curve (Fig. 6) and a point of inflection for the Hall constant curve (Fig. 8) are found.

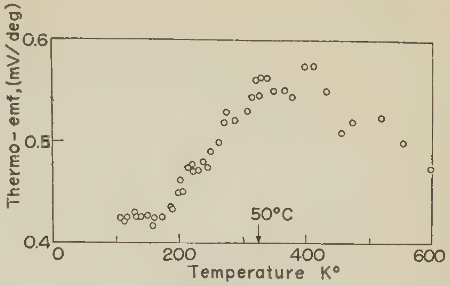

Fig. 6. Graph of thermo-electric power vs temperature for MnTe.

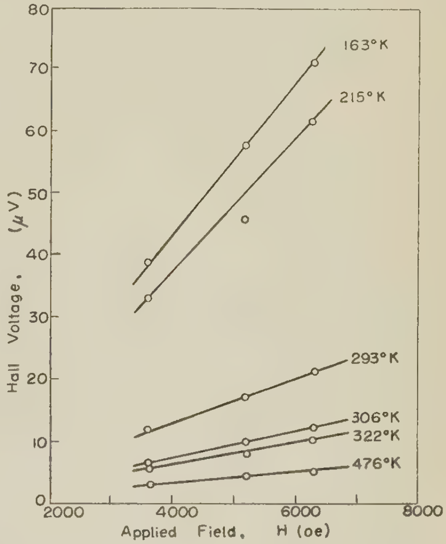

Fig. 7. Graph of Hall voltage vs applied field for MnTe.

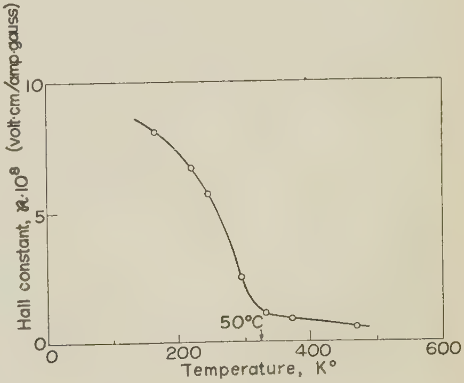

Fig. 8. Graph of Hall constants vs temperature for MnTe.

## § 4. Discussions

The results of the magnetic measurements showed the details of the behaviour of the susceptibility of MnTe in the vicinity of the

Néel point, i.e., we found a characteristic deviation from a simple $\lambda$-shape antiferromagnetic transition. Although this deviation is very small, we believe that the abrupt change in slope of the susceptibility curve at 37°C (310°K) correspond to the Néel temperature reported by Squire, and the maximum point at 55°C (328°K) to that reported by Serre. As mentioned in the preceeding section, the maximum at 55°C in fact broadens according to a heat history of the specimen. This broadening might have happened in the case of Squire. The anomalies in the resistivity and other electrical properties found at about 50°C (323°K) may be correlated with the maximum of the susceptibility curve at 55°C rather than to the abrupt change at 37°C. However, further experimental evidences (in particular of the specific heat or of the crystalline structure around the Néel point) may be necessary for the decision of the Néel point.

It should be mentioned that the temperature dependence of the electrical resistivity is very similar to that of the magnetic susceptibility, especially in the lower temperature region below 100°C. This is similar to the results reported by Squire. As shown in Fig. 5, conduction in MnTe changes its character in passing the Néel point from high to lower temperature, from a semi-conductor like conduction to a metallic one. We consider that this is an evidence of the influence of the magnetic properties of this compound on the conduction process at the Néel temperature. The decrease in conductivity with increasing temperature below the Néel point and the corresponding increases in thermo-emf and in Hall constant are qualitatively interpretable by supposing that the conduction in MnTe is contributed predominantly by holes above Néel temperature, while below the Néel temperature the part played by electrons increases with decreasing temperature.

## § 5. Conclusion

Results which are partly consistent to those of the previous works of Squire[2)] and Serre[3)] were obtained for MnTe in this experiment. It was also established that $MnTe_{1+x}$ is constituted of two phases involving MnTe and $MnTe_2$ in the range $0<x<1$.

The authors wish to thank Professor T. Nagamiya of Osaka University for kind discussions, Professor T. Hirone of Tohoku University and Professor Y. Mashiyama of Naniwa University for their warm encouragements.

# The Effects of Covalency on the Nuclear Magnetic Resonance in Ionic Crystals

By Kei YOSIDA and Tôru MORIYA

*Department of Physics, Osaka University*

(Received August 29, 1955)

Effects of covalency on the nuclear magnetic resonance in ionic crystals are discussed on the basis of perturbation calculations. Formulas for the chemical shift, the $I$-$I$ coupling and the quadrupolar relaxation time are derived. Using the degree of covalency deduced from the experimental values of the chemical shift, the coefficient of the $I$-$I$ coupling and the quadrupolar relaxation time are estimated for some ionic crystals. It is shown that, when the degree of covalency is several percent, the quadrupolar relaxation time becomes much shorter than in pure ionic case. For instance, the relaxation time of Br in KBr, assuming the degree of covalency of 1 percent, is estimated to be 1 sec, which is only several times larger than the experimental value.

## § 1. Introduction

According to experimental studies of the nuclear magnetic resonance absorption in ionic crystals, there exist the following three important problems associated with the covalency participating in the interionic binding: one is the problem of the chemical shift of the resonance field, the second is the anomalous width of the resonance line and the third is the problem concerned with the relaxation time.

Gutowsky and MacGarvey[1)] measured the chemical shift of Rb and Cs in their halides and remarked that it might arise from covalency. Kanda[2)] measured the chemical shift of halogen ions in several metal halides and deduced numerically the degree of covalency in each halide. Since the halogen ion has a closed shell structure in its pure ionic state, there is no second order paramagnetic effect, but in its excited state, where one electron of halogen ion is transferred to one of the neighbouring metal ions, the second order paramagnetic effect appears on account of the $p$-character of the halogen electronic wave function. Therefore, if the ionic state of a halide is not pure but is mixed to a certain extent with the state of covalent bonding, we can expect a paramagnetic chemical shift which is proportional to the degree of covalency.

Watkins and Pound[3)] and Watkins[4)] have performed precise experiments of the halogen nuclear magnetic resonance absorption in ionic crystals. Especially, Watkins found relaxation times of the order of $10^{-1}\sim 10^{-2}$ sec in the single crystals of KBr and KI. Although in these samples the dominant mechanism of the relaxation can be considered to be quadrupolar, the theoretical value of the relaxation time calculated under the assumption that the electric field gradient acting on each nucleus arises mainly from the surrounding ionic charges is larger than the experimental value by a factor of $10^5$. Watkins discussed possible sources of this discrepancy and pointed out as the most dominant effect the deformation of the electron shell surronding the nucleus by the thermal vibrations of the ions. It can be considered that there are two types of deformation sufferred by the ions, one is the deformation due to the mixing of higher electronic states of the ion and the other is that due to the transfer of an electron of that ion to a nearest neighbour ion, that is, the covalent bonding. Watkins considered the first type in some detail and showed that this is considerably effective to shorten the theoretical relaxation time. On the other hand Townes and Dailey[5)] pointed out that in covalent bonding state there exists a large electric field gradient at the position of the nucleus. Kanda found that the reciprocal of the relaxation time is proportional to the degree of covalency in LiBr, AgBr and TlBr. Thus, also in nuclear quadrupole relaxation, the role of covalency cannot be overlooked. In fact, the $p$-character of the electronic wave function of the halogen ion in its covalent state can produce a considerably large field gradient.

Another effect of the covalency is the formation of an indirect coupling between nuclear spins. Ruderman and Kittel[6] developed the theory of the *I–I* coupling between nuclear spins in metals, and a little later Bloembergen and Rowland[7] showed that this *I–I* coupling is the main source of the anomalously broad line width in metallic thallium and thallic oxides, and they extended Ruderman-Kittel's theory to the case of semiconductors or ionic crystals on the basis of Wilson's semiconductor model. Very recently, also Kanda[8] found very broad resonance lines in Tl-halides which can not be interpreted in terms of the ordinary dipole-dipole interactions between nuclear moments and concluded that this width arises from the *I–I* coupling. This *I–I* coupling in ionic crystals can be understood only when the covalent states are taken into account as excited states.

The purpose of this paper is to develop the theory of the chemical shift, the *I–I* coupling and the quadrupolar relaxation time arising from the excited covalent states with the use of a simple perturbational treatment and of the Heitler-London model. For the chemical shift and the *I–I* coupling, formulas presented here are not essentially different from those obtained already by Ramsey[9], Saika and Slichter[10], Ramsey and Purcell[11] and Gutowsky, McCall and Slichter[12], but they are extensions to the case of ionic crystals, and these will be given in § 2 and 3. In § 4 and 5, the contributions from the covalency to the quadrupole relaxation time is calculated along the same line as in § 2 and 3.

## § 2. Chemical Shift

Gutowsky and McGarvey and Kanda found considerably large paramagnetic chemical shifts in nuclear resonance lines for halides of heavy metals such as Rb, Cs and Tl. It may be considered that this shift originates in the covalent bonding state which mixes to some extent with the pure ionic state. In this section, we shall calculate the coefficient of the chemical shift $\sigma$ on the basis of the perturbational treatment, taking as the zero-th approximation the purely ionic state.

First let us consider the shift of a halogen nucleus whose nuclear moment $\mu$ is assumed, for convenience, to point in the direction of the external magnetic field. Then the necessary perturbing Hamiltonian for the chemical shift is expressed as

$$V=V_t+\sum_i\left(\boldsymbol{H}+\frac{2\boldsymbol{\mu}}{r_i^3}\right)\cdot\mu_B\boldsymbol{l}_i\,. \tag{2.1}$$

Here $V_t$ means the Hamiltonian which makes an electron of the halogen ion jump into a neighbouring metal ion and is of an electric nature, and the second term expresssed by a summation over electrons belonging to the halogen ion represents the interaction energy of the electrons with the external field $\boldsymbol{H}$ and with the field arising from the nuclear magnetic moment. $r_i$ and $\boldsymbol{l}_i$ mean respectively the radial distance of the $i$-th electron from the halogen nucleus and its orbital angular momentum in units of $\hbar$, and $\mu_B$ is the Bohr magneton.

According to the perturbation scheme, the fourth order perturbed energy can be written in the following form:

$$\Delta E_4=-\sum_{n,n',n''}\frac{(g|V|n)(n|V|n')(n'|V|n'')(n''|V|g)}{(E_n-E_g)(E_{n'}-E_g)(E_{n''}-E_g)}\,, \tag{2.2}$$

where $E_g$ and $E_n$ denote the unperturbed energies of the ground and excited states. The most important terms in the summation of Eq. (2.2) are those in which the first and the third excited states, i.e. $n$ and $n''$, are the same covalent state in which one electron of the halogen ion, with such a $p$-wave function that extends towards a neighbouring metal ion, has been transferred to that metal ion. Such a transition of one electron is produced by the electric part of Eq. (2.1) $V_t$. Then, Eq. (2.2) can be simplified as

$$\Delta E_4=-\sum_{n}\frac{|(g|V_t|n)|^2}{(E_n-E_g)^2}\sum_{n'}\frac{(n|V_H|n')(n'|V_H|n)}{E_{n'}-E_g}\,. \tag{2.3}$$

Here the first summation is taken over all the nearest neighbouring metal ions of the halogen ion and $V_H$ denoted the magnetic part of the Hamiltonian (2.1). In order to obtain the chemical shift from the perturbed energy $\Delta E_4$, we must take out the field-dependent term from (2.3). Each excited state $n'$, which is connected by the field-dependent term of (2.1) with the state $n$ in which one $p$-electron is missing from the halogen ion, is the state produced by the transition of one electron on another $p$-orbital to the hole of the state $n$. Since four electrons are participating in this transition and the transition from the ground state to the $n$-state, $g$, $n$, and $n'$-states are represented by the following wave functions

either

$$\psi_g = \frac{1}{\sqrt{2^2 \cdot 4!}} \Sigma_p\, \delta_p P \varphi_0(1)\varphi_0(2)\varphi_{+1}(3)\varphi_{+1}(4)\{1\cdot 2\}\{3\cdot 4\}\,, \tag{2.4}$$

$$\psi_n = \frac{1}{\sqrt{2 \cdot 4!}} \Sigma_p\, \delta_p P \varphi_M(1)\varphi_0(2)\varphi_{+1}(3)\varphi_{+1}(4)\{1\cdot 2\}\{3\cdot 4\}\,, \tag{2.5}$$

$$\psi_{n'} = \frac{1}{\sqrt{2 \cdot 4!}} \Sigma_p\, \delta_p P \varphi_M(1)\varphi_0(2)\varphi_0(3)\varphi_{+1}(4)\{1\cdot 4\}\{2\cdot 3\}\,, \tag{2.6}$$

or

$$\psi_g = \frac{1}{\sqrt{2^2 \cdot 4!}} \Sigma_p\, \delta_p P \varphi_0(1)\varphi_0(2)\varphi_{-1}(3)\varphi_{-1}(4)\{1\cdot 2\}\{3\cdot 4\}\,, \tag{2.7}$$

$$\psi_n = \frac{1}{\sqrt{2 \cdot 4!}} \Sigma_p\, \delta_p P \varphi_M(1)\varphi_0(2)\varphi_{-1}(3)\varphi_{-1}(4)\{1\cdot 2\}\{3\cdot 4\}\,, \tag{2.8}$$

$$\psi_{n'} = \frac{1}{\sqrt{2 \cdot 4!}} \Sigma_p\, \delta_p P \varphi_M(1)\varphi_0(2)\varphi_0(3)\varphi_{-1}(4)\{1\cdot 4\}\{2\cdot 3\}\,. \tag{2.9}$$

Here $\varphi_M$ means the wave function of the electron transferred to the metal ion and is in general a hybridized orbital of $s$- and $p$-functions of the metal ion, $\varphi_0$, $\varphi_{\pm 1}$ denote the wave functions of the $p$-state in the halogen ion, suffixes 0, ±1 representing the $z$-component of the angular momentum $\boldsymbol{l}$. The $z$-axis is taken in the direction joining the halogen ion to the metal ion. In this case, $\varphi_0$ is the wave function which extends towards the $z$-axis. $\{12\}$ represents the antisymmetrized spin function, that is, the abbreviation of

$$\frac{1}{\sqrt{2}}\{\alpha(1)\beta(2)-\alpha(2)\beta(1)\}\,,$$

where $\alpha$ and $\beta$ respectively mean the spin functions of plus and minus spins. Further, it must be noted that the singlet states should be taken as the excited states $\psi_n$ and $\psi_{n'}$, as well as the ground state, since the perturbing Hamiltonian (2.1) does not contain any spin variable. $\psi_{n'}$ represented by (2.6) is the state in which one electron with the wave function of $\varphi_{+1}$ has been transferred to $\varphi_0$ state, while $\psi_{n'}$ represented by (2.9) is that in which one electron with $\varphi_{-1}$ has been transferred to $\varphi_0$ state. Therefore, in calculating the matrix element of $(n|V|n')$, $\varphi_n$ given by (2.5) must be used in combination with $\psi_{n'}$ given by (2.6), and $\varphi_n$ given by (2.8) with $\psi_{n'}$ given by (2.9). The summation with respect to $n'$ in (2.3) is taken over these two states of $n'$.

Now we denote the direction cosines of the external field $\boldsymbol{H}$ by $\alpha_n$, $\beta_n$ and $\gamma_n$, referring to the coordinate system in which the $z$-axis is the direction joining the halogen ion to the metal ion under consideration. After simple calculations we obtain

$$(n|V_H|n') = -\frac{1}{\sqrt{2}}\mu_B\left(H+2\mu\left\langle\frac{1}{r^3}\right\rangle_H\right)(\alpha_n \mp i\beta_n)\,, \tag{2.10}$$

$$\Sigma_{n'}\frac{(n|V_H|n')(n'|V_H|n)}{E_{n'}-E_g} = \frac{1}{\varDelta E'}\mu_B{}^2\left(H+2\mu\left\langle\frac{1}{r^3}\right\rangle_H\right)^2(\alpha_n{}^2+\beta_n{}^2)\,, \tag{2.11}$$

where $V_H$ represents the second term of (2.1), $E_{n'}-E_g$ is denoted by $\varDelta E'$ and $\left\langle\frac{1}{r^3}\right\rangle_H$ means the average value with respect to the radial part of the $p$-wave functions of the halogen ions. Summing up $(\alpha_n{}^2+\beta_n{}^2)$ over all the neighbouring metal ions we obtain

$$\Sigma_n(\alpha_n{}^2+\beta_n{}^2)=4\,, \qquad \text{for NaCl type}$$

$$=\frac{16}{3}\,. \qquad \text{for CsCl type}\,.$$

Thus if we denote $E_n-E_g$ by $\varDelta E$ and $|(g|V_t|n)|^2$ by $b^2$, $\varDelta E_4$ becomes

$$\Delta E_4 = -\frac{2}{3} z \frac{b^2}{\Delta E^2} \frac{1}{\Delta E'} \mu_B^2 \left(H + 2\mu \left\langle \frac{1}{r^3} \right\rangle_H \right)^2 , \tag{2.12}$$

where $z$ means the coordination number. The coefficient of the chemical shift $\sigma$ is given by the coefficient of the linear term with respect to $H\mu$ in (2.12), as Ramsey pointed out. Therefore we obtain for $\sigma$ of the halogen nucleus,

$$\sigma_H = -\frac{8}{3} z \frac{b^2}{\Delta E^2} \frac{1}{\Delta E'} \mu_B^2 \left\langle \frac{1}{r^3} \right\rangle_H . \tag{2.13}$$

Here it should be noted that $\Delta E$ is the energy of the state with covalent bonding, whereas $\Delta E'$ is that of the state without bonding. Therefore the former value is generally smaller than the latter. Moreover, $zb^2/(\Delta E)^2$ represents the degree of covalency and if we write this quantity as $\lambda$, although in this paper we shall use $\lambda$ for $b^2/(\Delta E)^2$, Eq. (2.13) becomes identical with the expression derived by Saika and Slichter in the case of molecules and that derived by Kanda in the case of ionic crystals.

Next we shall turn to the consideration of the chemical shift of the metal nucleus. In this case we must pay our attention to the electron transferred to the metal ion from the halogen ion, and take as the excited states $\psi_{n'}$ the states in which the transferred electron has changed its wave function from the $s$-$p$ hybridized orbital, favourable to the covalent bonding, to another $p$-orbital, namely

$$\begin{aligned} \psi_n &: \varphi_M = a_s \varphi_s^M + a_p \varphi_0^M , \\ \psi_n' &: \varphi_{\pm 1}^M , \end{aligned} \tag{2.14}$$

where $\varphi_s^M$, $\varphi_{0,\pm 1}^M$ mean the $s$-function and the three $p$-functions of the metal ions, 0, $\pm 1$ denoting the component of the angular momentum referred to the $z$-axis which is chosen in the direction connecting the metal ion with one halogen ion. If $\varphi_M$ is one of the usual tetrahedral orbitals, $a_s = \frac{1}{2}$ and $a_p = \frac{\sqrt{3}}{2}$. The perturbing Hamiltonian is of the type of (2.1), where $r_i$ is now to be interpreted as the distance from the metal nucleus. The calculation in this case becomes very simple because we need treat only one electron. Using similar notation to the case of halogen nucleus, we obtain the following result:

$$\Delta E_4 = -\sum_n \frac{b^2}{\Delta E^2} \frac{1}{\Delta E'} a_p^2 \mu_B^2 \times \left(H + 2\mu \left\langle \frac{1}{r^3} \right\rangle_M \right)^2 (\alpha_n^2 + \beta_n^2) , \tag{2.15}$$

where $\left\langle \frac{1}{r^3} \right\rangle_M$ means the average of $1/r^3$ over the radial part of the $p$-wave functions of the metal ion and the summation runs over the neighbouring halogen ions. From (2.15) the coefficient of the chemical shift for the metal nucleus, $\sigma_M$, is given by

$$\sigma_M = -\frac{8}{3} a_p^2 z \frac{b^2}{\Delta E^2} \frac{1}{\Delta E'} \mu_B^2 \left\langle \frac{1}{r^3} \right\rangle_M , \tag{2.16}$$

where $b$, $\Delta E$ are exactly the same as those appearing in (2.13) and $\Delta E'$ would be nearly equal to that of (2.13).

Up to now we have picked up only the fourth order perturbation. The second order perturbation must include such matrix elements as $(n|V_H|g)$, which can be explicity written down, as seen from (2.1), as

$$(n|H\mu_B \textstyle\sum_i l_i|g) + \left(n\middle| \sum_i \frac{2\mu}{r_i^3} \mu_B l_i \middle| g\right) .$$

Here the first term including the external field appearently vanishes because the ground state $g$ has a closed shell structure. Therefore, the second order perturbation contributes nothing to the chemical shift. Most of the third order terms vanish on account of the same reason, and the remaining parts would give only negligibly small contributions compared to the fourth order term. Thus we can regard the results of Eqs. (2.13) and (2.16) as the lowest order contributions in the perturbation approximation. In calculating $\sigma_M$ of the metal nucleus we confined our considerations to the case that the hybridized orbital consists of only $p$ and $s$-orbitals. For Rb and Cs, however, also d-orbitals may contribute to their chemical shifts. Therefore (2.16) should be modified to some extent in these cases.

The chemical shifts of the halogen nucleus in metal halides have been measured by Kanda. We shall estimate here the factor $\lambda = b^2/(\Delta E)^2$ in (2.13), a measure of the degree of covalency in these halides, assuming appropriate values for $\Delta E'$ and $\langle 1/r^3 \rangle$, as Kanda did in his paper. From the ionic picture on which we are standing, however, the value of $\Delta E'$ could be well appoximated by the following equation:

$$\Delta E' = \frac{(2\alpha - 1)e^2}{a} + E - I , \tag{2.17}$$

Table I.

| | cryst. structure | $a\times10^8$ | $E_{ev}$ | $I_{ev}$ | $\Delta E'_{ev}$ | $\left\langle\frac{1}{r^3}\right\rangle_H a_0^3$ | $-\sigma_{\exp}\times10^4$ | $\lambda=(b/\Delta E)^2$ |
|---|---|---|---|---|---|---|---|---|
| TlCl | CsCl | 3.31 | 3.75 | 6.07 | 8.63 | 7.16 | 2.51 | 0.039 |
| TlBr | CsCl | 3.44 | 3.52 | 6.07 | 7.99 | 13.55 | 6.2 | 0.047 |
| AgBr | NaCl | 2.88 | 3.52 | 6.54 | 8.45 | 13.55 | 1.89 | 0.020 |
| LiBr | NaCl | 2.745 | 3.48 | 5.37 | 11.2 | 13.55 | 0.896 | 0.013 |
| KI | NaCl | 3.53 | 3.13 | 4.32 | 9.00 | 18.0 | 1.48 | 0.013 |

where $a$ represents the interionic distance, $\alpha$ the Madelung constant, $I$ the ionization potential of the metal atom and $E$ the affinity of the halogen atom. For a more precise estimation, it might be necessary to take into account the effect of polarization, but since it is neither easy to estimate nor very serious, we omit it in our rather rough evaluation.

Actually, the excited states are such that the electron transferred from a halogen ion moves over all the surrounding metal ions, and thus they are split into several levels with different symmetries, while the excited states used in our perturbation calculations have been assumed to be degenerate. The real states, however, can be expressed as linear combinations of our degenerate functions, so that our $\varDelta E'$ represents approximately the centre of gravity of the split levels. The value of $\varDelta E'$ given by Eq. (2.17) corresponds to this centre of gavity of the levels.

Making use of the average values of $\langle 1/r^3\rangle$ estimated semi-empirically for several ions by Barnes and Smith[13] we obtain the values of $\lambda$ shown in Table I. These values multiplied by coordination number $z$ are nearly equal to the values of the degree of covalency obtained by Kanda.

## § 3. Indirect Interaction Between Nuclear Spins

In this section we shall turn our attention to the problem concerning the indirect spin coupling between nuclei. This problem can be treated with the use of the same method as that used in the preceding section. Namely, we shall start from the purely ionic state where all the interactions of the electrons with nuclear spins would disappear in the average because of the closed shell structures of the ions. The existence of the indirect couplings between nuclear shins becomes possible only when excited configurations are taken into account.

The perturbing Hamiltonian in this case consists of the interactions between electrons and nuclear spins. Namely,

$$V=V_t+V_L+V_D+V_F\ , \tag{3.1}$$

$$V_L=2\mu_B\hbar\left\{\gamma_H\sum_i\frac{(l_i\cdot I_H)}{r_{Hi}{}^3}+\gamma_M\sum_i\frac{(l_i\cdot I_M)}{r_{Mi}{}^3}\right\}\ , \tag{3.2}$$

$$\begin{aligned}V_D=2\mu_B\hbar[\gamma_H\textstyle\sum_i r_{Hi}^{-3}\{&-(s_i\cdot I_H)\\ &+3r_{Hi}^{-2}(s_i\cdot r_{Hi})(I_H\cdot r_{Hi})\}\\ &+\gamma_M\textstyle\sum_i r_{Mi}^{-3}\{-(s_i\cdot I_M)\\ &+3r_{Mi}^{-3}(s_i\cdot r_{Mi})(I_M\cdot r_{Mi})\}]\ ,\end{aligned} \tag{3.3}$$

$$\begin{aligned}V_F=\frac{16}{3}\pi\mu_B\hbar\{&\gamma_H\textstyle\sum_i\delta(r_i-r_H)(s_i\cdot I_H)\\ &+\gamma_M\textstyle\sum_i\delta(r_i-r_M)(s_i\cdot I_M)\}\ ,\end{aligned} \tag{3.4}$$

where $V_t$ represents, as in the preceding section, the electrostatic perturbation, which makes an electron transfer from a halogen ion to one of its nearest neighbouring metal ions, $V_L$ the interactions between the orbital moment $l_i$ of electron $i$ and the nuclear spins $I_H$ and $I_M$, $V_D$ those between electron spins $S_i$ and the nuclear spins and $V_F$ the Fermi interactions. $\gamma_H$ and $\gamma_M$ mean the gyromagnetic ratio of the nuclei and suffixes $H$ and $M$ represent the halogen and metal ions, respectively. Now we shall consider the indirect couplings between nuclear spins of nearest pairs of metal and halogen ions. Also in this case, the most important effective Hamiltonian giving rise to the interaction between nuclear spins would be given by Eq. (2.2), where the excited states $n$ and $n''$ are the covalent states in which one metal ion has an excess electron transferred from the neighbouring halogen ion. The wave function of the extra electron in the metal ion is, as before, expressed by (2.14) and that of the hole left in the halogen by the same $\varphi_{H0}$ as in the previous section, both of which extending in the direction connecting the metal ion with the halogen ion and having zero $z$-component of the angular momentum $l$. Then, we have a similar expression to Eq. (2.3), except that $V_H$ is replaced by $V_L$, $V_D$ and $V_F$. In this expression, however, we must take different excited states from those taken in § 2.

Since the perturbation $V_L$ does not contain any electron spin variable, $V_L$ has non-vanishing matrix element $(n|V_L|n')$ only for singlet states $n'$ because the ground state is singlet and so the covalent state is singlet, whereas the other $V_D$ and $V_F$ have vanishing elements for singlet $n'$ because they are linear with respect to the electron spin. Therefore we can divide the matrix elements of $V_L+V_D+V_F$ into parts and consider them separately. Since $V_L$ is linear with respect to the orbital moment of an electron, its matrix elements do not vanish only for such $\psi_{n'}$ for which the vacant $\varphi_{H0}$ state of the halogen ion has become occupied by another $p$-electron or for which a $p$-orbital of the metal ion has become occupied instead of the $\varphi_M$ orbital. For such $\psi_{n'}$, however, either of the matrix elements of $V_{LH}$ and $V_{LM}$ vanishes, so that any coupling between $I_H$ and $I_M$ does not occur from $V_L$.

As for $V_D$ and $V_F$, they are linear with respect to spin variables as mentioned above so that they have non-vanishing matrix elements only for triplet states $n'$. We shall now take two electrons out of six, one of which occupies the $\varphi_M$-orbital and the other the $\varphi_{H0}$-orbital. Then the orbital part of $\psi_n$ and $\psi_{n'}$ can be written as

$$\psi_n=\frac{1}{\sqrt{2}}\{\varphi_M(1)\varphi_{H0}(2)+\varphi_M(2)\varphi_{H0}(1)\}\,, \tag{3.5}$$

$$\psi_{n'}=\frac{1}{\sqrt{2}}\{\varphi_M(1)\varphi_{H0}(2)-\varphi_M(2)\varphi_{H0}(1)\}\,. \tag{3.6}$$

The other electrons may be put out of considerations for the present calculation. Let us first calculate the transition matrix element of $V_D$ between the states (3.5) and (3.6) reserving the spin variables as operators. Using (3.5), (3.6) and (3.3), we obtain the following expression:

$$\begin{aligned}(n|V_D|n')=-\mu_B\hbar\sum_{i=1,2}(-1)^i\Big[\gamma_M\int\varphi_M(i)r_{Mi}^{-3}\{-(s_i\cdot I_M)+3r_{Mi}^{-2}(s_i\cdot r_{Mi})(I_M\cdot r_{Mi})\}\varphi_M(i)d\tau_i\\ -\gamma_H\int\varphi_{H0}(i)r_{Hi}^{-3}\{-(s_i\cdot I_H)+3r_{Hi}^{-2}(s_i\cdot r_{Hi})\,(I_H\cdot r_{Hi})\}\,\varphi_{H0}(i)\,d\tau_i\Big]\,,\end{aligned} \tag{3.7}$$

where insignificant contributions arising from the non-diagonal elements between $\varphi_M$ and $\varphi_{H0}$ are omitted. The integrals included in the above expression can easily be calculated as

$$\begin{aligned}&\int\varphi_M(r)\frac{xy}{r^5}\varphi_M(r)d\tau=\int\varphi_{H0}(r)\frac{xy}{r^5}\varphi_{H0}(r)d\tau=0,\cdots\\ &\int\varphi_M(r)\frac{x^2}{r^5}\varphi_M(r)d\tau=\int\varphi_M(r)\frac{y^2}{r^5}\varphi_M(r)d\tau=a_s{}^2\frac{1}{3}\left\langle\frac{1}{r^3}\right\rangle_{MS}+a_p{}^2\frac{1}{5}\left\langle\frac{1}{r^3}\right\rangle_{MP}\,,\\ &\int\varphi_{H0}(r)\frac{x^2}{r^5}\varphi_{H0}(r)d\tau=\int\varphi_{H0}(r)\frac{y^2}{r^5}\varphi_{H0}(r)d\tau=\frac{1}{5}\left\langle\frac{1}{r^3}\right\rangle_H\,,\\ &\int\varphi_M(r)\frac{z^2}{r^5}\varphi_M(r)d\tau=a_s{}^2\frac{1}{3}\left\langle\frac{1}{r^3}\right\rangle_{MS}+a_p{}^2\frac{3}{5}\left\langle\frac{1}{r^3}\right\rangle_{MP}\,,\\ &\int\varphi_{H0}(r)\frac{z^2}{r^5}\varphi_{H0}(r)d\tau=\frac{3}{5}\left\langle\frac{1}{r^3}\right\rangle_H\,.\end{aligned}$$

Using these results, (3.7) becomes

$$\begin{aligned}(n|V_D|n')=\frac{2}{5}\mu_B\hbar\Big[\gamma_H\left\langle\frac{1}{r^3}\right\rangle_H\{(s_1-s_2)_x\cdot I_{Hx}+(s_1-s_2)_y\cdot I_{Hy}-2(s_1-s_2)_zI_{Hz}\}\\ -a_p{}^2\gamma_M\left\langle\frac{1}{r^3}\right\rangle_{MP}\{(s_1-s_2)_x\cdot I_{Mx}+(s_1-s_2)_y\cdot I_{My}-2(s_1-s_2)_z\cdot I_{Mz}\}\Big]\,.\end{aligned} \tag{3.8}$$

For $V_F$ a similar calculation yields

$$(n|V_F|n')=\frac{16}{3}\pi a_s{}^2\,\frac{1}{2}\mu_B\hbar\gamma_M|\varphi_{MS}(0)|^2(s_1-s_2)\cdot I_M\,, \tag{3.9}$$

where the contribution from $\varphi_{H0}$ does not appear because we are assuming $\varphi_{H0}$ as a pure $p$-function. Inserting (3.8) and (3.9) into (2.3) and nothing that the summation over $n$ is unnecessary in this case and that the summation over $n'$ can be replaced by the average of the products of spins included in (3.8) and (3.9) with respect to the singlet state, we obtain the following couplings between the two nuclear spins:

$$\frac{16}{25} a_p^2 \gamma_M \gamma_H \hbar^2 \lambda \frac{1}{\Delta E'} \mu_B^2 \left\langle \frac{1}{r^3} \right\rangle_H \left\langle \frac{1}{r^3} \right\rangle_{MP} (I_H \cdot I_M)\,, \tag{3.10a}$$

$$-\left\{ \frac{8}{25} a_p^2 \gamma_H \gamma_M \hbar^2 \lambda \frac{1}{\Delta E'} \mu_B^2 \left\langle \frac{1}{r^3} \right\rangle_H \left\langle \frac{1}{r^3} \right\rangle_{MP} + \frac{32}{15} a_s^2 \gamma_H \gamma_M \hbar^2 \pi \lambda \frac{1}{\Delta E'} \mu_B^2 |\varphi_{MS}(0)|^2 \left\langle \frac{1}{r^3} \right\rangle_H \right\} \times \{ I_{Hx} \cdot I_{Mx} + I_{Hy} \cdot I_{My} - I_{Mz} \cdot I_{Mz} \}\,. \tag{3.10b}$$

This result shows that exchange and pseudodipolar couplings are acting between $I_M$ and $I_H$. Expressions analogous to (3.10a) and (3.10b) have already been obtained by Gutowsky, MacCall and Slichter for the case of molecules and, independently of the present writers, by Kanda and Saito for the case of ionic crystals.

The ratios of the coefficients of the indirect couplings derived above to that of the oridinary dipole-dipole interaction $\hbar^2 \gamma_M \gamma_H / a^3$ are given by

$$\alpha_E = \frac{16}{25} a_p^2 \frac{\lambda}{\Delta E'} \mu_B^2 \left\langle \frac{1}{r^3} \right\rangle_H \left\langle \frac{1}{r^3} \right\rangle_{MP} a^3\,, \tag{3.11a}$$

$$\alpha_D = -\frac{\lambda}{\Delta E'} \left\langle \frac{1}{r^3} \right\rangle_M a^3 \mu_B^2 \left\{ \frac{8}{25} a_p^2 \left\langle \frac{1}{r^3} \right\rangle_{MP} + \frac{32}{15} \pi a_s^2 |\varphi_{MS}(0)|^2 \right\}\,. \tag{3.11b}$$

Kanda found a broad halogen resonance line in thallium halides, especially for TlCl, TlBr and TlI. If it could be assumed that such a broadening occurs due to indirect couplings between nuclear spins of neighbouring metal and halogen ions, such indirect couplings should be about three times for TlCl and about seven times for TlBr as effective as the ordinary dipole-dipole interactions. The estimated values from Eqs. (3.11a) and (3.11b) with the use of values of $\lambda$ in Table I, which have been deduced from experimental data of the chemical shift, are less than those due to dipole-dipole interactions by a factor of about ten for the bromide and 20 for the chloride if we put $a_p=1$ and $a_s=0$. The value of $|\varphi_{Ms}(0)|^2$ for the 7$s$-orbital of Tl estimated from experimental hyperfine separation is about $3\times10^{25}\,\mathrm{cm}^{-3}$ which is one half of $\left\langle \frac{1}{r^3} \right\rangle_{\mathrm{Tl}6p}$. Accordingly, even if we put $a_p=0$ and $a_s=1$ and use this value of $|\varphi_{Ms}(0)|^2$, they are multiplied by a factor of 5 on account of the large coefficient of the Fermi interaction but still too small by a factor of 20∼10 in order to explain the experimental width for both chloride and bromide. To take into consideration a mixing of the 6$s$-orbital of Tl in $\varphi_M$ will not improve the present situation. The second and third order contributions are of course very small compared to those of the fourth order.

It could not also be expected that the effect of the inner $s$-orbital of the halogen ion might improve this situation. The calculated value of $|\varphi_{3s}(0)|^2$ for Cl$^-$ by Hartree and Hartree[14)] is $6.8\times10^{25}\,\mathrm{cm}^{-3}$ for the 3$s$-orbital which is 1.5 times as large as $\langle 1/r^3 \rangle_{\mathrm{Cl}3p}$. Even though we take account of the large numerical factor for the Fermi interaction and assume a mixing of 50 percent 3$s$-orbital in $\varphi_{H0}$, we can only get a too small value by a factor of 5∼10 to account for the experimental results.

Furthermore, according to the analysis of the experimental data by Kanda for TlCl and TlBr, there exist exchange and pseudo-dipolar couplings between thallium nuclear spins which are of magnitude about three to ten times as large as the dipolar interactions. The existence of such large indirect couplings between thallium nuclear spins seems to suggest a considerably large overlapping of the wave function of the excited electron in a thallium ion with the neighbouring thallium ion. However, we shall leave this problem for a future discussion and turn to the problem of the relaxation time.

## § 4. Quadrupolar Relaxation I: Transition Probability

The importance of the quadrupole interaction in the spin-lattice relaxation of ionic crystals was first pointed out by Pound[15]. Subsequently Watkins[4] gave a more detailed discussion on this subject, especially for metal halides, and concluded that in KBr and KI the quadrupole interaction is the dominating relaxation mechanism. Recently Kanda[2] has also confirmed the same fact in LiBr, AgBr and TlBr. Theoretical studies of this mechanism have been done by Bloembergen[16], Watkins and recently by Kranendonk[17]. They showed that the simple point charge model of ionic crystals gives too long a relaxation time to explain the experimental results, that is, the experimental values are $10^{-2}$ sec or so while Kranendonk's precise calculation gives $3\times10^{3}\sim1\times10^{6}$ sec at room temperature. As the origin of this discrepancy Watkins considered the effect of the deformation of the ions and Kranendonk discussed the importance of the shielding, anti-shielding and covalent effects. In this section we shall consider the effect of the covalency on the quadrupolar relaxation of the halogen nuclear spin, basing our calculation on the perturbation scheme developed in the preceding two sections.

In the covalent state one $p$-electron is missing from the closed shell of a halogen ion. The asymmetry of the electron distribution produced by this hole generates a strong field gradient proportional to $\left\langle \frac{1}{r^3} \right\rangle_{av.}$ at the position of the halogen nucleus. On the other hand, the field gradient due to a point charge at a neighbouring lattice position is proportional to $1/a^3$, $a$ being interionic distance. If we assume the degree of covalency to be 3 percent, the relaxation time due to covalency would be shorter than in the pure ionic case by a factor of

$$\left(3\times10^{-2}\times\left\langle\frac{1}{r^3}\right\rangle_{av.}a^3\right)^{-2}\sim(3\times10^{-2}\times5\times10^{25}\times3\times10^{-23})^{-2}\sim10^{-3}\,.$$

Moreover, in Raman processes, a factor proportional to a linear combination of the first and second derivatives of the field gradient with respect to the interionic distance appears in the expression for the transition probabilities. In the case of the covalent state, these quantities correspond to the derivatives of the degree of covalency with respect to the interionic distance, which would be large compared to the derivatives of $1/r^3$ with respect to $r$ at $r=a$ i.e. the correspondings in the pure ionic case. As this may give rise to a factor of about $10^{-1}$, the relaxation time due to the covalency will be shorter by a factor of $10^{-4}$ than in pure ionic case.

From the above considerations we neglect the quadrupole interaction of the halogen nucleus with the surrounding ionic charges and take into account only the interaction with the electrons belonging to this nucleus. Then the interaction Hamiltonian of a halogen nucleus can be expressed as folllows:

$$V_Q=\sum_{\mu}Q_{\mu}W_{\mu} \tag{4.1}$$

$$\left\{\begin{aligned} Q_0 &=3I_z^2-I(I+1)\\ Q_{\pm1}&=\frac{1}{2}[I_z(I_x\pm iI_y)+(I_x\pm iI_y)I_z]\\ Q_{\pm2}&=(I_x\pm iI_y)^2\end{aligned}\right. \tag{4.2}$$

$$\left\{\begin{aligned} W_0 &=-\frac{A}{2}\sum_j(e/r_j^5)(3z_j^2-r_j^2)\\ W_{\pm1}&=-3A\sum_j(e/r_j^5)z_j(x_j\mp iy_j)\\ W_{\pm2}&=-\frac{3}{4}A\sum_j(e/r_j^5)(x_j\mp iy_j)^2\end{aligned}\right. \tag{4.3}$$

$$A=eQ/2I(2I-1)$$

where $r_j(x_j, y_j, z_j)$ is the position vector of the $j$-th electron belonging to that nucleus. In the present case of the halogen nucleus it may be sufficient to take $3p$-electrons into consideration. Although the above expression contains only electron coordinates, the lattice vibrations provide time-dependent deformations of the electron distribution, and accordingly the lattice coordinates can be considered as implicitly included in (4.1). In other words, the expectation value of $W_\mu$ with respect to the electronic state, which itself depends on lattice coordinates, must be regarded as a function of the lattice coordinates. This situation can be called the adiabatic approximation, because the motion of the lattice is assumed to be sufficiently slow compared to the electron motion. We shall now, as before, proceed with pertubational treatment. When we take the pure ionic state as the grounds state, $W_\mu$ vanishes identically. But the actual state includes partially the excited covalent states so that $W_\mu$ takes non-zero value when the lattice deforms from cubic symmetry as it vibrates. This can be shown by the third order perturbation calculation. Namely, we have

$$\Delta E_3=\sum_{nn'}\frac{(g|V_t|n)(n|V_Q|n')(n'|V_t|g)}{(E_n-E_g)(E_{n'}-E_g)} \tag{4.4}$$

as the third order energy expression. Here $g$ means the ground state and $n, n'$ mean the excited covalent states in which one $p$-electron of the halogen ion is transferred to the neighbouring $n$ or $n'$-th metal ion. The vacant $p$-orbital is naturally the one which has the maximum stretching in the direction to the metal 'atom' which has been generated by the transfer. In (4.4) $(n|V_Q|n')$ should be very small unless $n=n'$. Therefore, we can omit such terms and get

$$\begin{aligned}\Delta E_3&=\sum_n \lambda_n(n|V_Q|n)\\ &=\sum_\mu Q_\mu \sum_n \lambda_n(n|W_\mu|n)\,,\end{aligned} \tag{4.5}$$

where $\lambda_n=\dfrac{|(g|V_t|n)|^2}{(E_n-E_g)^2}=\left(\dfrac{b_n}{\Delta E_n}\right)^2$ is a measure of a degree of covalency, which may be regarded as a function of the distance only between the halogen nucleus and the $n$-th metal nucleus. We shall denote the coordinates of the $n$-th metal nucleus by $\boldsymbol{R}_n(X_n, Y_n, Z_n)$, taking the halogen nucleus as the origin. The direction cosines of $\boldsymbol{R}_n$ will be denoted by $l_n, m_n, n_n$. Further we introduce new coordinate system $\xi$, $\eta$ and $\zeta$ whose direction cosines are $(l_\xi, m_\xi, n_\xi)$, $(l_\eta, m_\eta, n_\eta)$, and $(l_n, m_n, n_n)$, respectively, and express $W_\mu$ in terms of $\xi$, $\eta$ and $\zeta$. For instance we have

$$\frac{1}{r^5}(3z^2-r^2)=\frac{1}{r^5}[3(n_\xi{}^2\xi^2+n_\eta{}^2\eta^2+n_n{}^2\zeta^2+2n_\xi n_\eta\xi_\eta+2n_\xi n_n\xi\zeta+2n_\eta n_n\eta\zeta)-r^2]\,.$$

The electronic distribution in the excited state $n$ is axially symmetric with respect to $\boldsymbol{R}_n$ or $\zeta$ so that the expectation values of the cross products $\xi\eta$, $\eta\zeta$ and $\zeta\xi$ vanish and those of $\xi^2$ and $\eta^2$ are equal to each other and can be put equal to that of $\frac{1}{2}(r^2-\zeta^2)$. Therefore we get

$$\left(n\left|\frac{1}{r_j{}^5}(3z_j{}^2-r_j{}^2)\right|n\right)=\frac{1}{2}\left(n\left|\frac{3\zeta_j{}^2-r_j{}^2}{r_j{}^5}\right|n\right)(3n_n{}^2-1)\,.$$

Summing up this expression over the five $p$-electrons, the following relation is obtained:

$$\left(n\left|\sum_j\frac{1}{r_j{}^5}(3z_j{}^2-r_j{}^2)\right|n\right)=-\frac{1}{2}\left\langle\frac{3\zeta^2-r^2}{r^5}\right\rangle_{p0}(3n_n{}^2-1)\,.$$

Similarly

$$\begin{aligned}\left(n\left|\sum_j\frac{1}{r_j{}^5}z_j(x_j\pm iy_j)\right|n\right)&=-\frac{1}{2}\left\langle\frac{3\zeta^2-r^2}{r^5}\right\rangle_{p0}n_n(l_n\pm im_n)\,,\\ \left(n\left|\sum_j\frac{1}{r_j{}^5}(x_j\pm iy_j)^2\right|n\right)&=-\frac{1}{2}\left\langle\frac{3\zeta^2-r^2}{r^5}\right\rangle_{p0}(l_n\pm im_n)^2\,.\end{aligned} \tag{4.6}$$

Here $\langle\ \rangle_{p0}$ means the expectation value with respect to the $p$-state corresponding to $l_\zeta=0$.

By means of Eq. (4.6) the second summation in (4.5), which will henceforth be abbreviated as $W_\mu$, can be expressed in the following simple form:

$$\begin{aligned}W_0&=A'\sum_n\lambda_n\left(n_n{}^2-\frac{1}{3}\right)\\ W_{\pm1}&=2A'\sum_n\lambda_n n_n(l_n\mp im_n)\\ W_{\pm2}&=\frac{1}{2}A'\sum_n\lambda_n(l_n\mp im_n)^2\,,\end{aligned} \tag{4.7}$$

where

$$A'=\frac{3}{4}eA\left\langle\frac{3\zeta^2-r^2}{r^5}\right\rangle_{p0}=\frac{3}{5}eA\left\langle\frac{1}{r^3}\right\rangle_H\,, \tag{4.8}$$

$\langle\ \rangle_H$ means the expectation value with respect to the valence $p$-electron of the halogen ion. Now we shall expand these expressions in powers of the small deviations from equilibrium positions. Let $\boldsymbol{R}_{n0}$ and $\alpha_n$, $\beta_n$, $\gamma_n$ be the distance and the direction cosines of the equilibrium position of the $n$-th metal ion measured from the halogen nucleus and $\delta\boldsymbol{R}_n(\delta X_n, \delta Y_n, \delta Z_n)$ the displacement vector. Then we have the following expressions:

$$\lambda(R_n)=\lambda+a\lambda'\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+\frac{1}{2}a\lambda'\left\{\left(\frac{\delta\boldsymbol{R}_n}{a}\right)^2-\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2\right\}+\frac{1}{2}a^2\lambda''\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2, \tag{4.9}$$

$$\begin{aligned}
l_n^2&=\alpha_n^2-2\alpha_n^2\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+2\alpha_n\frac{\delta X_n}{a}-\alpha_n^2\left(\frac{\delta\boldsymbol{R}_n}{a}\right)^2+4\alpha_n^2\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2\\
&\qquad-4\alpha_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)\frac{\delta X_n}{a}+\left(\frac{\delta X_n}{a}\right)^2,\\
m_n^2&=\beta_n^2-2\beta_n^2\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+2\beta_n\frac{\delta Y_n}{a}-\beta_n^2\left(\frac{\delta\boldsymbol{R}_n}{a}\right)^2+4\beta_n^2\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2\\
&\qquad-4\beta_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)\frac{\delta Y_n}{a}+\left(\frac{\delta Y_n}{a}\right)^2,\\
n_n^2&=\gamma_n^2-2\gamma_n^2\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+2\gamma_n\frac{\delta Z_n}{a}-\gamma_n^2\left(\frac{\delta R_n}{a}\right)^2+4\gamma_n^2\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2\\
&\qquad-4\gamma_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)\frac{\delta Z_n}{a}+\left(\frac{\delta Z_n}{a}\right)^2,
\end{aligned}\tag{4.10}$$

$$\begin{aligned}
l_nm_n&=\alpha_n\beta_n-2\alpha_n\beta_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+\alpha_n\frac{\delta Y_n}{a}+\beta_n\frac{\delta X_n}{a}-\alpha_n\beta_n\left(\frac{\delta\boldsymbol{R}_n}{a}\right)^2+4\alpha_n\beta_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2\\
&\qquad-2\alpha_n\frac{\delta Y_n}{a}\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)-2\beta_n\frac{\delta X_n}{a}\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+\frac{\delta X_n\delta Y_n}{a^2},\\
m_nn_n&=\beta_n\gamma_n-2\beta_n\gamma_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+\beta_n\frac{\delta Z_n}{a}+\gamma_n\frac{\delta Y_n}{a}-\beta_n\gamma_n\left(\frac{\delta\boldsymbol{R}_n}{a}\right)^2+4\beta_n\gamma_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2\\
&\qquad-2\beta_n\frac{\delta Z_n}{a}\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)-2\gamma_n\frac{\delta Y_n}{a}\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+\frac{\delta Y_n\delta Z_n}{a^2},\\
n_nl_n&=\gamma_n\alpha_n-2\gamma_n\alpha_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+\gamma_n\frac{\delta X_n}{a}+\alpha_n\frac{\delta Z_n}{a}-\gamma_n\alpha_n\left(\frac{\delta\boldsymbol{R}_n}{a}\right)^2+4\gamma_n\alpha_n\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)^2\\
&\qquad-2\gamma_n\frac{\delta X_n}{a}\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)-2\alpha_n\frac{\delta Z_n}{a}\left(\boldsymbol{n}\cdot\frac{\delta\boldsymbol{R}_n}{a}\right)+\frac{\delta Z_n\delta X_n}{a^2},
\end{aligned}$$

where $a=|\boldsymbol{R}_{n0}|$, the nearest neighbour distance in the equilibrium, and $\boldsymbol{n}$ is the unit vector whose components are $\alpha_n$, $\beta_n$, $\gamma_n$.

We shall neglect the small effect of direct processes on the relaxation and confine our calculation to the contribution from Raman processes which can be considered to be the main part of the relaxation mechanism at least at room temperature. Thus picking up in Eq. (4.6) the second order terms with respect to displacements, we have

$$\begin{aligned}
W_{\pm1}&=\frac{2A'}{a^2}\sum_n[u\{n^{\mp}\gamma_n(\delta\boldsymbol{R}_n)^2+2(\boldsymbol{n}\cdot\delta\boldsymbol{R}_n)(\gamma_n\delta R_n^{\mp}+n^{\mp}\delta Z_n)\}\\
&\qquad+vn^{\mp}\gamma_n(\boldsymbol{n}\cdot\delta\boldsymbol{R}_n)^2+\lambda\delta Z_n\delta R_n^{\mp}],\\
W_{\pm2}&=\frac{A'}{2a^2}\sum_n[u\{(n^{\mp})^2(\delta\boldsymbol{R}_n)^2+4n^{\mp}\delta R_n^{\mp}(\boldsymbol{n}\cdot\delta\boldsymbol{R}_n)\}\\
&\qquad+v(n^{\mp})^2(\boldsymbol{n}\cdot\delta\boldsymbol{R}_n)^2+\lambda(n^{\mp})^2(\delta R_n^{\mp})^2],
\end{aligned}\tag{4.11}$$

$$u=\frac{1}{2}a\lambda'-\lambda,\qquad v=4\lambda-\frac{5}{2}a\lambda'+\frac{1}{2}a^2\lambda'', \tag{4.11$'$}$$

where $\delta X_n\pm i\delta Y_n$ and $\alpha_n\pm i\beta_n$ have been replaced by $\delta R_n^{\pm}$ and $n^{\pm}$ respectively.

Next we shall express the displacements in terms of the normal coordinates of the lattice vibrations. We shall adopt a simplifying assumption employed by Kranendonk that all the ions in the crystal are equivalent as far as the lattice vibrations are concerned. Furthermore, the frequency distribution will be approximated by the Debye model. Then the displacement $s_n$ of the $n$-th metal ion from its equilibrium position $\boldsymbol{R}_{no}$ can be expressed in terms of the lattice normal modes as

$$\boldsymbol{s}_n = \sum_{k,p} a_{kp} \boldsymbol{e}_{kp} \exp(i\boldsymbol{k}\cdot\boldsymbol{R}_{no}) \,, \tag{4.12}$$

where $\boldsymbol{k}$ represents a wave vector, $p$ signifies one of the three directions of polarization, which are here assumed to be orthogonal to each other. Then the displacement relative to the halogen ion $\delta\boldsymbol{R}_n$ becomes, using the same notation as that of Kranendonk,

$$\delta\boldsymbol{R}_n = \sum_\sigma{}' q_\sigma B_n(\sigma) \boldsymbol{e}_\sigma \,, \tag{4.13}$$

where the prime means the summation over half the $k$-space and

$$q_\sigma = \delta(s,1)(a_{kp}+a_{-kp}) + i\delta(s,2)(a_{kp}-a_{-kp}) \,, \tag{4.14}$$

$$B_n(\sigma) = \delta(s,1)(\cos a\boldsymbol{k}\cdot\boldsymbol{n}-1) + \delta(s,2)\sin a\boldsymbol{k}\cdot\boldsymbol{n} \,, \tag{4.15}$$

and $\sigma$ stands for a set of $k, p$ and $s$, $s$ taking values 1 and 2. The normal coordinate $q_\sigma$ has the following non-vanishing matrix elements:

$$(n_\sigma+1\,|\,q_\sigma|\,n_\sigma) = (n_\sigma\,|\,q_\sigma\,|\,n_\sigma+1) = (\hbar/M\omega_k)^{1/2}\,(n_\sigma+1)^{1/2} \,, \tag{4.16}$$

where $M$ is the mass of the crystal and $\omega_k$ the angular frequency which is assumed to be independent of $p$ and of the direction of $\boldsymbol{k}$. We assume further that the phonon system is in equilibrium, that is, the average number of the phonons is given by

$$n_\sigma = \left[\exp\left(\frac{\hbar\omega_k}{\kappa T}\right) - 1\right]^{-1}, \tag{4.17}$$

$\kappa$ being the Boltzmann constant.

The transition probability $P(m, m+\mu)$ for Raman processes, in which a nuclear spin changes its direction from $I_z = m$ to $m+\mu$ and simultaneously absorption of one phonon and emission of one phonon, with adequate energies, occur, is given by

$$P(m, m+\mu) = \frac{2\pi}{\hbar}\left(\frac{V}{8\pi^3}\right)^2 \iint \sum_{\substack{p,s\\p',s'}} |V_Q(\sigma\sigma')_\mu|^2 \delta(\hbar\omega_k - \hbar\omega_{k'}) d^3\boldsymbol{k} d^3\boldsymbol{k}' , \tag{4.18}$$

where $V_Q(\sigma\sigma')_\mu$ means the matrix element of $V_Q$ between the initial and final states of a Raman process. The Zeeman energy of the nucleus can be neglected as compared with the phonon energy. If we take the directional average in the $k$-space, and use the relation $kv = \omega_k$, $v$ being the sound velocity, (4.18) becomes

$$P(m, m+\mu) = \frac{V^2}{8\pi^3 v^2 \hbar^2} \int_0^{\omega_m} k^4 \sum_{p,s} \{|\,V_Q(\sigma\sigma')_\mu\,|^2\} d\omega_k \,, \tag{4.19}$$

where $\{\ \ \}$ means the directional average and $\omega_m$ is the cut off frequency in the usual Debye model.

On the other hand, from (4.1) and (4.7), making use of (4.11) and (4.13), we obtain the following expression for $V_Q$:

$$V_Q = \frac{A'}{a^2} \sum_{\mu=-2}^{2} Q_\mu \sum_{\sigma\sigma'} q_\sigma q_{\sigma'} \sum_n B_{n\sigma} B_{n\sigma'} w_{\mu n}(\sigma\sigma') \,, \tag{4.20}$$

where

$$\begin{aligned} w_{\pm1,n}(\sigma\sigma') = 2[&u\{n^\mp \gamma_n(\boldsymbol{e}_\sigma\cdot\boldsymbol{e}_{\sigma'}) + (\boldsymbol{n}\cdot\boldsymbol{e}_{\sigma'})(\gamma_n e_\sigma{}^\mp + n^\mp e_{\sigma z}) \\ &+ (\boldsymbol{n}\cdot\boldsymbol{e}_\sigma)(\gamma_n e_{\sigma'}{}^\mp + n^\mp e_{\sigma' z})\} + v n^\mp \gamma_n (\boldsymbol{n}\cdot\boldsymbol{e}_\sigma)(\boldsymbol{n}\cdot\boldsymbol{e}_{\sigma'}) \\ &+ \tfrac{1}{2}\lambda(e_{\sigma z} e_{\sigma'}{}^\mp + e_{\sigma' z} e_\sigma{}^\mp)] \,, \end{aligned} \tag{4.21}$$

$$\begin{aligned} w_{\pm2,n}(\sigma\sigma') = \tfrac{1}{2}[&u\{(n^\mp)^2(\boldsymbol{e}_\sigma\cdot\boldsymbol{e}_{\sigma'}) + 2n^\mp e_\sigma{}^\mp(\boldsymbol{n}\cdot\boldsymbol{e}_{\sigma'}) + 2n^\mp e_{\sigma'}{}^\mp(\boldsymbol{n}\boldsymbol{e}_\sigma)\} \\ &+ v(n^\mp)^2(\boldsymbol{n}\cdot\boldsymbol{e}_\sigma)(\boldsymbol{n}\cdot\boldsymbol{e}_{\sigma'}) + \lambda(n^\mp)^2 e_\sigma{}^\mp e_{\sigma'}{}^\mp] \,, \end{aligned} \tag{4.22}$$

$e_\sigma^\pm$ standing for $e_{\sigma x} \pm i e_{\sigma y}$.

Accordingly, from (4.20) and (4.16), the transition matrix element becomes

$$V_Q(\sigma\sigma')_\mu = \frac{2A'\hbar Q_{\mu m}}{a^2 M \omega_k}\{(n_\sigma+1)n_{\sigma'}\}^{1/2} \sum_n B_{n\sigma} B_{n\sigma'} w_{\mu n}(\sigma\sigma') \,, \tag{4.23}$$

where

$$Q_{\mu m} = (m+\mu \,|\, Q_\mu \,|\, m) \,. \tag{4.24}$$

Using (4.17) the transition probability (4.19) becomes

$$P(m, m+\mu) = \frac{A'^2 |Q_{\mu m}|^2}{2\pi^3 a^4 d^2 v^2} \int_0^{\omega_m} \frac{k^4}{\omega^2} \frac{e^x}{(e^x-1)^2} M_\mu(ka) d\omega \,, \tag{4.25}$$

where $d$ is the density $M/V$, $x = \hbar\omega/\kappa T$ and

$$M_\mu(ka) = \sum_{\substack{p,s \\ p',s'}} \{ | \sum_n B_{n\sigma} B_{n\sigma'} w_{\mu n}(\sigma\sigma') |^2 \} \,. \tag{4.26}$$

In this summation terms with $s \neq s'$ vanish, so that

$$M_\mu(ka) = \sum_{nn'} \sum_s \{B_{n\sigma} B_{n\sigma'} B_{n'\sigma} B_{n'\sigma'}\} \sum_{pp'} w_{\mu n}{}^*(\sigma\sigma') w_{\mu n'}(\sigma\sigma') \,. \tag{2.26'}$$

Here we made use of the fact that $B_{n\sigma}$ does not depend on $p$ but depends on $k$ and $s$, while $w_{\mu n}(\sigma\sigma')$ depends on $p$ and $p'$ but neither on $s, s'$ nor on $k, k'$.

In the case of NaCl or CsCl structure, there are only four independent expressions of $\{B_{n\sigma} B_{n\sigma'} B_{n'\sigma} B_{n'\sigma'}\}$. Adopting the same notation as Kranendonk, they are:

For $n = \pm n'$

$$L_1(ka) = \{S_1{}^2\}^2 = \left\{\frac{1}{2} - \frac{1}{2} f(2ka)\right\}^2 \qquad \text{both for NaCl- and CsCl-types,}$$

$$L_2(ka) = \{C_1{}^2\}^2 = \left\{\frac{3}{2} - 2f(ka) + \frac{1}{2} f(2ka)\right\}^2 \qquad \text{both for NaCl- and CsCl-types.}$$

For $n \neq \pm n'$

$$L_3(ka) = \{S_1 S_2\}^2 = \begin{cases} 0 & \text{for NaCl-type,} \\ \left\{\frac{1}{2} f\left(\frac{2}{\sqrt{3}} ka\right) - \frac{1}{2} f\left(\frac{2\sqrt{2}}{\sqrt{3}} ka\right)\right\}^2 & \text{for CsCl-type,} \end{cases} \tag{4.27}$$

$$L_4(ka) = \{C_1 C_2\}^2 = \begin{cases} \{1 - 2f(ka) + f(\sqrt{2}\, ka)\}^2 & \text{for NaCl-type,} \\ \left\{1 - 2f(ka) + \frac{1}{2} f\left(\frac{2}{\sqrt{3}} ka\right) + \frac{1}{2} f\left(\frac{2\sqrt{2}}{\sqrt{3}} ka\right)\right\}^2 & \text{for CsCl-type,} \end{cases}$$

where

$$f(y) = \frac{\sin y}{y} \,, \qquad S_n = \sin a\boldsymbol{K}\cdot\boldsymbol{n} \,, \qquad C_n = \cos(a\boldsymbol{K}\cdot\boldsymbol{n}) - 1 \,.$$

Next we define, for convenience, the quantities

$$N_{\mu 1} = N_{\mu 2} = \sum_{\substack{nn' \\ (n=\pm n')}} \sum_{pp'} w_{\mu n}{}^*(\sigma\sigma') w_{\mu n'}(\sigma\sigma') \,,$$

$$N_{\mu 3} = N_{\mu 4} = \sum_{\substack{n,n' \\ (n\neq\pm n')}} \sum_{pp'} w_{\mu n}{}^*(\sigma\sigma') w_{\mu n'}(\sigma\sigma') \,. \tag{4.28}$$

Then Eq. (4.26) can be abbreviated as

$$M_\mu(ka) = \sum_{\nu=1}^{4} N_{\mu\nu} L_\nu(ka) \,. \tag{4.29}$$

This simplifies the expression for the transition probability (4.25). A further simplification is made by using the relation between the maximum Debye frequency or wave number and the Debye temperature:

$$\hbar\omega_m=\hbar v k_m=\kappa\Theta\ , \tag{4.30}$$

and introducing the reduced temperature $T^*$ defined by

$$T^*=T/\Theta\ .$$

Then we get the final expression for the transition probability:

$$P(m,\, m+\mu)=\frac{A'^2C^3|Q_{\mu m}|^2}{2\pi^3a^7d^2v^3}T^{*2}\sum_{\nu=1}^{4}N_{\mu\nu}D_\nu(T^*)\ , \tag{4.31}$$

$$D_\nu(T^*)=T^*\int_0^{1/T^*}\frac{x^2e^x}{(e^x-1)^2}L_\nu(cT^*x)dx\ , \tag{4.32}$$

where $c=k_ma$ is equal to $(6\pi^2)^{1/3}$ for NaCl-type and $(9\sqrt{3}\,\pi^2/2)^{1/3}$ for CsCl-type. At high temperatures, including room temperature, $D(T^*)$ can be expanded in descending powers of $T^*$, as Kranendonk did. Numerical expressions for $D_\nu$'s are then as follows:

for NaCl or simple cubic crystals (after Kranendonk)

$$\begin{aligned} &D_1(T^*)=0.20-0.0071/T^{*2}+\cdots && D_3(T^*)=0.50-0.031/T^{*2}+\cdots \\ &D_2(T^*)=0.92-0.055\ /T^{*2}+\cdots && D_4(T^*)=0.28-0.017/T^{*2}+\cdots \end{aligned} \tag{4.33}$$

for CsCl-type crystals

$$\begin{aligned} &D_1(T^*)=0.20-0.0067/T^{*2}+\cdots && D_3(T^*)=0.013-0.00036/T^{*2}+\cdots \\ &D_2(T^*)=1.17-0.066\ /T^{*2}+\cdots && D_4(T^*)=0.55-0.026/T^{*2}+\cdots \end{aligned} \tag{4.34}$$

Now it is left to calculate $N_{\mu\nu}$'s. The quantity $\sum_{pp'}w_{\mu n}^*(\sigma\sigma')w_{\mu n'}(\sigma\sigma')$ can be calculated straight-forwardly from Eq. (4.21) and (4.22). After somewhat lengthy calculations we obtain the following results:

$$\begin{aligned} \sum_{pp'}w_{1n}^*(\sigma\sigma')w_{1n'}(\sigma\sigma')=4[&u^2\{15(\alpha_n\alpha_{n'}+\beta_n\beta_{n'})\gamma_n\gamma_{n'}+2(\alpha_n\alpha_{n'}+\beta_n\beta_{n'})(\boldsymbol{n}\cdot\boldsymbol{n}') \\ &+4(\alpha_n^2+\beta_n^2)\gamma_{n'}^2+4\gamma_n\gamma_{n'}(\boldsymbol{n}\cdot\boldsymbol{n}')\}+v^2\{(\alpha_n\alpha_n'+\beta_n\beta_{n'})\gamma_n\gamma_{n'}(\boldsymbol{n}\cdot\boldsymbol{n}')^2\} \\ &+\lambda^2+uv\{2(\alpha_n\alpha_{n'}+\beta_n\beta_n')\gamma_n\gamma_{n'}+4(\alpha_n\alpha_{n'}+\beta_n\beta_{n'})\gamma_n^2(\boldsymbol{n}\cdot\boldsymbol{n}') \\ &+4(\alpha_n^2+\beta_n^2)\gamma_n\gamma_{n'}(\boldsymbol{n}\cdot\boldsymbol{n}')\}+\lambda u\{2(\alpha_n^2+\beta_n^2)+4\gamma_n^2\} \\ &+2\lambda v(\alpha_n^2+\beta_n^2)\gamma_n^2]\ , \end{aligned} \tag{4.35}$$

$$\begin{aligned} \sum_{pp'}w_{2n}^*(\sigma\sigma')w_{2n'}(\sigma\sigma')=u^2\Big[&\frac{11}{4}\{-(\alpha_n^2+\beta_n^2)(\alpha_{n'}^2+\beta_{n'}^2)+2(a_n\alpha_{n'}+\beta_n\beta_{n'})^2\} \\ &+4(\alpha_n\alpha_{n'}+\beta_n\beta_n')(\boldsymbol{n}\cdot\boldsymbol{n}')+2(\alpha_n^2+\beta_n^2)(\alpha_{n'}^2+\beta_{n'}^2)\Big] \\ &+\frac{1}{4}v^2\{-(\alpha_n^2+\beta_n^2)(\alpha_{n'}^2+\beta_{n'}^2)+2(\alpha_n\alpha_{n'}+\beta_n\beta_{n'})^2\}(\boldsymbol{n}\cdot\boldsymbol{n}')^2 \\ &+\lambda^2+uv\left\{\frac{1}{2}(\alpha_n-i\beta_n)^2(\alpha_{n'}+i\beta_{n'})^2+2(\alpha_n\alpha_{n'}+\beta_n\beta_{n'})(\alpha_n^2+\beta_n^2)(\boldsymbol{n}\cdot\boldsymbol{n}')\right\} \\ &+4\lambda u(\alpha_n^2+\beta_n^2)+\frac{1}{2}\lambda v(\alpha_n^2+\beta_n^2)^2\ . \end{aligned} \tag{4.36}$$

In the case of NaCl-type crystals, $(\boldsymbol{n}\cdot\boldsymbol{n}')=0$ for $n\neq\pm n'$ and $(\boldsymbol{n}\cdot\boldsymbol{n}')=\pm1$ for $n=\pm n'$. All the other terms are expressible in terms of $\gamma_n$ and $\gamma_{n'}$, for example,

$$\begin{aligned} (\alpha_n\alpha_{n'}+\beta_n\beta_{n'})\gamma_n\gamma_{n'}&=-\gamma_n^2\gamma_{n'}^2 && \text{for } n\neq n'\ , \\ &=(1-\gamma_n^2)\gamma_n^2 && \text{for } n=\pm n'. \end{aligned}$$

If we denote the direction cosines of the $z$-axis, i.e. the direction of the external field with respect to the crystal axes, by $\alpha_H$, $\beta_H$ and $\gamma_H$, $\gamma_n$ is equal to $\pm\alpha_H$ or $\pm\beta_H$ or $\pm\gamma_H$ according as the direction cosines of $n$ referred to the crystal axes are equal to $(\pm1, 0, 0)$ or $(0, \pm1, 0)$ or $(0, 0, \pm1)$. Therefore we can express $N_{\mu\nu}$'s as functions of $\alpha_H$, $\beta_H$, and $\gamma_H$, which appear only in a combined form $(\alpha_H^2\beta_H^2+\beta_H^2\gamma_H^2+\gamma_H^2\alpha_H^2)$ because of the cubic symmetry of the crystal. Thus we get the following results for NaCl-type crystals:

$$N_{11}=N_{12}=16(8u^2+3\lambda^2+8u\lambda)+\alpha\cdot16(38u^2+2v^2+20uv+4v\lambda)\,,$$

$$N_{14}=8(16u^2+12\lambda^2+32u\lambda)-\alpha\cdot8(61u^2+8uv-16v\lambda)\,,$$

$$\begin{aligned}N_{21}=N_{22}=&(70u^2+2v^2+12\lambda^2+20uv+32u\lambda+4v\lambda)\\&-\alpha(38u^2+2v^2+20uv+4v\lambda)\,,\end{aligned}$$

$$\begin{aligned}N_{24}=&(-6u^2+24\lambda^2-4uv+64u\lambda+8v\lambda)\\&+\alpha(38u^2+4uv-8v\lambda)\,.\end{aligned}$$

Using (4.11′) we can express these quantities as functions of $\lambda$, $\lambda'$, and $\lambda''$:

$$N_{11}=N_{12}=48\lambda^2\left[\left\{1-\frac{4}{3}\left(\frac{a\lambda'}{\lambda}\right)+\frac{2}{3}\left(\frac{a\lambda'}{\lambda}\right)^2\right\}+2\alpha\left\{1+\frac{1}{3}\left(\frac{a\lambda'}{\lambda}\right)-\frac{1}{2}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{1}{12}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\right],$$

$$N_{14}=32\lambda^2\left[\left\{-1+\left(\frac{a\lambda'}{\lambda}\right)^2\right\}+5\alpha\left\{1-\frac{9}{20}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{3}{5}\left(\frac{a^2\lambda''}{\lambda}\right)-\frac{1}{10}\left(\frac{a^2\lambda''}{\lambda}\right)\left(\frac{a\lambda'}{\lambda}\right)\right\}\right],$$

$$\begin{aligned}N_{21}=N_{22}=18\lambda^2\Bigg[&\left\{1-\frac{7}{9}\left(\frac{a\lambda'}{\lambda}\right)+\frac{5}{18}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{1}{30}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\\&-\frac{1}{3}\,\alpha\left\{1+\frac{1}{3}\left(\frac{a\lambda'}{\lambda}\right)-\frac{1}{2}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{1}{12}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\Bigg],\end{aligned}$$

$$\begin{aligned}N_{24}=2\lambda^2\Bigg[&\left\{1+\frac{7}{4}\left(\frac{a\lambda'}{\lambda}\right)^2+3\left(\frac{a^2\lambda''}{\lambda}\right)-\frac{1}{2}\left(\frac{a^2\lambda''}{\lambda}\right)\left(\frac{a\lambda'}{\lambda}\right)\right\}\\&-5\alpha\left\{1-\frac{9}{20}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{3}{5}\left(\frac{a^2\lambda''}{\lambda}\right)-\frac{1}{10}\left(\frac{a^2\lambda''}{\lambda}\right)\left(\frac{a\lambda'}{\lambda}\right)\right\}\Bigg].\end{aligned}\tag{4.37}$$

Also for the CsCl-type the calculation can be carried out in quite a similar way. The results are

$$\begin{aligned}N_{11}=N_{12}=\frac{320}{3}\lambda^2\Bigg[&\left\{1-\frac{2}{3}\left(\frac{a\lambda'}{\lambda}\right)+\frac{1}{5}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{1}{30}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\\&+\frac{4}{5}\,\alpha\left\{-1-\frac{1}{3}\left(\frac{a\lambda'}{\lambda}\right)+\frac{1}{2}\left(\frac{a\lambda'}{\lambda}\right)^2-\frac{1}{12}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\Bigg],\end{aligned}$$

$$\begin{aligned}N_{13}=N_{14}=\frac{64\times35}{81}\,\lambda^2\Bigg[&\left\{-1+\frac{26}{7}\left(\frac{a\lambda'}{\lambda}\right)+\frac{8}{7}\left(\frac{a^2\lambda''}{\lambda}\right)+\frac{8}{35}\left(\frac{a^2\lambda''}{\lambda}\right)\left(\frac{a\lambda'}{\lambda}\right)-\frac{33}{35}\left(\frac{a\lambda'}{\lambda}\right)^2-\frac{1}{70}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\\&+\frac{4}{7}\,\alpha\left\{-1-\frac{83}{5}\left(\frac{a\lambda'}{\lambda}\right)+\frac{113}{10}\left(\frac{a\lambda'}{\lambda}\right)^2-4\left(\frac{a^2\lambda''}{\lambda}\right)-\frac{4}{5}\left(\frac{a^2\lambda''}{\lambda}\right)\left(\frac{a\lambda'}{\lambda}\right)+\frac{1}{20}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\Bigg],\end{aligned}$$

$$\begin{aligned}N_{21}=N_{22}=\frac{64}{3}\lambda^2\Bigg[&\left\{1-\frac{11}{12}\left(\frac{a\lambda'}{\lambda}\right)+\frac{3}{8}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{1}{48}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\\&+\frac{1}{4}\,\alpha\left\{1+\frac{1}{3}\left(\frac{a\lambda'}{\lambda}\right)-\frac{1}{2}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{1}{12}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\Bigg],\end{aligned}$$

$$\begin{aligned}N_{23}=N_{24}=\frac{640}{81}\,\lambda^2\Bigg[&\left\{-1+\frac{47}{40}\left(\frac{a\lambda'}{\lambda}\right)+\frac{67}{80}\left(\frac{a\lambda'}{\lambda}\right)^2+\frac{1}{2}\left(\frac{a^2\lambda''}{\lambda}\right)+\frac{1}{10}\left(\frac{a^2\lambda''}{\lambda}\right)\left(\frac{a\lambda'}{\lambda}\right)-\frac{1}{160}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\\&+\frac{1}{8}\,\alpha\left\{1+\frac{83}{5}\left(\frac{a\lambda'}{\lambda}\right)-\frac{113}{10}\left(\frac{a\lambda'}{\lambda}\right)^2+4\left(\frac{a^2\lambda''}{\lambda}\right)+\frac{4}{5}\left(\frac{a^2\lambda''}{\lambda}\right)\left(\frac{a\lambda'}{\lambda}\right)-\frac{1}{20}\left(\frac{a^2\lambda''}{\lambda}\right)^2\right\}\Bigg].\end{aligned}$$

## § 5. Quadrupolar Relaxation II: Relaxation Time and Comparison with Experimental Data

In the previous section we have calculated the thermal transition probabilities between Zeeman levels by quadrupoler interaction. We shall now give theoretical expression for $T_1$ and compare it with experimental values determined by saturation method[18][14]. When the quadrupole interaction exists, the relaxation process cannot in general be described in terms of a unique characteristic time. However, when we observe an absorption line due to transition between specified two levels, a usual saturation curve will give a measure for the relaxation rate between these two levels. Watkins and Pound [3][4] found that, in resonance experiments for halogen nuclei in KBr and KI, only the central line corresponding to the transition between $m=\pm\frac{1}{2}$ levels was observable while the satellite lines were almost smeared out by the qnadrupole interaction with field gradients distributed at random in the crystals owing to irregular internal strains. This situation seems to be realized in any available alkali halide samples except when the nuclei have a very small or no quardrupole moment. Therefore we may safely assume that, also in Kanda's measurements of the Br resonance in metal bromides, only the central line was observed

As is well known, the saturation intensity of the resonance absorption obeys a simple $1/(1+x^2)$ law. In the case of spin $\frac{1}{2}$, $x^2$ is connected with the spin-lattice relaxation time $T_1$, the spin-spin relaxation time $T_2$ and the intensity of the r.f. field $H_1$ by

$$x^2=\gamma^2 H_1^2 T_1 T_2\,, \tag{5.1}$$

where $H_1$ is the amplitude of circularly polarized r.f. field, so that the amplitude of linearly polarized r.f. field must be taken as $2H_1$. In our case of $I>\frac{1}{2}$, we may still define $T_1$, for convenience, by Eq. (5.1). Of course $T_1$ thus defined has no usual significance, but anyhow it can be regarded as a sort of characteristic time of the relaxation process.

Theoretically the saturation factor can be calculated by considering surplus stationary population in $-\frac{1}{2}$ state over $\frac{1}{2}$ state in a given resonating r.f. field. The transition probability due to a r.f. field is

$$P_{m\rightleftarrows m-1}=\frac{1}{4}\gamma^2 H_1^2 g(\nu)(I+m)(I-m+1)\,, \tag{5.2}$$

where $g(\nu)$ is the normalized line shape function. The transition probabilities by the quadrupole interaction are

$$\begin{aligned} P(m,m+1)&=\frac{(2m+1)^2(I-m)(I+m+1)}{2I(2I-1)^2}W_1\,,\\ P(m,m+2)&\\ &=\frac{(I-m-1)(I+m+2)(I-m)(I+m+1)}{2I(2I-1)^2}W_2\,,\\ P(m+1,m)&=P(m,m+1)(1+\varDelta)\,,\\ P(m+2,m)&=P(m,m+2)(1+2\varDelta)\,, \end{aligned} \tag{5.3}$$

where $\varDelta=\hbar\omega_0/\kappa T$, $\omega_0$ being the Larmor frequency, and $W_1$ and $W_2$ are, as we saw in the previous section, functions of the orientation of the external magnetic field and are independent of $m$. By using these formulas we can write down the differential equations of the time variation of populations in Zeeman levels. From the stationary solution of these equations the surplus population, and consequently $T_1$, can be obtained. It is interesting to note that there is no quadrupolar transition between $+\frac{1}{2}$ and $-\frac{1}{2}$ states so that the relaxation between these two states takes place indirectly via the other states. The surplus population, which will be denoted by $n=n_{-1/2}-n_{1/2}$, and the relaxation time $T_1$ thus calculated are as follows:

for $I=3/2$,

$$\begin{aligned} n&=\frac{N}{4}\varDelta\frac{1}{1+\gamma^2 H_1^2 T_1 T_2}\,,\\ T_1&=\frac{1}{W_1}+\frac{1}{W_2}=\frac{1}{P\left(\frac{1}{2},\frac{3}{2}\right)}+\frac{1}{P\left(\frac{3}{2},-\frac{1}{2}\right)}\,, \end{aligned} \tag{5.4}$$

for $I=5/2$,

$$\begin{aligned} n&=\frac{N}{6}\varDelta\frac{1}{1+\gamma^2 H_1^2 T_1 T_2}\,,\\ T_1&=\frac{9}{4}\left\{\frac{1}{\frac{9}{10}W_2}+\frac{1}{\frac{W_1\cdot\frac{1}{2}W_2}{W_1+\frac{1}{2}W_2}+\frac{2}{5}W_1}\right\}\,,\\ &=\frac{9}{4}\left\{\frac{1}{P\left(\frac{1}{2},\frac{3}{2}\right)+\left(\frac{1}{P\left(\frac{1}{2},\frac{5}{2}\right)}+\frac{1}{P\left(\frac{5}{2},\frac{3}{2}\right)}\right)^{-1}}\right.\\ &\qquad\left.+\frac{1}{P\left(\frac{3}{2},\frac{1}{2}\right)}\right\}\,. \end{aligned} \tag{5.5}$$

Here the value of $\frac{1}{2}g(\nu)$ at the resonance frequency was replaced by $T_2$.

Table II. Numerical values of $N_{\mu\nu}$ calculated on the assumption: $\lambda \propto e^{-R/0.345}$.

| | $N_{11}\times 10^{-3}$ | $N_{14}\times 10^{-3}$ | $N_{21}\times 10^{-3}$ | $N_{24}\times 10^{-3}$ |
|---|---|---|---|---|
| LiBr | $2.6+29\alpha$ | $2.0+9.7\alpha$ | $2.45-1.8\alpha$ | $1.1-0.61\alpha$ |
| AgBr | $2.8+35.5\alpha$ | $2.2+11\alpha$ | $2.9-2.2\alpha$ | $1.25-0.70\alpha$ |
| TlBr | $38+66\alpha$ | $-9.9+34\alpha$ | $5.4+4.1\alpha$ | $-0.32-2.15\alpha$ |
| KBr | $3.6+62\alpha$ | $2.9+16\alpha$ | $4.8-3.9\alpha$ | $1.7-1.0\alpha$ |
| KI | $4.05+82\alpha$ | $3.3+20\alpha$ | $6.1-5.1\alpha$ | $2.1-1.2\alpha$ |

Table III. The experimental and calculated values of $T_1$.

| | experimental (sec.) | calculated (sec.) | |
|---|---|---|---|
| $Br^{79}$ in LiBr | 0.028 | $0.089(10^{-6}\Theta^3)/T^{*2}$ | $0.20(\Theta=180)$ |
| $Br^{79}$ in AgBr | 0.016 | 0.13 | |
| $Br^{79}$ in TlBr | 0.0060 | $0.057(10^{-6}\Theta^3)/T^{*2}$ | $0.025(\Theta=130)$ |
| $Br^{79}$ in KBr | 0.26 | $1.3(10^2\lambda)^{-2}$ | $0.77(\lambda=0.013)$ |
| $I^{127}$ in KI | 0.039 | 0.11 | |

In the case of powder samples the apparent saturation factor should be the average over all orientations of the above expressions. The apparent relaxation time $T_1{}^p$, in this case, may be defined by

$$\frac{1}{1+\gamma^2H_1{}^2T_1{}^pT_2}=\left\langle\frac{1}{1+\gamma^2H_1{}^2T_1T_2}\right\rangle_{\text{av. over directions}} \tag{5.6}$$

with the assumption that $T_2$ is isotropic.

Now we shall turn to the comparison with experiments. Watkins measured $T_1$ for the single crystals of KBr and KI with external field applied in the [100] direction, and Kanda measured $T_1$ for the powder specimens of LiBr, AgBr and TlBr. All these substances, except TlBr, have NaCl-type structure while TlBr has CsCl-type structure. Numerical values of the parameters in expression (4.31), which gives the thermal transition probability, can be obtained, are available for the majority of the substances under consideration, with the exception of $\lambda$, $\lambda'$ and $\lambda''$, which can be estimated as follows.

For the degree of covalency $\lambda$ we can take its values deduced from chemical shift data. To estimate $\lambda'$ and $\lambda''$, we must know the dependence of $\lambda$ on interionic distance. Since $\lambda$ is proportional to the square of the overlap integral, it is approximately proportional to the repulsive potential between ions, which itself is proportional to $\exp-(R/0.345)$ according to Born and Mayer's wellknown theory of ionic crystals, $R$ being the interionic distance in A unit.* So we may assume

$$\lambda \propto e^{-R/0.345} \tag{5.7}$$

From this we have $\lambda'/\lambda=-1/0.345$, and $\lambda''/\lambda=(1/0.345)^2$, respectively. There is another approximate method of the estimation. Honig, Mandel, Stitch and Townes[19] measured the microwave spectra of alkali halide molecules and deduced the degree of convalency for some of them, for example for LiBr and KI, which have been studied by Kanda for the case of solid. If we assume the functional form of the degree of covalency to be $c.\exp(-R/\rho)$ and utilize experimental values for two values of $R$, one for molecule and the other for solid, we can determine $\rho$. The values of $\rho$ so determined are 0.33 for LiBr and 0.42 for KI. These results support the assumption (5.7).

The values of $N_{\mu\nu}$'s calculated under the assumption (5.7) are given in Table II.

We summarize the calculated and experimental values of the relaxation time $T_1$ at room temperature in Table III. For powder samples we did not actually use Eq. (5.6), but approximated it, for simplicity, by (5.4), $W_1$ and $W_2$ being substituted by their directional averages. For the numerical values of the Debye temperature we employed those determined from specific heat data for AgBr and

---

* Strictly, the overlap integral questioned now is that between the wave function of the state of $Cl^-$ and that of the excited state of a metal ion. Therefore, the value of 0.345 may not be so reliable.

LiBr, and that determined from elastic data for KI. For LiBr and TlBr there are no available data, as far as we know, so that we left $\Theta$ and $T^*$ undetermined in this Table.

The calculated values of the relaxation time are, on the whole, about 3～10 times as long as the experimental values, whereas their ratios are resonable. As the possible origin of this discrepancy we can point out first that our treatment of the lattice vibrations is too much simplified. We took the simple Debye model and neglected the particular character of the optical modes which will be effective in the relaxation mechanism, though the number of normal modes was taken correctly so that the optical modes have been effectively taken into account as the high frequency part of the frequency spectrum. Nevertheless the treatment of the lattice vibrations is at any rate far from being satisfactory, and its crudeness might be an origin of the factor 3～10.

Ambiguities in determining the Debye temperature $\Theta$ or the sound velocity $v$ must also be pointed out. Further refinements of the treatment appear, however, to be very difficult and laborious at the present stage of the theory.

We remark here also that we have neglected the shielding and anti-shielding effects. It may be expected that when covalent electrons penetrate into the ion core, their interaction with the quadrupole moment will not be markedly affected by the shielding and anti-shielding effects. By any means, this point is left for further discussions.

In conclusion, the authors would like to express their cordial thanks to Dr. Kanda for informing us of his experimental results prior to publication. They are also much indebted to Professor T. Nagamiya and Professor J. Itoh for their illuminating discussions and valuable comments.

# Dipolar Broadening of the Central Line of a Magnetic Resonance for Half-integral Spin

By Kenjiro KAMBE
*College of Electro-Communications, Tokyo*
and John F. OLLOM
*West Virginia University, Morgantown, West Virginia*

(Received September 26, 1955)

The second moment of the central line of a magnetic resonance for half-integral spins, for which quadrupole coupling (nuclear spin case) or crystalline field effect (electronic spin case) is present, is calculated by the Van Vleck procedure. The interactions between like spins, unlike spins and semi-like spins are considered separately. The results are compared with the Van Vleck results for which no quadrupole coupling or crystalline effect is assumed.

The broadening of the magnetic resonance line due to the magnetic interaction between atoms has been discussed theoretically in several cases[1-7]. However, the line width in the following case has not been calculated, as far as we know. Namely, that is, the width of the central line of nuclear magnetic resonance in the system of half-integral spins, where the electric quadrupole coupling is present. The equivalent case in the paramagnetic resonance phenomena arises when the half-integral electronic spins are placed under the influence of the crystalline electric field. The electric quadrupole coupling or the crystalline field effect should be so large that the central line is well resolved from the satellite lines. For instance, for spin 3/2 case, the central line corresponds to the transition $m=1/2 \longleftrightarrow m=-1/2$, and it should be resolved from the satellite line which arises from the transition $m=(3/2) \longleftrightarrow m=(1/2)$ or $m=-(3/2) \longleftrightarrow m=-(1/2)$, where $m$ is the magnetic quantum number for individual spin.

In this paper, we will calculate the second moment of the central line by means of the well-known formula given by Van Vleck[1]:

$$\langle \Delta\nu^2\rangle_{\mathrm{Av}} = \langle \nu^2\rangle_{\mathrm{Av}} - \nu_0{}^2 = -h^{-2} T_r[\mathscr{H}_1 S_x - S_x \mathscr{H}_1]^2 / T_r S_x{}^2, \tag{1}$$

where $\nu_0$ is the frequency of the center of the central line, $\mathscr{H}_1$ the Hamiltonian of the interaction, $S_x$ the component of the total spin vector operator along the direction of the high frequency field.

The interaction Hamiltonian $\mathscr{H}_1$ takes different forms depending upon the type of the interaction. In the present paper, three types of interaction will be considered: (a) Interaction between resonant spins, (b) interaction between unlike spins, (c) interaction between semi-like spins. Here, resonant spins are the same species of spins with the same quadrupole coupling (nuclear spin case) or with the same crystalline field splittings (electronic spin case). Semi-like spins are the identical spins located at the different lattice sites, where the values of the quadrupole coupling constant or those of crystalline field are different. For semi-like spins the central line of the resonance coincides, since the central line is not affected by the crystalline field. Satellite lines do not coincide however. We will discuss the three cases separately in the following.

### (a) *Interaction Between Resonant Spins*

The interaction Hamiltonian in the usual notation is

$$\mathscr{H}_1 = \Sigma_{j>k} \mathscr{H}_{jk} = \Sigma_{j>k}\{\tilde{A}_{jk} \boldsymbol{S}_j \cdot \boldsymbol{S}_k + g^2\beta^2 r_{jk}{}^{-3}[\boldsymbol{S}_j \cdot \boldsymbol{S}_k - 3r_{jk}{}^{-3}(\boldsymbol{S}_j \boldsymbol{r}_{jk})(\boldsymbol{S}_k \cdot \boldsymbol{r}_{jk})]\} \tag{2}$$

We should not use, however, the whole matrix elements given by (2). Those matrix elements which contribute only to the satellite lines have to be omitted in applying (1). The same precaution should be taken with respect to $S_x$.

Since $\mathscr{H}_1$ is a sum of the two-body type operators, it is sufficient to consider the system of two spins $j$ and $k$. The unperturbed energies are

$$W(m_j, m_k)=g\beta H(m_j+m_k)+\delta(m_j^2+m_k^2)$$
$$-(2/3)\delta S(S+1) \qquad (3)$$

Here, the eigenstates are specified by the eigenvalues $m_j$ and $m_k$ of $S_{jz}$ and $S_{kz}$.

The matrix elements of $\mathscr{H}_{jk}$ connect the unperturbed states, which satisfy the selection rule

$$\Delta m_j\,,\ \Delta m_k=\pm 1 \text{ or } 0\,. \qquad (4)$$

Those matrix elements which connect the unperturbed states with different energies should be discarded, because these elements contribute only to the satellite lines. Besides the diagonal elements of $\mathscr{H}_{jk}$, the matrix elements connecting the states $(m, m')$ with the state $(m', m)$ should be retained, since $W(m, m')=W(m', m)$ by (3). Decomposing the expression of $\mathscr{H}_{jk}$ given by (2) into the form given by Equation (2) of Abragam and Kambe[7], and inspecting the matrix elements term by term, we find that the matrix elements which should be retained in the present problem are

$$(m, m'|\mathscr{H}_{jk}|m, m')$$
$$=[\tilde{A}_{jk}+g^2\beta^2 r_{jk}^{-3}(1-3\gamma_{jk}^2)]mm' \qquad (5)$$
$$(m, m-1|\mathscr{H}_{jk}|m-1, m)$$
$$=(m-1, m|\mathscr{H}_{jk}|m, m-1)$$
$$=\left[\frac{1}{2}\tilde{A}_{jk}-\frac{1}{4}g^2\beta^2 r_{jk}^{-3}(1-3\gamma_{jk}^2)\right]$$
$$\times(S+m)(S-m+1)\,. \qquad (6)$$

It is easily shown that the non-vanishing matrix elements of $S_x$ after discarding the irrelevant elements are

$$\left(m, \pm\frac{1}{2}\middle| S_{xj}+S_{xk}\middle| m, \mp\frac{1}{2}\right)$$
$$=\left(\pm\frac{1}{2}, m\middle| S_{xj}+S_{xk}\middle| \mp\frac{1}{2}, m\right)=\frac{1}{4}(2S+1)\,. \qquad (7)$$

The calculation of the traces involved in (1) is elementary and the result is

$$h^2\langle\Delta\nu^2\rangle_{\text{Av}}$$
$$=\left[\frac{S(S+1)}{3}+\frac{2S^2(S+1)^2-3S(S+1)+(1/8)}{2(2S+1)}\right]\Sigma_k{}'\tilde{A}_{jk}^2$$
$$+\left[-\frac{4}{3}S(S+1)+\frac{4S^2(S+1)^2+(7/4)}{2(2S+1)}\right]\Sigma_k{}'\tilde{A}_{jk}\frac{g^2\beta^2}{r_{jk}^3}\left(\frac{3}{2}\gamma_{jk}^2-\frac{1}{2}\right)$$
$$+\left[\frac{4}{3}S(S+1)+\frac{2S^2(S+1)^2+3S(S+1)+(13/8)}{2(2S+1)}\right]\Sigma_k{}'\frac{g^4\beta^4}{r_{jk}^6}\left(\frac{3}{2}\gamma_{jk}^2-\frac{1}{2}\right)^2. \qquad (8)$$

If there is no exchange, as in the nuclear resonance, $\tilde{A}_{jk}=0$. The resulting expression of the second moment is to be compared with the expression

$$h^2\langle\Delta\nu^2\rangle_{\text{Av}}$$
$$=3S(S+1)\Sigma_k{}'g^4\beta^4 r_{jk}^{-6}\left(\frac{3}{2}\gamma_{jk}^2-\frac{1}{2}\right)^2, \qquad (9)$$

which holds when there is no electric quadrupole coupling (nuclear spin case) or crystalline field splitting (electronic spin case). The expression (9) has been derived by Van Vleck.

The comparison has been done in Table I.

Table I. The ratio of the second moment $\langle\Delta\nu^2\rangle_{\text{Av}}$ for cases (a) and (c) to that of the straight resonance line given by (9). The exchange interactions are assumed to vanish.

| Spin | Case (a) | Case (c) |
|---|---|---|
| 1/2 | 1 | 1 |
| 3/2 | 9/10 | 4/5 |
| 5/2 | 107/105 | 257/315 |
| 7/2 | 881/756 | 164/189 |

(b) *Interaction Between Unlike Spins*

Now, we shall consider the contributions from the unlike neighbors to the broadening of the central line. Here we shall assume that the unlike neighbors have arbitrary spin $S'$. Then the effective interaction hamiltonian is

$$\mathscr{H}_1=\Sigma_{jk}{}'\,C_{jk}{}'\,S_{zj}\,S_{zk}{}' \qquad (10)$$

with

$$C_{jk}{}'=\tilde{A}_{jk}{}'+(1-3\gamma_{jk}{}')^2 gg'\beta^2 r_{jk}^{-3}. \qquad (11)$$

All other matrix elements of the interaction should be discarded because they contribute only to the satellite lines.

The $x$ component of moment $S_x$ to be used in (1) involves only the summation $\Sigma_j S_{xj}$ over the unprimed spins, and the matrix elements of $S_{xj}$ to be used are

$$\left(\pm\frac{1}{2}\middle| S_{xj}\middle|\mp\frac{1}{2}\right)=\frac{1}{4}(2S+1)\,.$$

After some elementary calculation, we get

$$h^2\langle\Delta\nu^2\rangle_{\mathrm{Av}}=\frac{1}{3}S'(S'+1)\Sigma_k' C_{jk}'^2\,, \qquad (12)$$

as the contribution from unlike neighbors to the second moment of the central line. This is exactly the same expression which Van Vleck has given as the contribution from the unlike neighbors with spin $S'$ to the broadening of the resonance line from spin $S$ without taking into account the effect of the crystalline field.

### (c) *Interaction Between Semi-Like Spins*

Although they are located at the different lattice sites, semi-like spins are the same species of spins. Therefore, the interaction hamiltonian is given by (2) as in the case of (a). However, the matrix elements of $\mathscr{H}_1$ to be retained in calculating (1) are different from those used in the case (a).

The unperturbed energies of two semi-like spins are given by

$$W(m, m')=g\beta H(m+m')+\delta m^2+\delta' m'^2 \qquad (13)$$

Here one should note that the quadrupole coupling constants are different for semi-like spins. The energy of state $(m, m')$ is not equal to that of the state $(m,' m)$ except when $m=\pm\frac{1}{2}$ and $m'=\pm\frac{1}{2}$. The diagonal elements of $\mathscr{H}_1$ should be retained as in the case (a), but only the elements given by (6) with $m=\frac{1}{2}$ should be retained among the off-diagonal elements. The matrix elements of $S_x$ to be retained are same as in the Case (a).

The second moment of the central line arising from the interaction with the semi-like neighbors is

$$\begin{aligned}
&h^2\langle\Delta\nu^2\rangle_{\mathrm{Av}}\\
&=\left[\frac{1}{3}S(S+1)-\frac{1}{4}(2S+1)+\frac{(2S+1)^3}{32}\right]\Sigma_k'\tilde{A}_{jk}^2\\
&\quad+\left[-\frac{4}{3}S(S+1)+\frac{1}{4}(2S+1)+\frac{(2S+1)^3}{16}\right]\Sigma_k'\tilde{A}_{jk}\frac{g^2\beta^2}{r_{jk}^3}\left(\frac{3}{2}\gamma_{jk}^2-\frac{1}{2}\right)\\
&\quad+\left[\frac{4}{3}S(S+1)+\frac{1}{2}(2S+1)+\frac{(2S+1)^3}{32}\right]\Sigma_k'\frac{g^4\beta^4}{r_{jk}^6}\left(\frac{3}{2}\gamma_{jk}^2-\frac{1}{2}\right)^2. \qquad (14)
\end{aligned}$$

The second moment without exchange is compared with the Van Vleck formula (9) in Table I.

We wish to thank Professor Van Vleck and Professor Bloembergen for discussion. One of us (K.K.) would like to thank Prof. Bloembergen for suggesting this problem. He also indebted to the Office of Naval Research for the financial support which enabled him to do this work during his stay at Harvard University from 1953 to 1954.

# On the Plastic Deformation of $\alpha$-brass Single Crystals by Compression

By Hiroshi KIMURA

*Institute of Industrial Science, University of Tokyo, Chiba City*

(Received April 25, 1955)

The relationship between the crystallographic orientation of specimens and the easy glide was examined with $\alpha$-brass single crystals deformed by compression. Micrographic observations were performed and discussed together.

Besides these main studies, it was found that the hardening in copper alloys due to low temperature annealing after cold working, which was observed in polycrystalline specimen, was not observed in single crystals.

## §1. Introduction

There are many studies with aluminum single crystals in the field of plastic deformation, and it has been found that the shape of shear stress-strain curve depends on the crystallographic orientation of specimen, and that the appearance of slip bands also depends on the orientation of the specimen.

As for the other metals except aluminum, few studies have been reported. It is dangerous to think that the plastic properties of aluminum are typical for the face-centered cubic crystals. To avoid this danger it is necessary that more siudies are carried on with many face-centered cubic metals and alloys other than aluminum.

Mathewson and his co-workers[1], in their studies of the plasticity of $\alpha$-brass, reported that the slip bands were clustered, that there were no deformation bands (kink bands) and that the asterism of Lauespots was not observed. It was also found that the shear stress-strain curves had a long range of easy glide. But the relationship between these phenomena and the crystallographic orientations of specimens cannot be discussed, because the number of specimens used is not enough.

Hardening of copper alloys due to low temperature annealing after cold working is one of the current problems[2][3], but there are few studies with single crystals.

The author, therefore, studied the following two problems using $\alpha$-brass single crystals:

1. How the shear stress-strain curves and the appearance of slip bands depend on the crystallographic orientations of specimens.
2. The change of yield point due to low temperature annealing after cold working.

## §2. Experimental Method

Single crystals were made by melting and solidifying the alloy which was casted in our laboratory from electrolytic copper and pure zinc. They were 11 mm in diameter and 120–130 mm in length.

Their crystallographic orientations were determined by optical method. After the determination of orientation, two flat faces were made on the side surfaces of these single crystal rods and they were polished mechanically. One of the faces was parallel and the other normal to the plane containing the axis of rod and the slip direction. These two faces were named *A*-plane and *B*-plane respectively. And then, these rods were cut into pieces of 10 mm in length, which were used as specimens.

The end surfaces of the specimens were made parallel, and the specimens were annealed for 2 hours at 200°C in an oil-bath and electropolished. The two flat faces were examined by means of X-ray and found to be free from the stress due to mechanical polishing. The specimens were compressed a little over the yield point and observed by light microscope. Then, they were deformed about 30% in shear strain and the shear stress-strain curves were obtained.

Some of the specimens were used for the low temperature annealing experiment. They were deformed about 30% in shear strain and annealed for 2 hours at 175°C and their yield points were measured by deforming them again. The second deformation was about 40% in shear, then they were annealed again for 2 hours at 125°C and the yield points were measured again.

The samples for chemical analysis were taken from the bottom and the middle part of each rod. The chemical compositions and the crystallographic orientations of single crystal rods were shown in Table I and Fig. 1.

Table I. The Chemical Composition of Single Crystal Rods.

| No. of Crystals | Cu | Zn | Fe |
|---|---|---|---|
| 1 | 80.5% | 18.3% | 1.2% |
| 2 | 79.6 | 20.0 | 0.4 |
| 3 | 78.7 | 21.0 | 0.3 |
| 4 | 82.2 | 17.2 | 0.6 |
| 5 | 86.4 | 13.1 | 0.5 |
| 6 | 72.4 | 27.1 | 0.5 |

## § 3. Experimental Results and Discussions

### (1) *The Relationship between the Shape of Shear Stress-Strain Curves and the Crystallographic Orientation of Specimens.*

Fig. 2 shows the shear stress-strain curves for the crystals, of which axial orientations are shown in Fig. 1. According to the classical calculation of Taylor and Elam, crystals No. 1 and 5 are deformed by single slip system until the strains pointed by the arrows are reached, and after these points double slips occur; the other crystals are deformed by single slip system through the whole range shown in Fig. 2.

It is found from these figures that the crystals, of which axial orientations are near the middle of [100]-[111] side, show a long range of easy glide. It may be concluded that such crystals that satisfy the following two conditions have a long range of easy glide:

1) The axial orientation of the crystal is far from the three apexes of stereographic triangle.
2) The crystal has a long distance of slip process in which only one slip system is active.

This can be interpreted as follows: The classical geometrical plane and direction of the maximum shear stress may not have very important meaning, when the axial orientation of the crystal is near to one of the apexes of stereographic triangle. The axis may change slightly its direction favourablly for other slip systems, and then those new slip systems will easily become active. If more than two slip systems are active, the rate of hardening becomes larger because of the interaction hardening. In the case of ordinary double slip, the interaction hardening does, of course, operate.

Microscopic observation seems to support the above discussion. Generally speaking, the longer range of easy glide a crystal has, the simpler is the appearance of slip bands. And in the crystals, which harden rapidly, two or three slip systems are active and the appearance of slip bands is complicated. In Photo. 1, which shows a part of $A$-plane of specimens No. 2, we can see that three slip systems are active.

### (2) *Some Microscopic Observations*

#### (a) *Primary Slip*

Slip bands were clustered in all specimens and never uniformly distributed. Deformation bands (kink bands) were not observed. We can also see the interactions between slip bands and etch pits produced by electropolishing. These are shown in Photo. 2 and 3, which show the *A*-plane and *B*-plane of specimen No. 2 respectively. In *A*-plane slip bands are hardly disturbed by etch pits (black figures), but they are almost straight and pass through the pits. However, in *B*-plane slip bands are markedly disturbed by etch pits. Near the compression ends of *B*-plane the slip bands

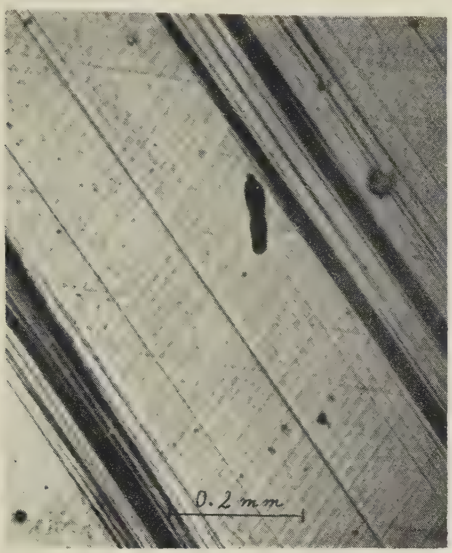

Photo. 1. Slip bands in *A*-plane of crystal No. 2. (Shear Strain 4%). Three systems are active.

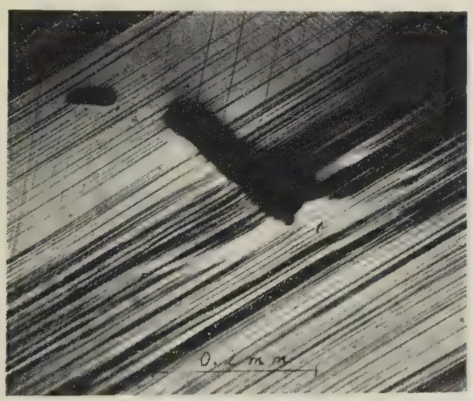

Photo. 2. The interaction between slip bands and etch pit in *A*-plane of crystal No. 2. (Shear strain 12%).

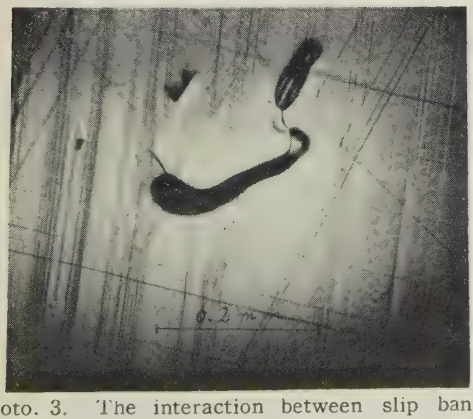

Photo. 3. The interaction between slip bands and etch pit in *B*-plane of crystal No. 2. (Shear strain 12%).

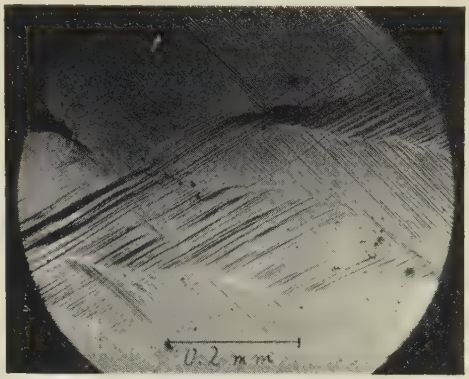

Photo. 4. Special appearance of bands of secondary slip in *A*-plane of crystal No. 2. (Shear strain 12%).

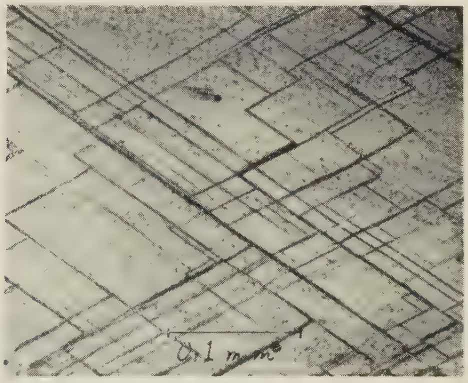

Photo. 5. Cross-slip in *A*-plane of crystal No. 3. (Shear strain 20%).

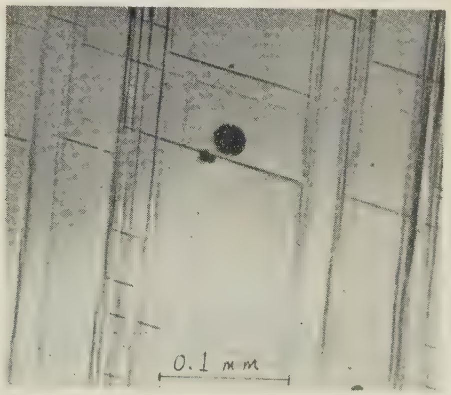

Photo. 6. Cross-slip in *B*-plane of crystal No. 2. (Shear strain 4%).

are not clustered so markedly as in the middle part of the specimen.

(b) *Bands of Secondary Slip and Cross-Slip*

*A*-plane: The appearance of slip bands in the middle part of the specimen differs from that in the part near both ends, and at the boundary between the middle part and the end parts slip bands sometimes show special appearances (Photo. 4). They show bands of secondary slip. Sometimes cross-slip appears instead of the bands of secondary slip (Photo. 5). The slip systems that are active are $(111)$–$[\bar{1}01]$ system, which is predicted system, and $(\bar{1}\bar{1}1)$–$[011]$ system. These slip patterns described above would be interpreted in terms of grip effect.

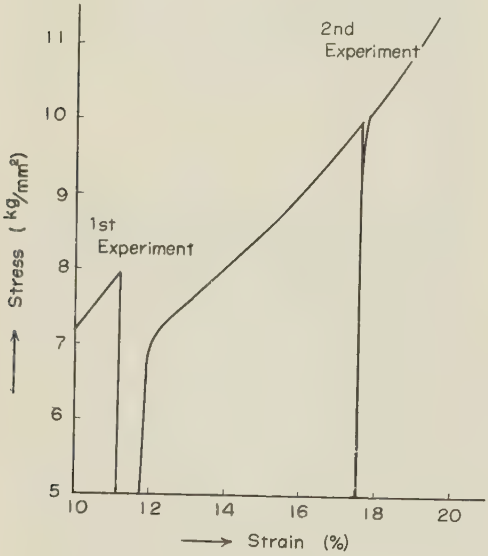

Fig. 4. The effect of annealing on the yield point of α-brass. (Crystal No. 6).

*B*-plane: *B*-planes are not so complicated as *A*-planes. Usually the predicted system is predominant. Sometimes typical cross-slip is observed, as shown in Photo. 6.

(3) *The Change of the Yield Point by Low Temperature Annealing after Cold Working*

It is well known that cold worked specimen of copper alloys, especially the $\alpha$-phase alloy, becomes harder when they are subjected to suitable low temperature annealing[2][3]. But there are few studies with single crystals.

In this work the annealing conditions were decided by Mishima's studies[4]. He studied the tensile strength of polycrystalline $\alpha$-brass and found that the tensile strength of specimens which were subjected to more than 8% elongation was increased by 175°C×2 hours annealing. The specimens used in the present experiment were subjected to compression of more than 9% and less than 17%, most of them 10%. By 175°C×2 hours annealing their yield points recovered for several per cent and no hardening was observed. Then, they were compressed again and annealed. The degree of second compression were between 17% and 28%, most of them were 23%. The annealing was performed for 2 hours at 125°C. Again, no hardening was observed and this time no recovery was observed, either. One of the results is shown in Fig. 4.

It should be noticed that hardening phenomenon is observed in polycrystalline specimen, but not in single crystal.

## §4. Conclusions

From above experimental results and discussions, the following conclusions are drawn for $\alpha$-brass single crystals deformed by compression.

(1) Such crystals that satisfy the following two conditions have a long range of easy glide:
1. The axial orientation of the crystal is far from the three apexes of stereographic triangle.
2. The crystal has a long distance of slip process in which only one slip system is active,

(2) Slip systems other than the predicted one become active even in single slip range, and they are the main causes that makes the rate hardening large.

(3) Kink bands are not observed, but cross-slip and bands of secondary slip are usually seen. They may be the results of grip effect.

(4) The low temperature annealing hardening in copper alloys, which is observed in polycrystalline specimen, are not observed in single crystals.

### Acknowledgement

This study is one of my works in the graduate course under Professor Isshiki, and I want to express my hearty gratitude to him for his kind direction and encouragement throughout the work. I must also express my hearty thanks to Professor Hasiguti and Dr. Kanzaki who has given many useful suggestions and discussions as well as the kind

directions. To Mrs. Inaba who has earnestly helped me in my experiments, I am also greateful.

Three photographs in this work were taken when I studied the possibility of short range order in $\alpha$-brass under Professor Tani, to whom also my great thanks must be given.

# On the Floating Probe Method for the Measurement of Ionized Gas

By Kenzo YAMAMOTO and Takayoshi OKUDA
*Faculty of Engineering, Nagoya University*

(Received August 29, 1955)

Several problems connected with the floating probe method are discussed and solved. Analysing the variation of ion current due to sheath expansion, the authors obtain the criterion for applicability of the usual double probe method and also the general expression available for the estimation of electron temperature.

From the relation between probe characteristic and electron energy distribution, a floating triple method is newly proposed. This method is useful for the measuring of energy distribution in electrodeless or h.f. discharges.

By special use of the floating double or triple probe, the measurement of potential distribution in such a quasi-plasma as ion sheath and the transition region between plasma and ion sheath can be attained. As one example, the floating potential becomes measurable.

The floating, or insulating, potential is discussed in detail and expression is given showing good agreement with measured values.

## §1. Introduction

To the experimental method proposed by Reifman and Dow[1] for double probe measurements in gaseous discharges, using two probe electrodes having no connections with electrodes of discharges, fundamental treatments were simultaneousely advanced by Johnson and Malter[2] and by Kojima and Takayama[3] based upon their own interpretations. The method of this floating double probe has the following two merits in a comparison with the single probe method developed by Langmuir and Mott-Smith[4]. (1) The probe electrodes are in a floating state having no relation to the electrodes of discharge; (2) The amount of current flowing into the probe is so small that the probe measurement does not have any effect on the plasma because it does not exceed the saturation value of the positive ion current.

Under conditions where it can be used, the practical value of the double probe method should be recognized especially in its application to changing plasma, viz. after-glow, electrodeless and high frequency discharges, in none of which the standard potential can be given under any circumstances, suggesting an application of the double probe method as the only one enabling us to measure such plasma.

In this paper we give the correct application of the double probe theory and discuss

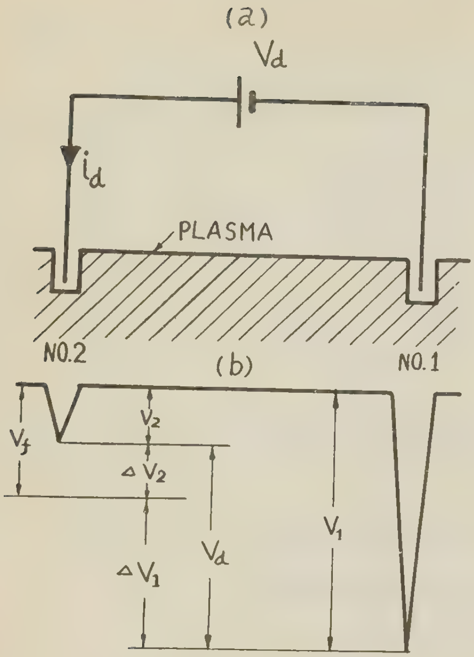

Fig. 1. Basic circuit and potential diagram for the double probe method.

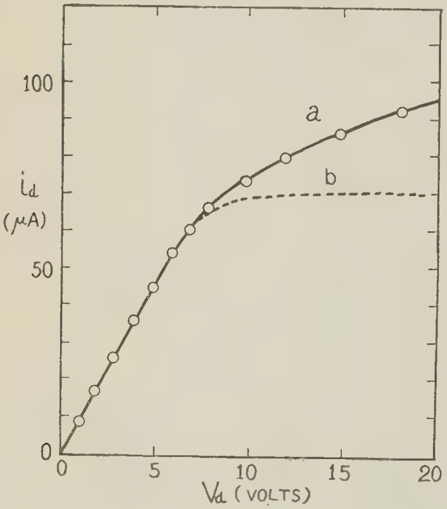

Fig. 2. Typical voltage-current characteristic of the dooble probe method.
Curve *a*, experimentally obtained characteristic, with a slope, low voltage arc of argon, pressure 2 mm Hg, voltage 60.5 voltage current 15 mA.
Curve *b*, idealized characteristic, with no slope.

some problems in connection with this method, extending it into a new method—the triple floating method.

## § 2. Correct Application of Double Probe Theory

When the voltage applied to probes is increased, an increase of positive ion current caused by expansion of the sheath area can be observed even in the saturated part of the flowing current in double probe circuit. When plasma density is of the ordinary value, we do not usually expect the existence of a slope in the saturated part of a probe characteristic curve because the expansion is small, but in many cases a slight or even a remarkable slope may appear, which leads to an error in the estimation of plasma quantities. Here, we make some corrections in the process of estimation.

Making use of the analysis of ideal case by Johnson and Malter[2] in which the probe characteristic has a symmetrical form with no slope in its saturated part, the following expressions of probe current in terms of associated voltage are naturally derived.

Notation of these terms are shown in Fig. 1.

$$i_{p1}+i_{p2}=I_p=i_{e1}+i_{e2} \tag{1}$$

$$\left.\begin{aligned} i_{e1}&=F_1 j_{01}\exp(-\phi V_1)\,,\\ i_{e2}&=F_2 j_{02}\exp(-\phi V_2)\end{aligned}\right\} \tag{2}$$

$$V_1=V_2+V_d \tag{3}$$

$$i_d=i_{p1}-i_{e1}=i_{e2}-i_{p2} \tag{4}$$

where $i_{p1}$, $i_{p2}$=positive ion current to probe
$i_{e1}$, $i_{e2}$=electron currrent to probe
$i_d$=probe current
$I_p$=sum of both ion current
$F_1$, $F_2$=surface area of probe
$V_1$, $V_2$=voltage applied across the space charge sheath serrounding probe
$V_d$=voltage applied between two probes, No. 1 and No. 2
$T_e$=electron temperature
$\phi=e/kT_e=11{,}600/T_e$ °K

The subscripts 1 and 2 refer to Probes No. 1 and No. 2, respectively. For simplicity if

$$F_1=F_2=F\,,\quad j_{01}=j_{02}=j_0$$

and

$$\left.\begin{aligned} & \\ & i_{p1}=i_{p2}=i_p=(1/2)I_p\end{aligned}\right\} \tag{5}$$

then the theoretical expressions of double probe characteristic with no slope in the saturated part can be expressed as follows:

$$\left.\begin{aligned} \ln[(I_p/i_{e2})-1]&=-\phi V_d\\ \ln[(I_p/i_{e1})-1]&=\phi V_d\end{aligned}\right\} \tag{6}$$

$$i_d=(I_p/2)\tanh(\phi V_d/2) \tag{7}$$

These are the results derived by Johnson and Malter[2].

Now in cases where the saturated part of probe characteristic has a slope (see Fig. 2), e.g. where $I_p$ is a function of $V_d$ rather than a constant, in order to obtain the exact values of electron temperature, electron concentration and electron energy distribution, we should separate the electron current from the positive ion current of this function.

(i) *Variation of Positive Ion Current and Probe Current with Probe Voltage when the Saturated Part has a Slope*

First we have the following derivative of equation (1) with respect to $V_d$:

$$\frac{dI_p}{dV_d}=\frac{di_{p1}}{dV_1}\frac{dV_1}{dV_d}+\frac{di_{p2}}{dV_2}\frac{dV_2}{dV_d} \qquad (8)$$

For simplicity we may here assume the symmetry of probe characteristic. Inserting $i_{e1}$ and $i_{e2}$ of equations (2) into equations (6), we immediately have

$$\left.\begin{aligned} V_1&=-(1/\phi)\ln I_p\\ &\quad+(1/\phi)\ln F_0 j_0\{\exp(\phi V_d)+1\}\\ V_2&=-(1/\phi)\ln I_p\\ &\quad+(1/\phi)\ln F_0 j_0\{\exp(-\phi V_d)+1\} \end{aligned}\right\} \qquad (9)$$

or their derivatives:

$$\left.\begin{aligned} dV_1/dV_d&=-(1/\phi I_p)(dI_p/dV_d)\\ &\quad+\exp(\phi V_d)/\{\exp(\phi V_d)+1\}\\ dV_2/dV_d&=-(1/\phi I_p)(dI_p/dV_d)\\ &\quad-\{\exp(\phi V_d)+1\}^{-1}, \quad V_d>0 \end{aligned}\right\} \qquad (10)$$

Here we define $S$ as the ratio between the increase of positive ion current and that of potential across sheath due to sheath expansion, i.e.

$$di_{p1}/dV_1=di_{p2}/dV_2=S \qquad (11)$$

In a rough approximation, we can assume that $S$ is constant throughout the whole range of voltage in this problem. Then, combining equations (8), (10) and (11) we have the following general relation between $I_p$ and $V_d$,

$$dI_p/dV_d=[S\phi I_p/(2S+\phi I_p)]\tanh(\phi V_d/2) \qquad (12)$$

The solution of this equation is

$$I_p\exp(\phi I_p/2S)=2A\exp(\phi A/S)\cdot\cosh(\phi V_d/2) \qquad (13)$$

where

$$2A=[I_p]_{V_d=0} \quad \text{or} \quad [i_{p1}]_{V_d=0}=[i_{p2}]_{V_d=0}=A \qquad (14)$$

Typical plots of equation (13) are shown in Fig. 3.

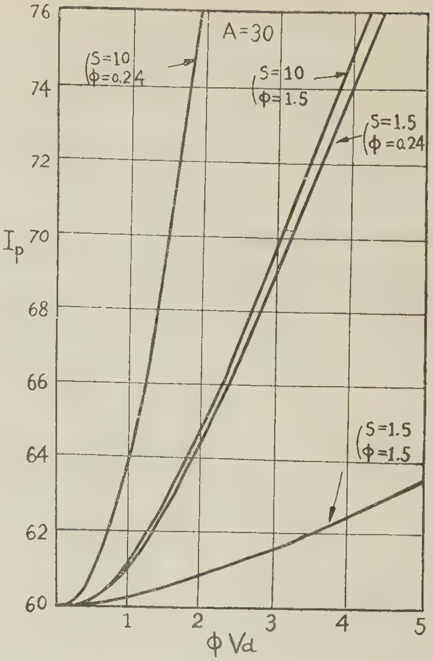

Fig. 3. Variation of total ion current ($I_p=i_{p1}+i_{p2}$) with $\phi V_d$, taking $S$ and $\phi$ as parameters, $A=30$.

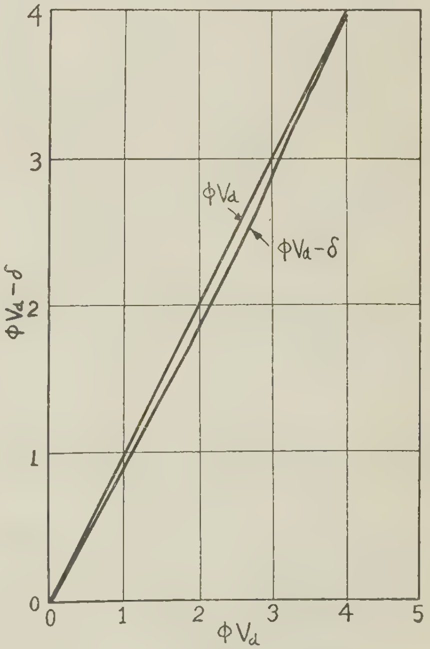

Fig. 4. Plot of $\phi V_d$ vs. $\phi V_d-\delta$.

Next step is to obtain the expressions for $i_{p1}$, $i_{p2}$ and $i_d$ as functions of $V_d$. Using the relation $di_{p1,2}/dV_d=(di_{p1,2}/dV_{1,2})(dV_{1,2}/dV_d)$ with (10), (11) and (14) at once we can get

$$\left.\begin{aligned} i_{p1}&=(S/\phi)\ln[A\{1+\exp(\phi V_d)\}/I_p\}+A\\ i_{p2}&=(S/\phi)\ln[A\{1+\exp(-\phi V_d)\}/I_p\}+A \end{aligned}\right\} \qquad (15)$$

From equation (15) and the relation

$$\ln[(i_{p1}-i_d)/(i_{p2}+i_d)]=-\phi V_d \qquad (16)$$

$i_a$ can be expressed by

$$i_a = A+(S/\phi)\ln(A/I_p)\}\tanh(\phi V_a/2) + V_aS-(S/\phi)\delta \qquad (17)$$

where

$$\phi V_a-\delta=\{1+\exp(-\phi V_a)\}^{-1}[\ln(\exp\phi V_a+1) -\exp(-\phi V_a)\ln\{1+\exp(-\phi V_a)\}] \qquad (18)$$

The probe characteristic with slope in the saturated part is not expressed by equation (7) but by equations (17) and (18), in which $\delta$ becomes smaller when $\phi V_a$ is either considerably greater or much smaller than unity, as shown in Fig. 4.

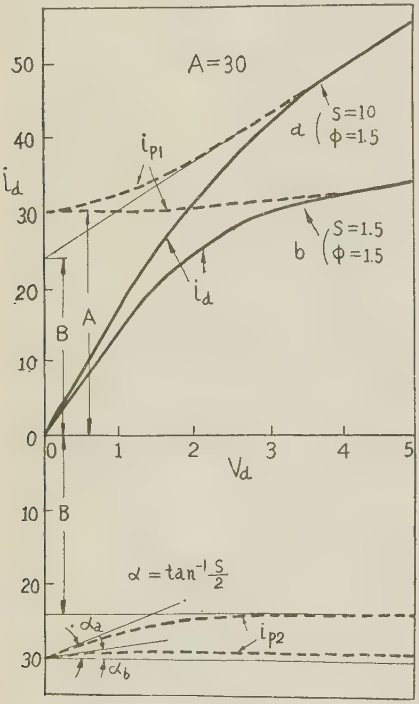

Fig. 5. Analytical double probe characteristic and each ion current for two cases, assuming $S=10$, $\phi=1.5$, A=30 and $S=1.5$, $\phi=1.5$, A=30.
Curve $a$, $S=10$, $\phi=1.5$.
Curve $b$, $S=1.5$, $\phi=1.5$.

(ii) *Expressions for Positive Ion Current*

Instead of equation (15) we can have the following expressions for $i_{p1}$ and $i_{p2}$ which we get by inserting equation (13) into (15)

$$\left.\begin{aligned} i_{p1} &= I_p/2+(S/2)V_a \\ i_{p2} &= I_p/2-(S/2)V_a\,, \quad V_a>0 \end{aligned}\right\} \qquad (19)$$

showing that both $i_{p1}$ and $i_{p2}$ in the region of $V_a>0$ near to $V_a$=zero have the same slope:

$$(di_{p1}/dV_a)_{Va=0}=(di_{p2}/dV_a)_{Va=0}=S/2 \qquad (20)$$

or, one-half of the degree of slope of the saturated part. When $V_a$ increases, the slope of $i_{p1}$ increases up to $S$, while that of $i_{p2}$ decreases down to zero at large $|V_a|$.

We show below how the ultimate values at $V_a=0$ of $i_{p1}$ and $i_{p2}$ can be derived. As in Fig. 5, if we denote $B$ for the value at which a straight line extending from the large value of $V_a$ along probe characteristic cuts the axis of $V_a=0$, then for large values of $V_a$ the characteristic curve can be expressed by

$$I_p=2B+SV_a \qquad (21)$$

and

$$\left.\begin{aligned} i_{p1} &= B+SV_a \\ i_{p2} &= B\,, \quad V_a>0 \end{aligned}\right\} \qquad (22)$$

instead of (19).

Under the above considerations we shall present a criterion for the applicability of the double proble method. From equation (17), we have

$$(di_a/dV_a)_{Va=0}=\{A-(S/\phi)\ln 2\}\phi/2+S \qquad (23)$$

If the slope $(di_a/dV_a)_{Va=0}$ is much greater than $S$ (the slope at large $V_a$)*, then the probe characteristic has in effect a saturated part. Therefore, the conditions of

$$(di_a/dV_a)_{Va=0} \gg S \qquad (24)$$

or

$$A \gg 0.693(S/\phi) \qquad (25)$$

are necessary for the application of the usual double probe method. In most cases $S$ is so small that equation (25) is satisfied.

(iii) *Determination of Electron Temperature*

The use of the log-plot method for determining electron temperature, one of the methods proposed by Johnson and Malter2), is not appropriate unless the exact form of

---

* In the double probe characteristic $i_p$ near $V_a=0$ has a complicated form while at large $V_a$, it is clear from equations (17) and (19) that

$$(di_a/dV_a)_{Va\to\infty}=S$$
$$(di_{p1}/dV_a)=S/2+(1/2\phi)(dI_p/d\phi V_a)$$
$$(di_{p2}/dV_a)=-S/2+(1/2\phi)(dI_p/d\phi V_a)\,.$$

Inasmuch as the second terms of these last two equations become $S/2$ when $V_a$ tends to an infinite (see Fig. 3), we have at large $V_a$

$$di_{p1}/dV_a=S\,, \qquad di_{p2}/dV_a=0$$

proving that the slope at large $V_a$ in the double probe method is equal to that in the single probe method. For example, in our experiment

single probe method: $S=1.2\,\mu A/V$, $(i_p)_{Vf}=67\,\mu A$
double probe method: $S=1.2\,\mu A/V$, $(i_p)_{Va\to\infty}=69\,\mu A$
($V_f$ means the floating potential)

positive ion current can be obtained. Fortunately when $S$ is small, electron currrent can be obtained with almost no error by subtracting an approximately evaluated ion current from probe current, so that the electron temperature can be determined. However if $S$ is large, this approximation can not be permitted because $i_p$ becomes a complicated function of $V_d$.

Here we shall find the formula of electron temperature, including the effect of $S$, by making a correction in the equivalent resistance method[2)] in which the electron temperature is calculated by both $di_d/dV_d$ and $i_p$ at $V_d=0$. From equation (6)

$$i_{e2}=I_p/\{1+\exp(-\phi V_d)\} \tag{26}$$

Differentiating this equation with respect to $V_d$ and setting $V_d=0$, we can write

$$(di_{e2}/dV_d)_{Vd=0}=A\phi/2 \tag{27}$$

Since $\quad di_{e2}/dV_d=di_d/dV_d+di_{p2}/dV_d$ ,

equation (27) leads to

$$(di_{e2}/dV_d)_{Vd=0}=(1/R_0)-(S/2) \tag{28}$$

where $R_0$ is termed "equivalent resistance".

Combining equations (27) and (28) we have the following expression for the electron temperature $T_e$;

$$A\phi/2=1/R_0-S/2$$

or

$$T_e=(e/2k)A(1/R_0-S/2)$$

$$=5,800A(1/R_0-S/2) \quad °\mathrm{K}\,. \tag{29}$$

This formula holds generally in all cases either with or without a slope in the saturated part, including Johnson-Malter's expression as a special case of $S=0$.

The value of $A$, i.e. the value of $i_p$ at $V_d=0$ can be estimated by the same procedure as used by Johnson-Malter. When $V_d$ vs. $i_d$ characteristic has a sufficient symmetry, it is reasonable for practical purposes to choose as the value of $A$ the value of $i_d$ at $V_d=0.15V_s$ on the extraporated line of $i_p$ along the saturated curve, where $V_s$ is a certain value of $V_d$ at which the saturation begins. According to the calculations aided by equations (13) and (19), we have also recognized that the estimated $A$ becomes the value of $i_d$ at $V_d=(0.14\sim0.18)V_s$.

From equation (29) it can be clearly seen that with a large $R_0$, by neglecting $S$ there is a considerable error which results in the under-estimation of the electron temperature.

### (iv) *Electron energy Distribution*

Previous considerations based upon the Maxwell-Boltzmann distribution of electron velocities are not justifiable with such special plasmas as in the negative glow.

In the double probe method, the probes automatically settle near the so-called floating potential, forming positive ion sheaths around themselves, and permitting electrons of such high energy to flow into the probes as to overcome the retarding fields of the sheaths. The floating potential is always much greater than the potential corresponding to the most probable velocity, so that the electrons collected by probes come from portion of higher velocities in the distribution. For example, in $T_e=1000°\mathrm{K}$ in argon[2)] the ratio of collected electrons to total electrons amounts to merely 0.21%, where $V_f$ is 0.5 volt, while the potential corresponding to the most probable velocity is 0.08 volt.

It has been extensively reported that some deviations from the Maxwell-Boltzmann distribution often arise in the portion of higher velocities, depending upon the kind of gas and $E/p$, where $E$ is electric field and $p$ pressure. In such cases in the double probe method, considerable errors may be introduced in the estimation of plasma quantities.

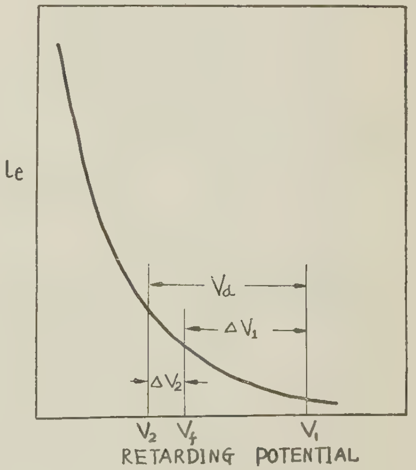

Fig. 6. Electron current as a function of retarding potential, illustrating correspondency with double probe characteristic.

Now we shall illustrate the way in which the higher portion in the velocity distribution curve contributes to the probe characteristic. If the analysis could succeed, we would

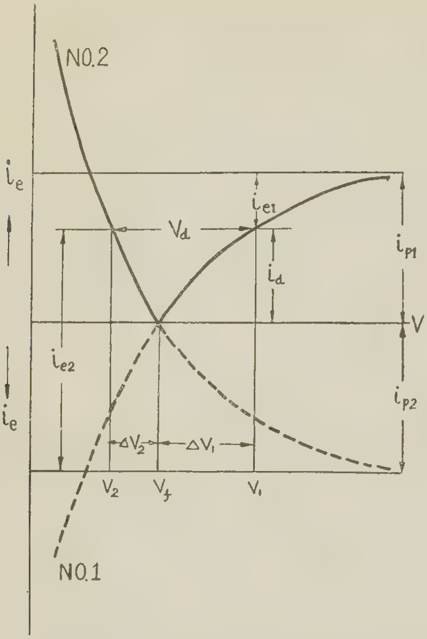

Fig. 7. Relation between electron current as a function of retarding potential and probe current as a function of probe voltage, without slope.

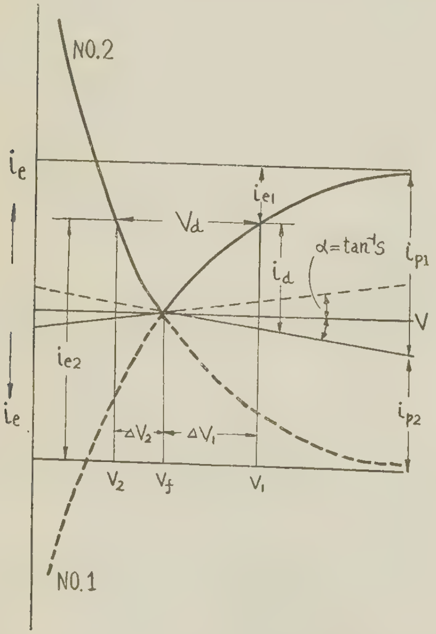

Fig. 8. Relation between electron current as a function of retarding potential and probe current as a function of probe voltage, with slope.

acquire quantitative knowledge on the collected current in non-Maxwellian cases.

Fig. 1 shows schematically a rough outline of the potential distributed to the two probes

between which a voltage $V_d$ is applied. If $V_d=0$, both probes have the equal floating potential $V_f$. If $V_d>0$, the potential of No. 1 probe is decreased by $\Delta V_1$ and that of No. 2 increased by $\Delta V_2$. We can divide $V_d$ into $\Delta V_1$ and $\Delta V_2$ along the curve of collected electron current vs. negative potential shown in Fig. 6, the relation being always $\Delta V_1>\Delta V_2$.

First, considering such an ideal case as $S=0$, the operation of double probes can be schematically illustrated as in Fig. 7. By lapping inversely the curves of No. 2 at the point of $V=V_f$, the figure shows the relations between the probe potential, the saturated positive ion current and the electron current collected by the two probes. The solid lines refer to the operation for $V_d>0$ and the dotted lined the operation for $V_d<0$.

From Fig. 7, it is evident that

$$V_d=\Delta V_1+\Delta V_2=V_1-V_2 \qquad (30)$$

Taking the voltage difference $V_d$ between the two branches of solid lines vs. $i_d$, we can obtain the simple relation $i_d=i_p\tanh(\phi V_d/2)$ if we assume Maxwell-Boltzmann distribution.

Next, taking slope into consideration, the only thing to do is to rotate the abscissa around the point $V=V_f$ by an angle $\theta=\tan^{-1}S$ (see Fig. 8).

These illustrations are useful for the analysis of non-Maxwellian distribution in which $i_{e1}$ and $i_{e2}$ can not be expressed by such a simple exponential form with respect to $V$ as equation (7).

Figs. 9 and 10 show typical non-Maxwellian examples obtained in the negative glow of d.c. glow discharge in air and in the glow surrounding hot cathode in low voltage argon arc, respectively.

## § 3. Triple Probe Method

Hitherto the only method capable of determining the electron energy distribution was the single probe method developed by Langmuir and Mott-Smith. However, this is not applicable to electrodeless or high frequency discharge because it gives no fixed potential for the base of probe.

Here we propose a "triple probe method", adding to the double probe method the third probe, which is always held at the floating potential in order to make the floating probe able to measure the electron energy distribution.

Fig. 11 shows a connection diagram of the triple probe method. If we adjust a potential divider so that the current $i_{d3}$ flowing into No. 3 probe is zero, then the potential of No. 3 probe becomes equal to the floating potential $V_f$ and No. 1 and 2 remain the usual double probe for the measurement. The potential difference between No. 1 and No. 3 then becomes equal to $\Delta V_1$ and that between No. 2 and No. 3 to $\Delta V_2$. At the same time we can get the relations between both $\Delta V_1$ and $i_{e1}$, and $\Delta V_2$ and $i_{e2}$ from the double probe characteristic. Thus the curve of electron current vs. voltage near $V_f$ can be drawn, from which the electron energy dis-

tribution can be decided by Druyvesteyn's method[5]. For the separation of $i_e$ from $i_d$, the procedure given in paragragh II, (i) must be applied.

We describe here the experimental results obtained by using this method for high frequency electrodeless discharge. Three probes equally separated are placed on an equipotential plane in a discharge tube with air of $1.7\sim10^{-3}$ mm Hg, frequency of 77 M.c. Table I shows a result of the experiment, pressure $1\times10^{-2}$ mm Hg, applied high frequency voltage 215 V.

From many measurements of energy distribution in the h.f. discharge the following conclusions are deduced;

(1) Mean energy decreases with increasing pressure.

(2) Electron energy distribution tends toward the Maxwellian when the pressure rises.

(3) Generally, there appears a deficiency in the higher energy portion, as shown in Fig. 12.

These experimental results are consistent with Margenau's theoretical analysis[6].

Although the triple probe method is not available for determining the whole range of energy distribution, it is useful in cases where the single probe method cannot be applied.

## § 4. Applications of Floating Triple and Double Probe Methods for the Ion Sheath and the Transition Region between Plasma and Sheath

In this section we describe another application of triple probe method as well as special use of double probe method for determining potential distribution in positive ion sheath and in the transition region between plasma and ion sheath.

When two of three probes or one of a double probe are inserted into a plasma and the remaining one probe into "quasi-plasma" such as the ion sheath or the transition region between plasma and sheath, the probe characteristic must be changed.

(i) *Triple Probe Method*

As shown in Fig. 13, when No. 1 and No. 2 probes are set at the points of equal potential in a plasma for the purpose of usual double probe measurement and movable No. 3 probe, adjusted to be no current, is settled at a point in a quasi-plasma under measurement, then the deviation *V* of the potential at the point in the quasi-plasma from the plasma potential can be obtained by comparing the potential of No. 3 of this state with that in the plasma. By transfering No. 3 probe from the plasma into the transition region along the equipotential plane, we can observe the potential change throughout the whole region of transition.

This statement is based upon the following experimental fact. When a plane electrode floats in a plasma producing a positive ion sheath around itself, and when No. 3 probe approaches infinitely near the plane electrode, then $\varDelta V_1 - \varDelta V_1'$ becomes experimentally equal to the floating potential $V_{fp}$ where $\varDelta V_1$ is the potential difference between No. 1 and No. 3, placing the latter in a plasma and $\varDelta V_1'$ is the potential difference between No. 1 and No. 3, placing No. 3 in the transition region or in the ion sheath, and where $V_{fp}$ is the floating potential of the plane electrode.

As an example, in the glow discharge of a discharge current 30 mA in air of 2.5 mmHg, using an insulating plane electrode of 0.5 cm × 0.5 cm and a thin wire probe of 0.0035 cm diameter, we obtained 24.5 V for the value of $\varDelta V_1 - \varDelta V_1'$, while the floating potential of the plane electrode $V_{fp}$ was 25.2 V measured by the single probe method. Therefore we may assume that the following relation is held at any point in the transition region or the ion sheath.

$$\varDelta V_1' - \varDelta V_1 = V \qquad (31)$$

This fact shows that by trasfering No. 3 probe from the plasma to a point where the potential is lower by $V$ than the potential of the plasma, the potential of No. 3 probe rises by $V$. Fig. 14 indicates a potential curve near an insulating plane electrode, obtained by this method.

Now we shall give consideration to the above measurment. When two probes of geometrically equal dimensions are placed in equal plasma states, the double probe characteristic shows symmetrical curve. No. 3 probe does not influence the double probe characteristic because No. 3 probe is always used in floating state or without current.

The electron density $n_e$ at a point where the potential is lower by $V$ with respect to the plasma, is expressed by Boltzmann's relation

$$n_e = n_0 \exp(-eV/kT_e) \qquad (32)$$

where $n_0$ is the electron density of the plasma. Asssuming the quasi-neutrality, we have $n_e \approx n_p$, where $n_p$ is the positive ion density.

For simplicity, assuming that $E/p$ of plasma is small enough so that the positive ion current flowing into No. 3 is

$$\begin{aligned} i_{pf} &= (n_0 e \bar{v}_p/4)(2\pi r_c') \exp(-eV/kT_e) \\ &= 1.87 \times 10^{-8} (n_0 e/4)(T_p/M)^{1/2} (2\pi r_c') \\ &\quad \times \exp(-eV/kT_e) \qquad (33) \end{aligned}$$

where $\bar{v}_p$ is mean thermal velocity of positive ion, $M$ is mass of ion, $T_p$ is positive ion temperature and $r_c'$ is radius of positive ion sheath in the quasi-plasma.

The electron currrent of No. 3 probe is

$$\begin{aligned} i_{ef} &= j_{e0} \exp(-eV/kT_e) \cdot \exp(-eV_f'/kT_e) \cdot (2\pi r_a) \\ &= 1.87 \times 10^{-8} (n_0 e/4)(T_e/m)^{1/2} (2\pi r_a) \\ &\quad \times \exp\{-e(V+V_f')/kT_e\} \qquad (34) \end{aligned}$$

where $j_{e0}$ is random electron current density in plasma, $V_f'$ is floating potential in the quasi-plasma, $r_a$ is radius of the probe and $m$ is electron mass. From the condition of no current, we have

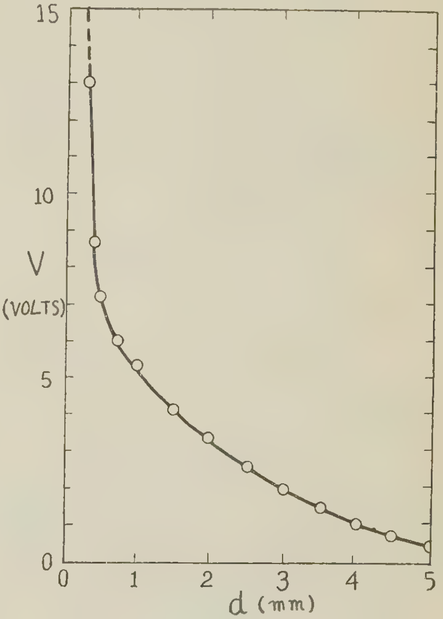

Fig. 14. Measured potential distribution near the floating plane electrode, air of pressure 2.5 mm Hg, current 40 mA, probe voltage $V_d = 40$ V. Potential $V$ is measured with respect to plasma potential. Distances $d$ is measured from the floating plane electrode.

$$i_{pf} = i_{ef} \qquad (35)$$

or $\quad V_f' = (kT_e/e) \ln[(r_a/r_c')(T_e M/T_p m)^{1/2}]$ . (36)

On the other hand, when No. 3 probe is placed in the plasma, its floating potential $V_f$ is given by

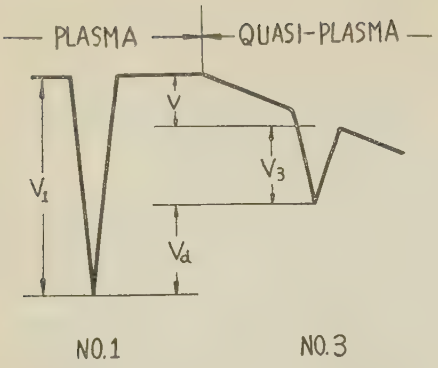

Fig. 15. Potential diagram for the double probe method applied to quasi-plasma.

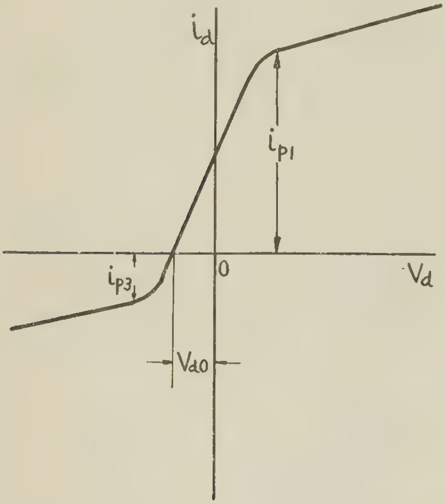

Fig. 16. Double probe characteristic for quasi-plasma.

$$V_f=(kT_e/e)\ln[(r_a/r_c)(T_eM/T_pm)^{1/2}] \qquad (37)$$

where $r_c$ is the radius of ion sheath produced around No. 3 probe when No. 3 probe is placed in the plasma.

From (36) and (37) we get at once

$$V_f-V_f'=(kT_e/e)\ln(r_c'/r_c) \qquad (38)$$

and from (31) and (38) we get

$$(kT_e/e)\ln(r_c'/r_c)=2V\,. \qquad (39)$$

This indicates the relation between the expansion of ion sheath and the potential deviation from plasma.

From (38) and (39) we get

$$V_f'=V_f-2V \qquad (40)$$

viz., at the point where the potential is lower by $V$ than the potential of a plasma, the floating potential is lower by $2V$ than the floating potential of the plasma.

According to the above consideration, we can find the potential distribution in the transition region and eventually can know floating potential of a floating probe by means of extrapolation of potential distribution to the floating probe.

(ii) *Double Probe Method*

In the double probe measurement, omitting No. 2 probe in the triple probe method (Fig. 15), the probe characteristic is not symmetrical but rather asymmetrical as indicated in Fig. 16. In cases where each probe is not of equal potential, we can describe the relations following Johnson and Malter.

Denoting electron current densities $j_{01}$, $j_{03}$, positive ion currents $i_{p1}$, $i_{p3}$ for each probe, in place of (3), we have

$$V_1-V_d=V_3+V \qquad (41)$$

From equation (1), (2) and (41)

$$(I_p/i_{e3})-1=i_{e1}/i_{e3}=(j_{01}/j_{03})\exp\{-\phi(V_1-V_3)\}$$
$$=(j_{01}/j_{03})\exp\{-\phi(V+V_d)\} \qquad (42)$$

at a point on the probe characteristic curve where the probe currrent becomes zero we have

$$i_{e1}=i_{p1} \quad \text{and} \quad i_{e3}=i_{p3} \qquad (43)$$

Denoting $V_{d0}$ for the value of $V_d$ which satisfies the above condition, from (42) and (43) we have

$$i_{p1}/i_{p3}=j_{01}/j_{03}\exp\{-\phi(V+V_{d0})\} \qquad (44)$$

or

$$V=-V_{d0}-(1/\phi)\ln(i_{p1}j_{03}/i_{p3}j_{01})\,. \qquad (45)$$

This relation is useful for a simple measurement of potential gradient in a positive column in which, as the second term can be omitted, we have

$$V=|V_{d0}|\,. \qquad (46)$$

When one probe No. 3 is placed in the transition region, relation are as follows:

$$j_{03}=j_{01}\exp(-\phi V)\,. \qquad (47)$$

From (44) and (47),

$$i_{p1}/i_{p3}=\exp(\phi|V_d|)\,. \qquad (48)$$

Inserting (47) into (42),

$$i_{e1}/i_{e3}=\exp(-\phi V_d)\,. \qquad (49)$$

By using equation (4) or $i_{e1}/i_{e3}=(i_{p1}-i_d)/(i_{p3}+i_d)$, we have

$$i_d=\frac{i_{p1}-(i_{e1}/i_{e3})i_{p3}}{1+(i_{e1}/i_{e3})}\,. \qquad (50)$$

Inserting (48) and (49) into (50),

$$i_d = \frac{i_{p1}}{1+\exp(-\phi V_d)}[1-\exp\{-\phi(V_d-V_{d0})\}] \tag{51}$$

and

$$[i_d]_{Vd=0} = \{1-\exp(\phi V_{d0})\}(i_{p1}/2)\ . \tag{52}$$

Assuming the positive ion energy to be constant, we have

$$j_{p3} = j_{p1}\exp(-\phi V)$$

or

$$i_{p1}/i_{p3} = (r_{c1}/r_{c3})\exp(\phi V) \tag{53}$$

where $j_p$ is the positive ion current density. From (39) and (48), we get

$$V = |V_{d0}|\ . \tag{54}$$

Thus by means of double probe we can also obtain the potential distribution. Table II indicates some results giving the measured values of $V$ by the triple probe method (column 2) which agree fairly well with those measured by double probe method (column 3), outside the boundary ($d=2$ mm). In the sheath ($d<2$ mm) the potentials measured by triple probe method do not coincide with that by double probe method. The error seems to arise from the disturbance caused by the inserting of probe in the sheath, absorbing the current.

Table II. Observed potential deviations from plasma potential at several points near the floating plane electrode. D. c. glow discharge of air, pressure 2.5 mm Hg, current 30 mA, plane electrode of 0.5 cm × 0.5 cm, wire probe of diameter 0.0035 cm.

| $d$ (mm) | $V$ (V) | | $i_{p3}$ ($\mu$A) |
|---|---|---|---|
| | triple | double | |
| 6 | 0.2 | 0.3 | 22.7 |
| 4 | 1.0 | 1.2 | 22.4 |
| 3 | 2.0 | 2.2 | 22.2 |
| 2 | 3.5 | 4.1 | 21.4 |
| 1 | 5.3 | 8.4 | 16.6 |
| 0.5 | 10.0 | 16.5 | 9.7 |

$d$: distance from the floating plane electrode (mm).
$V$: potential deviation from plasma potential (V).
$i_{p3}$: saturated probe current of No. 3 probe ($\mu$A).

## § 5. On the Floating Potential

The only defect of the double probe method lies in that it gives no information on the space and floating, or insulating, potentials. Particularly, it is necessary to know the floating potential because that is the standard of potential or energy in the measurement of energy distribution.

As has already been pointed out by Tonks and Langmuir⁷⁾, the ratio between saturation values of electron and positive ion current is not given by $(T_eM/T_pm)^{1/2}$. Consequently, the expression (37) for $V_f$ is not justifiably held. It is confirmed by the experiment that the calculation using equation (37) could agree with the observation only when the ion temperature would be as high as, or sometimes higher than, the electron temperature. We cannot explain the measured value of $V_f$, even when permitting the use of the high ion temperatures lately reported by several investigators, for instance $T_p \approx (1/3 \sim 1/10)T_e$ by Boyd⁸⁾

In ordinary plasma, the collection of positive ion by probe must be caused by some mechanism other than thermal motion of positive ion.

Bohm⁹⁾ stated that the boundary between sheath and plasma in low pressure should be found where the following relation is satisfied.

$$eV_0 = kT_e/2 \tag{55}$$

where $eV_0$ is the mean energy of positive ion at the boundary, i.e.

$$eV_0 = eV + kT_p/3 \tag{56}$$

The mean velocity of positive ion at the boundary is

$$v_p = \sqrt{\frac{2}{M}}\sqrt{eV_0} = \sqrt{\frac{2}{M}}\sqrt{eV+\frac{kT_p}{3}}$$
$$= \sqrt{\frac{2}{M}}\sqrt{\frac{kT_e}{2}} \tag{57}$$

We may here assume

$$n_p \approx n_e = n_0\exp(-eV/kT_e)\ . \tag{58}$$

Therefore the positive ion current density $j_p$ which flows into the boundary is

$$j_p = \sqrt{\frac{2}{M}}\sqrt{\frac{kT_e}{2}}\,n_0\exp(-eV/kT_e) \tag{59}$$

or, neglecting $T_p$,

$$j_p = n_0\sqrt{\frac{2}{M}}\sqrt{\frac{kT_e}{2}}\,e^{-1/2} = 0.4288n_0\sqrt{\frac{2kT_e}{M}}^{**} \tag{60}$$

---

** Equation (60) resembles Langmuir's equations of wall current dependent on electron temperature.

Notations P, C and S signify plane, cylindrical and spherical forms of plasma, respectively; L the long mean free path; $\lambda$ ions produced proportionally to electron density; J constant ion production.

$$j_p = Kn_0(2kT_e/M)^{1/2}$$

| | 60 | 39.000 | 6,500 | 14.0 | 14.2 | 21.8 |

* Ion temperature in the Table of $V_f$ are calculated by the following equation:

$$T_p=T_g/2+1/2\{T_g{}^2+1.66(eE\lambda_{0p}/kp)^2\}^{1/2}$$

where $T_g$ = gas temperature (°K). $k$ = Boltzmanns constant.
$e$ = electronic charge. $\lambda_{0p}$ = ionic mean free path at 1 mmHg (cm).
$p$ = pressure (mmHg). $E$ = electric field (V/cm).

** For plane probe, we must use following equation instead of (37).

$$V_f=(kTe/e)\ln(TeM/T_pm)^{1/2}\,. \qquad (37\text{-II})$$

From Bohm's equation and the relation

$$j_p=j_e\exp(-eV_f/kT_e)\,,$$

we get an expression for $V_f$ of plane probe

$$V_f=\frac{kT_e}{e}\ln\left[\frac{(n_0/4)(8kT_e/\pi m)^{1/2}}{0.4288(2kTe/M)^{1/2}}\right]$$

$$=\frac{kT_e}{e}\ln\left(0.6578\sqrt{\frac{M}{m}}\right) \qquad (61)$$

and numerically

for $N_2$ $V_f=5{,}004\,T_e/11{,}600$ °K
Ar $V_f=5{,}599\,T_e/11{,}600$ °K
Hg $V_f=6{,}405\,T_e/11{,}600$ °K

If we use the expression (61) for $V_f$ of plane probe, the calculated values agree fairly well with the observed values, as shown in Table III.

We can note in Table III that the observed value is always smaller than the calculated value, a difference which increases with increased pressure, and which seems to be caused by a disturbance resulting from insertion of probe in a plasma of small density.

## Conclusion

The authors herein discuss all the problems which arise in practical uses of floating probe method, and shows ways to overcome the difficulties encountered in measurement.

There remain no serious problems connected with idealized plasma. There are various kinds of plasma which have not yet been exactly measured owing to the limitations of probe method. The triple probe method and some corrections in the double probe method may be conveniently used to make such measurements.

# On the Sheen Gloss

By Hirosi HASUNUMA and Jiro NARA

*Department of Applied Physics, Faculty of Engineering,*
*University of Tokyo*

(Received September 10, 1955)

Experiments of sheen gloss of metals and theoretical explanation of them are given. Sheen gloss is related with the specularly reflected light which appears by a incident angle above a critical angle $\theta_c$. $\theta_c$ is connected with the r.m.s. roughness $h$ as:

$$2h\cos\theta_c=\lambda/k \qquad k=2\sim3$$

This formula is explained by a theory similar to the Kirchhoff's diffraction theory, treating the roughness as a stationary random function given by Ornstein-Uhlenbeck process. Scattered light is separated to $R$- and $D$-comp. the former corresponds to sheen and its brightness is given as a function of incident angle $\psi$ by

$$\exp\left(-\frac{16\pi^2h^2}{\lambda^2}\cos^2\psi\right) .$$

$D$- comp. is the part that represents scattered light.

## § 1. Introduction

The light incident upon a rough surface is scattered to every direction. The intensity of light reflected at the specular angle is a measure of gloss of the surface and is called specular gloss. When the angle of incidence is glazing, intensity at the specular angle is distinctly increased. This is a different kind of gloss and is called sheen gloss¹⁾.

Barkas²⁾ had given a theory of diffuse reflection of papers based on geometrical optics and separated each scattered light beam to specular and diffuse component. The specular component is the one which is reflected by mirror facets distributed on the surface of the paper and follows the Fresnel's formula. The diffuse component is the one which is scattered by particls in the interior of the paper and obeys the Lambert's low. Kurita, Yano and the authers³⁾ have pointed out that although the Barkas' theory is formally applicable to matt papers²⁾⁴⁾, it can not be applied to glossy papers because the diffuse component calculated by his theory takes even a negative value. The analysis indicates that at least for grazing incidence, so called specular components do not follow the Fresnel's formula. We⁵⁾ also pointed out in the case of coated papers that the intensity at the specular angle considerably increases as the angle of incidence increased, the rate of increase being larger than that expected from the Fresnel's formula. These results are related with sheen. Accordingly sheen should be explained by wave optics.

Jentzsch⁶⁾ pointed out that some rough surfaces behave like smooth surfaces when the angle of incidence is larger than the critical angle and derived the following relation from the viewpoint of the Rayleigh's limit:

$$2h'\cos\theta_c=\lambda/4 .$$

Here $\theta_c$ is the critical angle, $h'$ the roughness height of the surface and $\lambda$ the wave length of light. There are a few papers in which the discussion concerning sheen gloss and the critical angle are given.

We have investigated experimentally, for metals, relations between the critical angles and the roughness of surfaces and the intensity of scattered light near the critical angle, then explained them by the wave optical theory similar to that given by Davies⁷⁾.

## § 2. The Measurement of Critical Angles⁸⁾

The method is the same as that of Jentzsch. Fig. 1 is the essentials of the apparatus used. The test pattern is a set of narrow slit drawn on a silvered glass plate by the intervals of 0.1 mm. The test pieces are situated between microscope objective and eye-piece. The angle of incidence can be freely changed, keeping the angle of view the same as the angle of incidence. When the angle of the centre line of the eye-piece coincide with the critical angle, images of slits in the left half of the field of view are sharp because the angle of reflection exceeds the critical angle, and images in the right half are diffuse in contrast with them. By such a way the critical angle can be determined.

L: Light source. F: Filter (Corning glass λ550 mμ). C: Condenser lens. Q: Test pattern. T: Sample. Ob: Microscope Objective (10×). Oc: Ocular (5×).

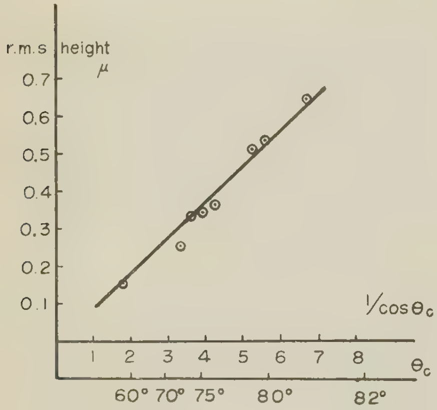

Fig. 2. Relation between r.m.s. height and critical angle.

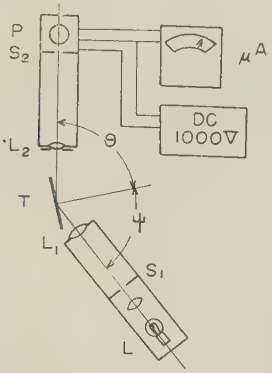

Fig. 3. Goniophotometer.
P: Photomultiplier 931. $S_2$: Slit 1.5 mm width. T: Sample. $L_2$: Lens with aperture stop φ10 mm *f*, 14.5 cm. $L_1$: Lens φ60 mm *f* 18 cm. $S_1$: Slit 1.5 mm width. L: Light source.

Test pieces used are steel plates lapped by $Al_2O_3$ powder of different grain size. The r.m.s. roughness $h$ of plates are measured by an Abott's profilometer.

The relation between $\theta_c$ and $h$ obtained is given in Fig. 2, the abscissa being written in scale of $1/\cos\theta_c$. From the inclination of the line, the following formula is obtained:

$$2h\cos\theta_c=\lambda/k \qquad (1)$$

Here $k$ is a constant and for steel $k=3$.

The similar experiment by the other test pieces show that the constant $k$ is not always the same but changes from metal to metal and also by the lapping process of the samples, for example for steel polished with sand paper $k=2.2$ and for chrome plated brass $k=2$.

It should be noted here that the effective light beam for observation is not absolutely parallel one but has the angle subtended by the pupil to the point in the range of clear vision, i.e., about 30′∼1°.

## § 3. The Measurement by a Goniophotometer[9)]

Fig. 3 gives the goniophotometer used. The light source is a small lamp having a linearly wounded filament and the receiver is a 931 photomultiplier tube fed by a stabilized source. The out put current is read by microammeter directly. The flux reaching the receiver is limited to an angle of 40′ by a slit of 1.5 mm width at $S_2$ and the incident flux has an angle of 30′ depending on the size of the slit $S_1$. The dimention of the optical system is carefully selected so that the brightness is directly read.

By this apparatus, the intensity of the light at the specular direction vs. the incident angle (named the curve of sheen) and the intensity of scattered light near the critical angle vs. the angle of incidence (named the goniophtometer curve) is measured. The test pieces are the same as that used in the preceding measurement.

Fig. 4 shows the curves of sheen taken with lapped steel surfaces, the intensity being written by log-scale with arbitrary unit. Each curve consists of two straight lines, crossed just at the critical angle of each test pieces.

The same charactor of curves are seen by the other test pieces, such as ones made of chrome plated brass or of ground glass.

The goniophotometer curves are taken fixing the receiver angle at $\theta_c$, $\theta_c+5°$ and $\theta_c-5°$, and changing the angle of incidence from the specular direction toward a smaller angle. Some examples of the curves taken are given in Fig. 5, abscissa $\varphi$ indicating the differences between the angle of the receiver and the angle of incidence. The intensities are also given by log-scale. When the angle of specular reflection exceeds the critical angle, the curves $(\theta_c+5°)$ consist of two part. The one, named *R*-comp., appearing only in the vicinity of the specular reflection, has a strong intensity. The half width of them may be very small, but the accurate value can not be known due to the insufficient resolving power of our apparatus. The other component, named *D*-comp., extends over a wider angular range. The log. intensity of it decreases linearly with $\varphi$. The intensity of the *R*-comp. decreases as the angle of receiver approaches to the critical angle and nearly vanish as the former reaches the later. The curves $\theta_c-5°$ consists of *D*-comp. only. In general the inclination of *D*-comp. differs by $h$ as well as by the methods by which they are prepared.

## § 4. Theoritical Consideration

If we limit the problem to the case of metals and approximate them as perfect conductors, the approximation of the Kirchhoff's diffraction theory is applicable. This means that the polarization of reflected light and the variation of intensity with incident angle is neglected. Davies had given a theory for the reflection of wave by this approximation. We have used his theory making a little modification on the statistical property of the surface, and limiting to the case that the receiver is in the plane of incidence.

Metal surfaces prepared by the methods such as lapping, grinding and paper polish have irregular profile and the height $z$ of any point $(x, y)$ should be given statistically. A necessary and most simple model of such a surface is to take $z$ as a random variable obeying the stationary linear Markov process. That is, a surface is considered to be given by the probability density $P(z)$ and the correlation coefficient $\langle zz' \rangle = h^2\rho(r)$, $r$ being the distance of two point $(x, y)$ and $(x', y')$.

It will further be assumed that the distribution of height $z$ is Gaussian:

$$P(z)=\frac{1}{h\sqrt{2\pi}}\exp\left(-\frac{z^2}{2h^2}\right) \qquad (2)$$

$h$ is the r.m.s. value of the roughness of the surface. There is no experimental data for the correlation function $\rho(r)$. In the following calculation it is assumed for the sake of simplicity that the correlation exists only in the direction of $x$. It is also assumed that the process is that of the stationary Markov's. Then the distribution is that of the Ornstein-Uhlenbeck process* and the correlation coefficient is given by:

$$\rho(r)=\exp\{-\beta|x'-x|\}\,. \qquad (3)$$

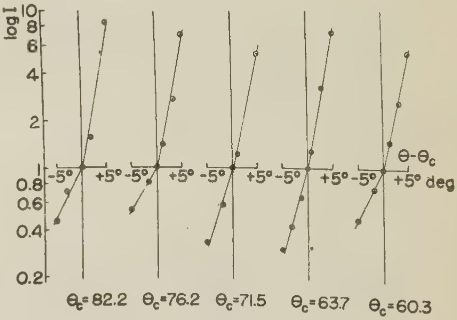

Fig. 4. Curves of sheen.

Then the conditional probability density $P(z, z', r)$, the probability of finding $z'$ at $(x', y')$ when $z$ at $(x, y)$ is given, can be written by the general theory of probability as follows:

$$P(z, z', r)=\frac{1}{\sqrt{2\pi}\,h(1-\rho^2)^{1/2}}\times\exp\left\{-\frac{(z'-z\rho)^2}{2h^2(1-\rho^2)}\right\}. \qquad (4)$$

Thus the surface is represented by two constants $h$ and $\beta$. The former is the r.m.s. height and is easily measureable, but the later is completely unknown. The further consideration shows that $h\beta$ indicates the mean inclination of the profile of the surface. It is known from the roughness curves that the order of magnitude of the inclination of metal surface is generally 0.1 radian or less. In general the length $1/\beta$ is much shorter than the aperture diameter of the optical system.

---

* This assumption is different from that of Davies'.

Consider a plane wave obliquely incident on a rough rectangular reflector of dimensions $2L$ and $2M$, the plane of incidence being parallel to the side $2L$. If we take $\psi$ as the angle of incidence, $\theta$ as the angle of scattering, $C$ as the amplitude of incident wave and $x, y$ as the rectangular coordinate taken on the mean surface, $x$ being parallel to the side $2L$. Then as in the usual diffraction problem, the field $E$ at a distance $R$ is: putting

$$\left.\begin{aligned} q&=\frac{2\pi}{\lambda}(\sin\theta-\sin\psi)\\ p&=\frac{2\pi}{\lambda}(\cos\theta+\cos\psi)\end{aligned}\right\} \tag{5}$$

$$f=-\frac{iC}{4\pi R}\left(q\frac{dz}{dx}+p\right)\cdot\exp i(qx+pz) \tag{6}$$

$$E=\int_{-M}^{M}dy\int_{-L}^{L}dx\, f(x, y, z)\,. \tag{9}$$

The intensity of the light is given by

$$I=|E|^2/8\pi\,.$$

We are interested to the statistical mean valus $\langle E\rangle$ and $\langle I\rangle$, as $z$ is the random function. The average is taken over an ensemble of such reflectors, all having the same statistical properties. It will be assumed that this ensemble average is the same as the time average:

$$\begin{aligned}\langle E\rangle&=\left\langle\iint f(x, y, z)dxdy\right\rangle\\ &=\iint\langle f(x, y, z)\rangle dxdy\end{aligned} \tag{8}$$

It is evident that

$$\langle|E|^2\rangle=\langle E\rangle^2+\langle|E-\langle E\rangle|^2\rangle \tag{9}$$

The statistical mean of $dz/dx$ is zero. If the correlation of $dz/dx$ be assumed zero, the calculation can be furnished by a similar method to that of Davies':

$$\begin{aligned}\langle E\rangle&=-\frac{iCMp}{2\pi R}\int_{-L}^{L}\exp(iqx)\,dx\\ &\quad\times\int_{-\infty}^{\infty}P(z)\exp(ipz)dz \qquad (10)\\ &=E_0\exp\left(-\frac{p^2h^2}{2}\right) \qquad (11)\end{aligned}$$

The exponential factor is the Fourier's transform of $P(z)$. $E_0$ is given by putting $z=0$ in the above equation (10) and is the amplitude of diffraction pattern by the slit of the width $2L$.

$$E_0=\frac{iCMp}{\pi R}\,\frac{\sin qL}{q} \tag{12}$$

As $2L$ is sufficiently large, the fringe has a very narrow width in the vicinity of specular direction, i.e, $q=0$. $\langle E\rangle$ has the pattern of $E_0$ modified by the factor $\exp(-p^2h^2/2)$ which practically does not influence the width of the pattern. Thus the component of the intensity corresponding to $\langle E\rangle$ appears, speaking in a sense of geometrical optics, only in the direction of specular reflection and may be called the $R$-comp. as it corresponds to that of the experiment.

Furthermore, taking into account:

$$\int P(z, z', r)\exp(-ipz')dz'=\exp\left\{-\frac{p^2h^2}{2}(1-\rho^2)-ip\rho z\right\} \tag{13}$$

$$\begin{aligned}\langle|E-\langle E\rangle|^2\rangle&=\frac{c^2M^2p^2}{4\pi^2R^2}\int_{-L}^{L}\int_{-L}^{L}dxdx'\exp\{-q(x'-x)\}\\ &\quad\times\iint dzdz'P(z)P(z, z', r)\{\exp(ipz)-\exp(-p^2h^2/2)\}\{\exp(-ipz')-\exp(-p^2h^2/2)\}\\ &=\frac{c^2M^2p^2}{4\pi^2R^2}\int_{-L}^{L}\int_{-L}^{L}dxdx'\exp\{-q(x'-x)\}\exp(-p^2h^2)\{\exp(p^2h^2\rho)-1\}\,.\end{aligned} \tag{14}$$

We can expand the exponential term as follows:

$$\exp(p^2h^2\rho)=\sum_{n=0}^{\infty}\frac{(p^2h^2)^n}{n!}\exp\{-n\beta|x'-x|\} \tag{15}$$

Hence

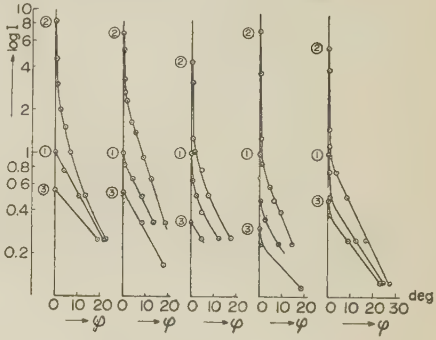
$$\begin{aligned}\langle|E-\langle E\rangle|^2=\frac{c^2M^2p^2}{4\pi^2R^2}\exp(-p^2h^2)\sum_{n=1}^{\infty}\frac{(p^2h^2)^n}{n!}\Bigg[&\frac{4n\beta L}{n^2\beta^2+q^2}-\frac{2(n^2\beta^2-q^2)}{(n^2\beta^2+q^2)^2}\\ &+2\exp(2n\beta L)\frac{(n^2\beta^2-q^2)\cos 2qL-2n\beta q\sin 2qL}{(n^2\beta^2+q^2)^2}\Bigg]\,.\end{aligned} \tag{16}$$

We can neglect the 2nd and 3rd terms as $L \gg 1/\beta$.

$$\langle|E-\langle E\rangle|^2\rangle = \frac{c^2M^2L}{\pi^2R^2}\frac{1}{\beta}\exp(-p^2h^2)\sum_{n=1}^{\infty}\frac{(p^2h^2)^n}{n\cdot n!}\frac{1}{1+q^2/n^2\beta^2} \tag{17}$$

The intensity corresponding to $\langle|E-\langle E\rangle|^2\rangle$ has a maximum at $q=0$ and distribute to a wide range of $q$, and may be called the $D$-comp.. The total intensity distribution of the light scattered from a fixed area are given by taking a proper constant $I_0$:

$$\langle I\rangle = \langle I\rangle_1 + \langle I\rangle_2 = \frac{\lambda^2}{16\pi^2}I_0 p^2\exp(-p^2h^2)\left[\frac{\sin^2 qL}{q^2L^2} + \frac{1}{L\beta}\sum_{n=1}^{\infty}\frac{(p^2h^2)^n}{n\cdot n!}\frac{1}{1+q^2/n^2\beta^2}\right] \tag{18}$$



① $\theta_c$, ② $\theta_c+5°$, ③ $\theta_c-5°$

Fig. 5. Goniophotometer curves.

The intensity given by (18) is that of the total flux of scattered light from a given area, and consequently the brightness $B$ is given dividing it by $\cos\theta$.

$$B = \langle I\rangle/\cos\theta\,. \tag{19}$$

If the eye or the photocell receives a reflected light beam covering an angular range from $\theta_1$ to $\theta_2$, the intensity measured is given by

$$\bar{I} = \int_{\theta_1}^{\theta_2}\langle I\rangle d\theta \tag{20}$$

or

$$\bar{B} = \int_{\theta_1}^{\theta_2}\frac{\langle I\rangle}{\cos\theta}d\theta\,. \tag{21}$$

## § 5. Comparison with Experiment

For the comparison of the experiment with the theory, we have to estimate the angular aperture of the light beam received. If the slit at the focal plane of the receiver lens has a width $d$, the light beam received has angular aperture $2\varepsilon$:

$$2\varepsilon = d/f \tag{22}$$

$f$ is the focal length of the lens.

Then the intensity measured at the specular direction is:

$$\bar{I} = 2\int_{\psi}^{\psi+\varepsilon}(\langle I\rangle_1 + \langle I\rangle_2)d\theta \tag{23}$$

$\varepsilon$ being considered small.

Since the width of the $R$-comp. is much smaller than $\varepsilon$, the 1st term of (23) can be approximated as follows:

$$dq = \frac{2\pi}{\lambda}\cos\psi\, d\theta$$

$$\frac{\lambda^2 I_0}{16\pi^2}\int_{\psi-\varepsilon}^{\psi+\varepsilon}p^2\exp(-p^2h^2)\left(\frac{\sin qL}{qL}\right)^2 d\theta$$

$$= \frac{\lambda^2}{16\pi^2}\frac{\lambda I_0}{\pi L\cos\psi}p_0^2\exp(-p_0^2h^2)$$

$$\times\int_0^{\infty}\left(\frac{\sin qL}{qL}\right)^2 d(qL)$$

$$= \frac{\lambda}{2L}\frac{I_0}{\cos\psi}\cos^2\psi\exp(-p_0^2h^2) \tag{24}$$

here $\qquad p_0 = 4\pi\cos\psi/\lambda\,.$ (25)

The 2nd term of $\langle I\rangle$, although has a maximum at $q=0$, is not so sharp as the 1st term and may be put constant in the range $\varepsilon$ as 1st approximation. We obtain the intensity corresponding to the $D$-comp., substituting the 2nd term of integral (23) by the value of $(\langle I\rangle)_{q=0}$ multipled by $2\varepsilon$ as 1st approximation.

i.e. $\quad \dfrac{\lambda^2}{16\pi^2}2\varepsilon I_0 p_0^2\exp(-p_0^2h^2)\dfrac{1}{L\beta}\displaystyle\sum_{n=1}^{\infty}\frac{(p_0h)^n}{n\cdot n!}\,.$

(26)

The total brightness $\bar{B}$ is:

$$\bar{B} = \frac{L_0\lambda}{2L}\left\{B_1 + \frac{4\varepsilon}{\beta\lambda}B_2\right\} \tag{27}$$

$$B_1 = \exp(-p_0^2h^2) \tag{28}$$

$$B_2 = \cos\psi\exp(-p_0^2h^2)\sum_{n=1}^{\infty}\frac{(p_0^2h^2)^n}{n\cdot n!} \tag{29}$$

$B_2$ can be expressed by the exponential integral $\overline{E_i}(\xi)$:

$$\overline{E}_i(\xi)=\sum_{n=1}^{\infty}\frac{\xi^n}{n\cdot n!}+C\xi\ . \qquad (30)$$

For small values of the argument, $\overline{E}_i(\xi)$ is given by tables* and for large values of the argument, it is given by an assymptotic series:

$$\overline{E}_i(\xi)=\frac{\exp(\xi)}{\xi}\left\{1+\frac{1}{\xi}+\frac{2!}{\xi^2}+\cdots\right\} \qquad (31)$$

$C$ is the Euler's constant and is 0.577.

If we take $2\varepsilon=40'$, i.e., 1/170 radian, and assume that $1/\beta=5\mu=10\lambda$ as a allowable value, we get the factor

$$\frac{4\varepsilon}{\lambda\beta}\doteq\frac{1}{4} \qquad (32)$$

Curves $B_1+\frac{1}{4}B_2$ are plotted for $h=\lambda/2$ and $\lambda/3.14$ in Fig. 6. It is seen that the curve is represented by bent straight lines, similar to that given by the experiment. The upper line corresponding to $B_1$ decreases rapidly with $\psi$ and the lower line corresponding to $B_2$ changes slowly in the region 1~0.1. Roughly speaking, it can be said that the bending point of these straight lines are the points where $B_1$ takes a negligible value or $\exp(-p_0^2h^2)$ takes value of the order 0.01, i.e.,

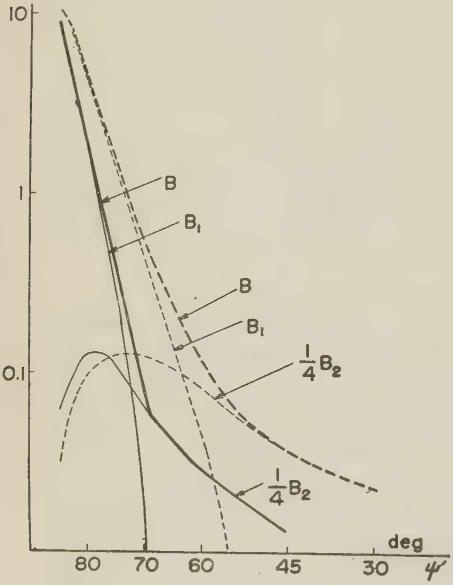


Fig. 6. Calculated curves of sheen.
full lines $h=\lambda/2$, dotted lines $h=\lambda/3.14$

$$p_0^2h^2=\left(\frac{4\pi h}{\lambda}\cos\psi\right)^2=4$$

or

$$\frac{2h}{\lambda}\cos\psi\doteq1/3\ . \qquad (33)$$

The relation (33) coinside with (1), which we have gotten experimentally for lapped steel samples. Such a perfect coinsidence may be accidental because we have made many assumption in the course of calculation.

The goniophotometer curves are given by plotting (18) as a function of $\theta$ of $\psi$ fixing $\psi$ or $\theta$. The $R$-comp. given by the 1st term exists in a very narrow region at the direction of $\theta=\psi$ only. When $\psi$ is smaller than the critical angle, the magnitude of the 1st term is smaller than the 2nd term as discussed by the preceding calculation. This is the case of our experiment.

The $D$-comp. of the experiment (Fig. 5) are given by the 2nd term of (18). The slope of lines takes any values as desired by the proper choice of the unknown constant $\beta$, so it will be meaningless to calculate the slope of each individual curve. If we assume a value 5~10 $\mu$ for $1/\beta$, the 2nd term reprents a curve close to that of the experiment. Thus qualitatively it may be said that the above theory agrees with the experiment.

## §. 6. Discussion

The $R$-comp. concern only with $P(z)$ and not with $\rho(r)$. The amplitude of the reflected light may be obtained as the Fourier transform of the probability density. If we assume some distribution $P'(z)$, differing a little to that of the Gaussian, and suppose the Fourier transform of it as $Q(p^2h^2)$, then we have to put $Q(p^2h^2)$ instead of the exponential term in the equation (11) for the $R$-comp.. While the charactor that the $R$-comp. decreases rapidly by the increase of $ph$ is reserved. This is the case of the most of the metal surfaces.

$D$-comp. are obtained taking into account the correlation of the distribution of the height of each point on the surface. The $1/\beta$ in (3) is a measure of the range where the correlation extend. The coefficient of $D$-comp. is smaller than that of $R$-comp. by the ratio $1/\beta:L$ as indicated by the result (18). If we assume the other correlation than (3), the expression of $B_2$ may change and it will be characterized by a constant other than $\beta$. If we indicate the range of the correlation in this case as $1/\beta'$, which is of the order of $1/\beta$ the coefficient of $B_2$ may be the order of $1/\beta L$ as expected from the physical meaning of the term.

---

* e.g. Jahnke and Emde, Tab. of Functions, p. 82 (1933).

Thus the appearence of sheen gloss (or *R*-comp) and the sharp bend of goniophotometer curve may be similar to that we have calculated. The critical angle is defined by the bending point. The numerical value in the equation (33) corresponding to the constant $k$ in the equation (1) may differ by the nature of the roughness or the nature of the surface.

Our calculation includes other basic assumption. We have assumed that no shadow effect is present, e.g. that the incident ray reach to every point of the surface being undisturbed by the neighbouring peaks and that the reflected ray does not strike the neighbouring surface. This may be the most common case of the scattering by metal surface as the roughness slopes of them are generally small. But for the case of grazing angle some error are expected from this factor. We have assumed also one directional correlation (3) for the surface. This may influence the numerical values given in the § 5.

## § 7. Conclusions

Experiments related with sheen gloss and a theoretical interpretation of them are given by the following results:

1) The reflected light from a rough metal surface consists of two parts, that is, the one named *R*-comp. which obeys the law of regular reflection and the other named *D*-comp. which constitutes the scattered light.

2) The intensity of the *R*-comp. is given by the probability density of the roughness only. If we assume that the distribution is Gaussian, the brightness of the *R*-comp. is given by

$$\exp\left\{-\frac{16\pi^2 h^2}{\lambda^2}\cos^2\psi\right\}.$$

The variation of intensity by the angle of incidence $\psi$ is much larger than that of Fresnel's coefficient.

3) The *R*-comp. appears only when the incident angle is larger than the critical angle $\theta_c$, and it is too weak to be observed when the incident angle is smaller than $\theta_c$. The relation between $\theta_c$ and the r.m.s. value of roughness $h$ is given by

$$2h\cos\theta_c=\lambda/k$$

where $k=2\sim3$ differing by the difference of material and by the method of machining of surfaces.

4) The appearence of the *R*-comp. is the cause of sheen gloss.

5) The *D*-comp. is due to the existance of the correlation of the height of two points on the surface. The intensity of *D*-comp. is given by the 2nd term of (18), assuming the statistics of the surface as given by the Ornstein-Uhlenbeck process.

# A Cloud Chamber Study of the Cosmic-Ray Hard Showers

By Saburo MIYAKE, Kensaku HINOTANI,
*Institute of Polytechnics, Osaka City University*
and Kan-ichi NUNOGAKI
*Faculty of Science, Osaka University*

(Received March 2, 1955)

Cosmic ray hard showers produced in iron and in lead have been studied by using the multiplate cloud chamber at 2740 m above sea level.

Primary energies of the meson producing showers were estimated from the angular and the momentum distributions of the secondaries by various methods and the results were compared with each other. The observed hard showers were classified according to their median angles.

About half of the showers which belong to the smaller median angle group may be interpreted as that they have been produced at the periphery of the Pb nuclei. They amount to about 20% of total hard showers.

The mean free path for the production of hard showers was obtained as $250\pm50$ gr/cm$^2$ in lead, and the mean free path of the charge exchange scattering of pions was $1.0\pm0.3$ Kg/cm$^2$ in lead for energies greater than 1 Bev.

## § 1. Introduction

The hard showers which are produced by nucleon-nucleus collision have been analysed assuming that the hard showers produced by nucleon-nucleus collision may not be much different from those produced by nucleon-nucleon collision[1]. This treatment, however, may not be appropriate for the energy of the interaction by which only a few mesons are produced, and it is expected that the difference of the character of the hard shower produced by the nucleon-nucleon collision and the nucleon-nucleus collision becomes bigger for the heavier nucleus.

In this paper, some evidences, which show that the above treatment is too simple to understand the hard shower, will be reported. Some of the experimental results will be discussed mentioning that some of the hard showers are plausibly interpreted as to be produced by elementary nucleon-nucleon collisions though they are produced in complex nuclei.

This experiment was performed in the cosmic ray observatory of the Osaka City University at Mt. Norikura (2740 meter elevation) from July to October in 1953.

## § 2. Experimental Arrangement

As shown in Fig. 1, a multiplate cloud chamber arranged beneath a high pressure cloud chamber[2] was used to observe the hard showers.

The hard shower, originated in the iron wall (8 cm thick) of the latter chamber or the iron ceiling (1 cm thick) of the former chamber, was named "Fe shower", and the one originated in five lead plates (1 cm thick) within the former chamber was named "Pb shower".

The cloud chamber was filled with 1.5 atm. argon, the illuminated region of the chamber was 30 cm × 50 cm × 20 cm, and the photographs were taken stereoscopically at an angle of 23° by two cameras.

The cloud chamber was triggered by a coincidence of G. M. counters which are described in the following;

| tray | diameter | length | numbers |
|---|---|---|---|
| **A** | 4 cm | 50 cm | 10 |
| **B** | 2 cm | 25 cm | 17 |
| **C** | 4 cm | 30 cm | 15 |
| **D** | 4 cm | 50 cm | 15 |

The coincidence of at least two G. M. counters in **B**, **C** and **D** and the anticoincidence of **A** was required for the triggering of the cloud chamber. The anticoincidence was to exclude air showers. The coincidence rate of this counter system was about 15/hr.

Each counter tray **B**, **C** and **D** was connected to hodoscope circuits and the hodoscope figures were used in order to check whether the tracks in the chamber were coincident tracks or not.

## § 3. Fe Shower

The Fe showers was defined as those showers which shows more than three tracks of penetrating particles. If a cascade shower originated from same point was seen clearly, it was counted as a penetrating particle.

380 of Fe showers were obtained and examined for the production of Pb showers by the shower particles of Fe shower. 97 of them were analysed in detail to present the following information on Fe showers.

### (A) Multiplicity and angular distribution

Fig. 2 shows the integral multiplicity distribution and the zenith angle distribution of charged secondary particles. The average multiplicity was 2.1±0.2 and the mean angle is 20 degrees. These values have to be corrected for the geometrical condition, as described in § 3 (D).

### (B) Properties of the secondary particles

The shower particles of 97 Fe showers which produce 44 nuclear interactions in lead plates are listed.

| | |
|---|---|
| charged | 30 |
| neutral | 11 |
| questionable | 3 |

This gives some information on the meson components of the secondaries. If the number of protons is equal to that of neutrons and events with neutral primaries are due to neutrons, and the nuclear interaction mean free path of nucleon and mesons are equal³⁾, the fraction of the charged meson component in the charged secondaries is given as follows,

$$\frac{\pi^{\pm}}{\text{charged secondaries}}=\frac{30-11}{30}=0.63\pm0.20.$$

It is possible to estimate that the number of neutral pions was 57 from the number of cascade showers. By combining this with the number of charged mesons estimated as 126 from the above fraction, we obtained;

$$\pi^0/\pi^{\pm}=0.45\pm0.15\ .$$

These results show that about 60% of charged secondaries were pions and the rest were protons⁴⁾, and that number of neutral pions was about half of charged ones.

The mean free path of these charged shower particles for nuclear interaction was estimated as 250±50 g/cm² in lead, by using the length of traversing lead plates and the number of the events. This value does not include nuclear scattering or small energy events which are not observed, and it will be seen that the cross section of the total nuclear interaction of the shower particle is not so different from the geometrical one.

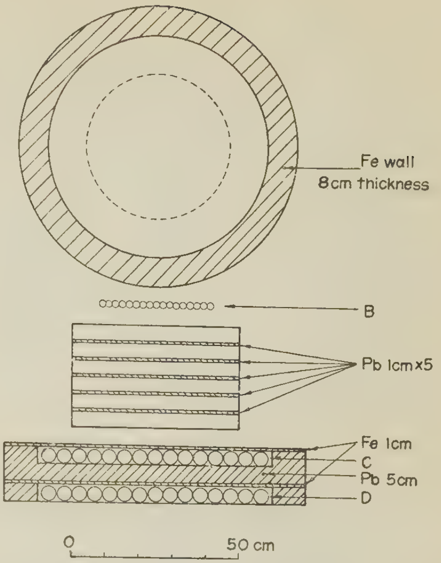

Fig. 1. Experimental arrangement for investigation of hard showers observed in normal pressure cloud chamber.

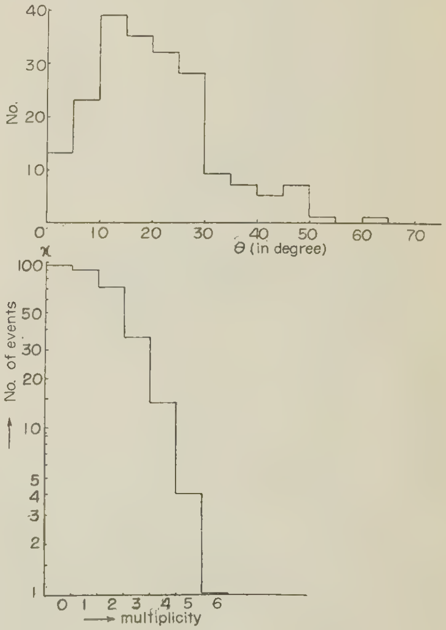

Fig. 2. Angular distribution of secondaries and integral multiplicity distribution of Fe showers.

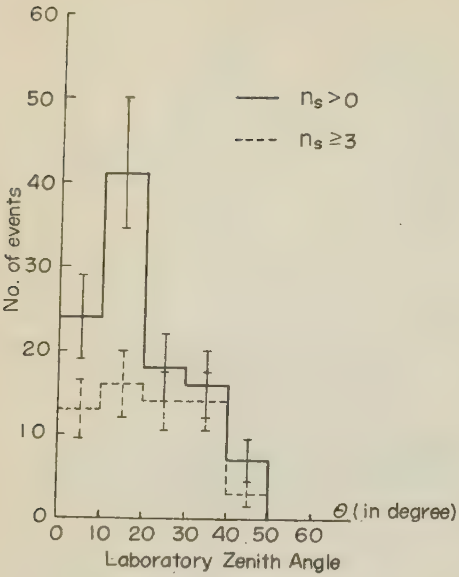

Fig. 3. Zenith angle distribution of the primary particles of Pb showers.

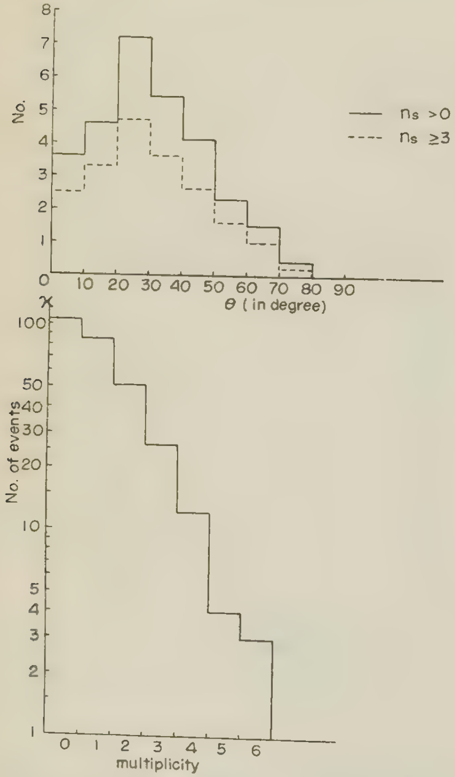

Fig. 4. Angular distribution of secondaries and integral multiplicity distribution of Pb showers.

(C) Energy distribution of the shower particles

Energy distribution was obtained by measuring the scattering in lead plates[5]. The result is shown in the following table. The shower particles were divided into two groups according to the mean zenith angle of the shower.

| group | | momentum range<br>below<br>500 Mev/c | <br>500 to<br>1000 Mev/c | <br>above<br>1 Bev/c |
|---|---|---|---|---|
| I | 0° to 20° | 20% | 30% | 50% |
| II | 20° to 30° | 33% | 44% | 23% |

(D) Estimation of the primary energy of Fe shower from the angular distribution

By the well known relation of nucleon nucleon collision[1]

$$\tan(\theta_{1/2})=1/\gamma$$

the primary energy was estimated by the median angle of the secondaries.

For group I, including showers with a median angle of below 20°, $\gamma_c$ was estimated as 5. But, it must be corrected for the particles which were missed. Assuming that the angular distribution of the shower secondaries is proportional to $\cos^n\theta$, the correction has been done and the corrected value of $\gamma_c$ was 4.3. Thus, it was estimated that the apparent average energy was 35 Bev for the primary energies of Fe showers.

## §4. Pb Shower

167 of Pb showers were produced by shower particles of 380 Fe showers. Definition of Pb shower is similar to one of Fe shower.

(A) Properties of the Pb shower primaries

The primaries of the Pb showers are consist of 120 charged and 47 neutral particles. The fraction of the meson component of the charged primaries was estimated as 0.60±0.07 from similar consideration described in § 3 B.

The zenith angle distribution of these primaries was shown in Fig. 3. These angles were real zenith angles using the stereoscopical measurement. In the case of neutral primary of Pb shower, the direction which connects the both origins of the Fe and Pb shower was used as the trace of the neutral shower particle if it was consistent with the axis of the secondary flux of Pb showers.

The events, in which the direction of the primaries was ambiguous, and the one which occurred in the border of the illuminated region or in the last Pb plate, were excluded and 107 events were used for the discussion which will be mentioned in later sections.

Table I.

| | Group | | | |
|---|---|---|---|---|
| | **I** | **II** | **III** | **IV** |
| Median angle | 0°~20° | 20°~30° | 30°~40° | >40° |
| No. of events | 17 | 37 | 33 | 20 |
| Average multipicity | 2.4<br>3.8 | 2.8<br>3.8 | 2.8<br>3.9 | 2.7 (total)<br>4.0 ($n_s \geqq 3$) |

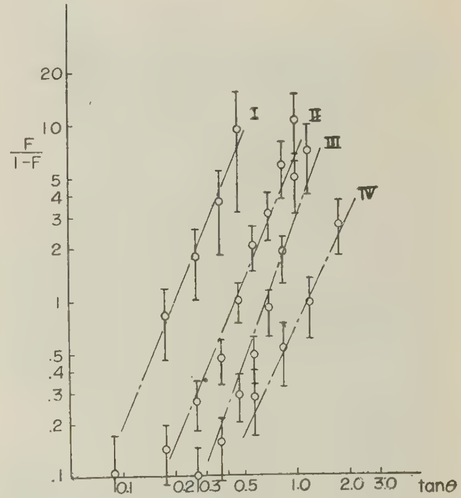

Fig. 5. F-plots for showers originating in Pb for each group.

(**B**) Multiplicity and angular distribution

The integral multiplicity distribution and the distribution of the angles between the incident particles and the charged secondaries are shown in Fig. 4. The angle was derived from each zenith and azimuthal angles by the formula of the spherical trigonometry.

The average multiplicity and the mean angle of the charged secondaries were 2.7±0.3 and 30.5°±1.5° respectively. The average projected angle between the incident and the secondaries was 20.5°±1.0°. From the comparison of the mean angle and the mean projected angle it is concluded that the observed charged secondaries were emitted uniformly in azimuthal angle.

The events, which have at least 3 secondaries, were classified in four groups by the median angle, namely, 0° to 20°, 20° to 30°, 30° to 40° and more than 40° respectively. The average primary energy of each group has been estimated in the following.

(**C**) Energy estimation of the showers from the angular distribution[1)]

Assuming the shower particles are emitted isotropically in c.m.s. and $\beta_c/\beta_\pi=1$, (where $\beta_c$ =velocity of c.m.s. and $\beta_\pi$=velocity of the secondary particle in c.m.s.) the following equation was obtained,

$$\tan^2\theta=\frac{F(\theta)}{\gamma_c^2(1-F(\theta))}\ . \qquad (1)$$

In this equation, $F(\theta)$ is the fraction of the particles emitted within the angle $\phi$ in c.m.s. and is given by $F=\sin^2(\phi/2)$ and $\gamma_c=1/(1-\beta_c^2)^{1/2}$. $\theta$ is the angle of emission in l.s. related to the angle $\phi$ by the following formula

$$\tan\theta=\tan(\phi/2)/\gamma_c\ . \qquad (2)$$

$F(\theta)$ for each group are plotted in Fig. 5. When the shower is not isotropic but is symmetry for the forward and the backward direction in the c.m.s., $\gamma_c$ is determined from $F=1/2$. The average apparent energies of the showers for each of these groups are estimated and listed in Table I. Geometrical correction has been done on the basis of assumption that the angular distribution is $\cos^n\theta$.

(**D**) Energy estimation of the shower by scattering measurement

Momenta of the secondary particles were measured using the multiple scattering by lead plates (11.3 g/cm² per one sheet) in the chamber, and those of each group were classified into several subgroups by their real

Table II. The $p\beta$ distribution of the shower particles from scattering measurement. (in Mev/c)

| Group | Emitted angle 0°~10° | 10°~20° | 20°~30° | 30°~40° | 40°~60° | >60° |
|---|---|---|---|---|---|---|
| I | 807 | 403 | 278 | | — | — |
| II | 550 | | 530 | 320 | 330 | |
| III | 755 | | 581 | 515 | 490 | 432 |

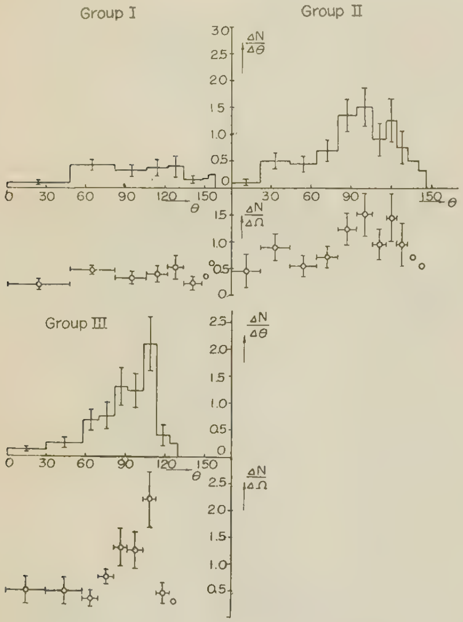

Fig. 6. Differential angular distribution of the secondary particles in the center of mass system for lead showers.

angles to the primary. In order to obtain the average $p\beta$ of each subgroup, the mean scattering angles of all tracks which belong to each subgroup were used, except the cases of wider scattering angles than 3 times of the mean value.

Assuming that the all secondaries are pions, the relation between momenta and angles gives the estimates of shower energies by two methods[6], 1) the shower particles are emitted with the uniform energy in c.m.s. and 2) the summation of the momenta of the charged secondary particles on the incident direction is equal to zero in c.m.s.

The results of the energy estimation in both cases are summarized in Table I, and the $p\beta$ distributions of the shower secondaries for each subgroups are given in Table II.

This analysis was carried out assuming nucleon-nucleon collision, but this is not appropriate because there are some indications of nucleon-nucleous collision accordingly the following inconsistencies arose.

**a**) a group of larger median angle has rather higher multiplicity, in spite of the estimated energy being lower,

**b**) as seen from the observed momenta of the secondaries, a group of larger median angle has not necessarily lower average energy,

**c**) when the energy is estimated from the median angle, the group **I** has much higher energy than that obtained by other estimations. (though one of the reason may be statistical fluctuation for grouping)

**d**) in $F$ plot, the slope of the curve for larger median angle group is not consistent with Eq. (1) which shows that the slope must be 2.

(**E**) Properties of Pb showers

1) Angular distribution of the secondaries in c.m.s.

Since the angular distribution of the secondaries in c.m.s. is not clear from $F$-plot, $\Delta N/\Delta\theta$ and $\Delta N/\Delta\Omega$, computed by equation (2), are plotted in Fig. 6.

From these figures, the following features are seen,

**a**) the distribution of the secondaries is not isotropic, but shows somewhat large value in perpendicular direction in c.m.s. to the incident. This tendency is clearly seen in the larger angle group.

**b**) in the smaller median angle group, the distribution seems to have two maxima.

As these features may be due to the successive collisions in the nucleus, the ratio of the frequency of the showers with slow particles to that without them has been figured out. The slow particles are observed as black tracks probably in same bias for each group. According to this result, the smaller median angle group has the larger ratio of the showers containing no slow particle, namely, 50% for group **I**, 25% for group **II**, 30% for group **III** and nearly zero for group **IV**.

2) Number of neutral pions

Measuring the ratio of high energy $\gamma$ rays to penetrating particles the relative number of $\pi^0$ and charged secondaries was estimated[4]. The results are given in Table I, but these ratio may be somewhat smaller by missing low energy $\gamma$ ray and one emitted in wide angle.

It can be seen that the proportion of $\pi^0$ decreases as the median angle increases. This would be also explained by considering that the protons due to successive collisions in lead nucleus may be contained[7].

## § 5. The Charge Exchange Scattering of Pions in Lead

Recently, several results of the experiments[3,8-12] for the charge exchange scattering at various energies were reported. High energy photons arising from the interaction of energetic pion with nuclei are mostly attributed to the charge exchange scattering of charged pions namely, $\pi^+ + N \rightarrow \pi^0 + P$ and $\pi^- + P \rightarrow \pi^0 + N$.

Fermi et al.[8,9] have shown that cross sections for the above processes are nearly equal at energy range 100–200 Mev, and the cross section for the only possible competing processes $\pi^- + P \rightarrow N + \gamma$, $\pi^+ + N \rightarrow P + \gamma$, has a magnitude of only 2% of the charge exchange. Therefore, the possibility that the photon arises from other mechanism was neglected in this case.

The charge exchange scattering events were picked up by the following conditions,

1) The shower particle of Fe shower has to penetrate at least two lead plates without multiplication and, then, start cascade showers.
2) the events must contain neither heavy track nor penetrating particle.

Some of the event, $\pi^+ + N \rightarrow P + \pi^0$ may be missed by the condition 2), but this condition is necessary to exclude the hard shower which may have this appearance.

The events selected by this procedure are also ascertained by studying the other 230 electron showers originated from lead plates in the chamber. The frequency of the electron showers of $\gamma$ ray or electron primary decreases strongly after passing through one sheet of the lead plate to about 15%, and

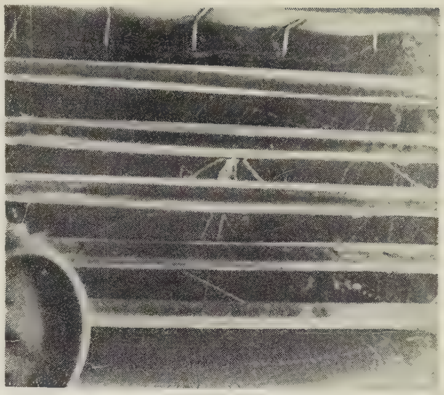

Fig. 7. An example of low energy Pb shower produced by neutron.

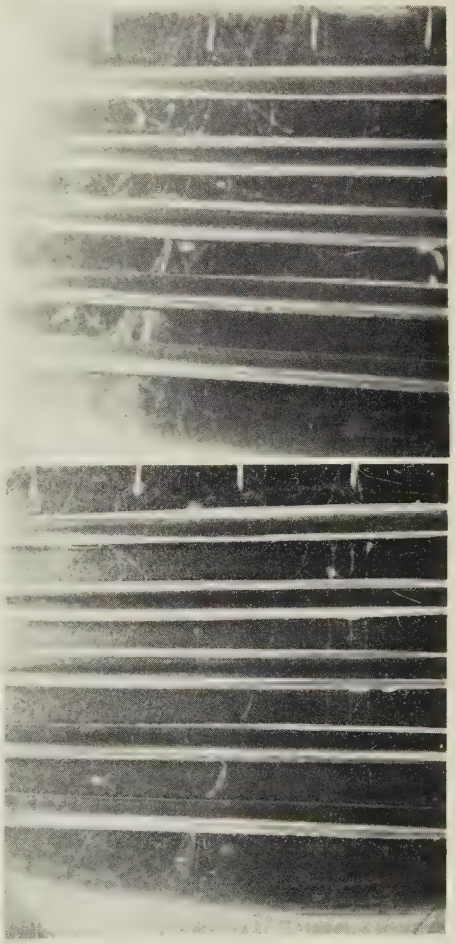

Fig. 8. Two examples of charge exchange scattering.

most of them are not accompanied by Fe shower of the same origin. Then it is possible to estimate the frequency of the charge exchange scattering of pions without contribution of electron initiated showers.

As the results, 10 probable events were observed. The energies of these events were estimated from the size of the cascade showers[13] and the angle of the two cores of the cascade showers, and all events have energies greater than 1 Bev.

As described in § 3, (**B**) and (**C**), pion component in charged secondaries is about 60 %, and about 50% of them have momentum greater than 1 Bev/c. It is concluded that the mean free path of pions of this energy range for the event is 1.0±0.3 Kg/cm².

Lock and Yekutiele[10] have given a large charge exchange cross section (30% geometric) for 160 Mev mesons in nuclear emulsion, and G. Salvini has estimated the cross section for complex nucleus as follows

$$0.16\sigma_{\text{total}} \leqslant \sigma_{\text{ch.ex.}} \leqslant (0.31\pm0.1)\sigma_{\text{total}}$$

for energies 200–1000 Mev. The ratio 0.25 of this event to nuclear interaction, obtained in this experiment, is somewhat lower as compared with these results, although it is contained in this region. It may be explained by considering that the contribution of the hard shower is not so small in this energy region (>1 Bev).

## § 6. Discussion

Since the hard showers, observed in this experiment, were treated as meson producing interaction by the single collision, it is unavoidable that some inconsistencies have resulted. As described in § 4 (**D**), it is not plausible that the high energy hard showers have low multiplicity, even if the energy dependency of the multiplicity is not so strong[14].

It may be plausible to suppose that about half of the events which belong to the groups of smaller median angle were produced by collisions at the periphery of the nucleus. This supposition can be ascertained by the angular distribution of the secondaries and the ratio of the neutral pions to the charged one, described in § 4, (**E**), Most of the showers which belong to the larger angle group are supposed to be nearly head-on collision between the incident particle and the target nucleus. By the successive collisions in the nucleus, it would be expected that the several angular distributions are superposed and the resultant distribution has somewhat large value in perpendicular direction to the incident and the contribution of the recoil protons is also large.

This interpretation shows that the classification of the hard showers in heavy nucleus by apparent median angle is not good enough to classify the energies of the showers in this energy region, but rather proves the aspects of the collisions, without the problem of the fluctuations of the secondary particles.

On the mean free path of the charge exchange scattering, it should be considered that the high energy pion collides with the almost free nucleon at the periphery of lead nucleus, because if such high energy pion collides nearly head-on to the lead nucleus, it will be observed as hard shower.

Under these consideration, it may be concluded that the cross section of the charge exchange scattering in the case of $\pi$-nucleon interaction at this energy region is nearly comparable to that of hard showers, and the probability for single collision is about 20% of the total events in lead.

## § 7. Acknowledgement

The authors are indebted to Professor Y. Watase for his valuable advice and encouragement and express their thanks to Mr. T. Shiota lor his financial support for this work. Thanks are also due to Mr. T. Matano for his invaluable aid during the observation.

# Short Notes

J. PHYS. SOC. JAPAN **11** (1956) 83~84

## On the Impurity Conduction in Germanium

By Yasuo KANAI and Riro NII

*The Electrical Communication Laboratory,*
*Nippon Telegraph and Telephone Public*
*Corporation, Tokyo, Japan*

(Received September 26, 1955)

Recently Hung and Gliessmann1) observed an anomalous behaviour of the Hall coefficient in the course of the investigation of the electrical properties of germanium at very low temperatures. They found that, when the temperature was lowered, the Hall coefficient did not increase infinitely but once reached a maximum value and then began to decrease. Further investigations by them2) and Fritzsche and Lark-Horovitz3) showed that the anomaly of the Hall coefficient was well explained by assuming the existence of the impurity conduction at very low temperatures. In their experiments the impurity is the ordinary donor or acceptor, and the energy difference of the donor or acceptor level from the conduction or valence band is so small that the impurity conduction is observed only at very low (i.e. liquid helium) temperatures. If the other impurity, the level of which lies apart from the bottom of the conduction band or the top of the valence band, is added to germanium, it may be expected that the impurity conduction will occur at higher temperatures.

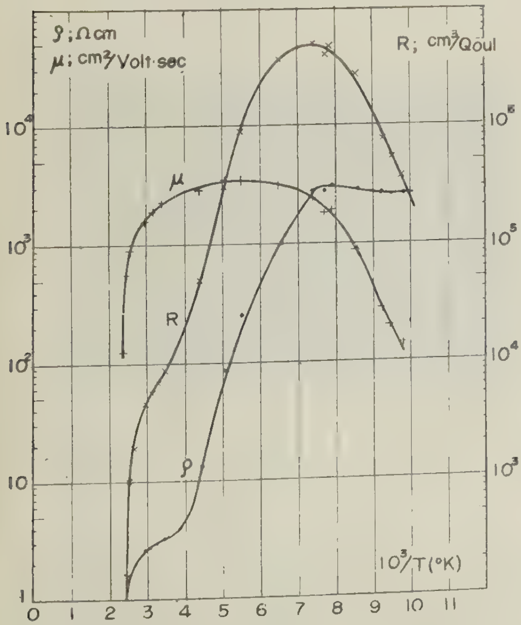

Fig. 1. The resistivity ($\rho$), Hall coefficient ($R$), and Hall mobility ($\mu=R/\rho$) as a function of the inverse absolute temperature. The sample is a nickel-doped $p$-type germanium.

Germanium samples in which nickel4) was added as such impurity have been prepared, and their electrical properties were measured from room temperature to liquid air temperature. The uniformity5) of the samples was checked and the effects of carrier multiplication by the photon or avalanche breakdown were carefully avoided. A typical example of the experimental results on $p$-type sample is shown in Fig. 1, and it shows that the decrease of the Hall coefficient at low temperature occurs. Although the mechanism of the so-called impurity conduction is not clear at present, we shall analyse our data by the conventional method. If we assume that the carrier in the impurity band is hole in this sample, then the conductivity $\sigma$ and the Hall coefficient $R$ are given by the next fourmula;

$$\sigma=e(n_v\mu_v+n_i\mu_i)$$

$$R=e(r_vn_v\mu_v^2+r_in_i\mu_i^2)/(n_vu_v+n_i\mu_i)^2$$

where

$e$; the absolute value of the electronic charge.
$n_i$, $\mu_i$; the density and mobility of the hole in the impurity band.
$n_v$, $\mu_v$; the density and mobility of the hole in the valence band.
$r$; numerical factor which depends upon the statistics and the scattering mechanism of the carrier.

In our experiment, holes in the valence band are scattered mainly by the impurity ions, so $r_v$ is approximately 1.9. But information about $r_i$ is quite insufficient, hence we assume, for simplicity, that $r_v=r_i=1$. Furthermore, if we consider the fact that $n_v+n_i=N$ ($N$; the hole density in the impurity band at 0°K.), then, after simple calculations, the maximum value of $R$ occurs at the condition $n_i\mu_i = n_v\mu_v$, and at this temperature the following simple relations are hold;

$$2R_m\sigma_m = \mu_i + \mu_v \doteqdot \mu_v$$
$$R_mR_S\sigma_m^2 = \mu_i\mu_v$$
$$3.1\times10^{18}\cdot\sigma_m/\mu_i = n_i$$
$$n_i\mu_i/\mu_v = n_v$$

where

$\sigma_m$; the value of the conductivity at which the Hall coefficient has the maximum value $R_m$.

$R_S$; the saturation value of the Hall coefficient at high temperature.

and the units of $\sigma$, $R$, $\mu$ and $n$ are mho/cm., cm³/coulomb, cm²/volt.sec. and no./c.c. respectively.

For example, if we analyse our experimental data by the above formula, the following results are obtained.

$\mu_v \doteqdot 3\times10^3$ cm²/volt.sec.
$\mu_i \doteqdot 1$ cm²/volt.sec.
$n_i \doteqdot 1\times10^{15}$/c.c. at −140°C.
$n_v \doteqdot 3\times10^{11}$/c.c.

Further systematic investigations are now in progress.

# Pure Quadrupole Spectra of Phosphonitrile Chloride Polymers

By Kazuo Torizuka

*Tokyo Gakugei University, Koganei, Tokyo, Japan*

(Received September 30, 1955)

Nuclear quadrupole resonances of two phosphonitrile chloride polymers, $(PNCl_2)_3$ and $(PNCl_2)_4$, have been measured by the method of frequency modulated super-regenerative detector at room temperature. Crystals of about 2 gram were used as samples. The measured resonance frequencies of $Cl^{35}$ are listed in table I. Among them the resonances of $(PNCl_2)_3$ are doublets. The seperations are about 80 kc/sec for the resonance of 27.87 mc/sec and about 75 kc/sec for the resonance of 27.58 mc/sec. The resonance absorptions of $Cl^{37}$ were also observed at the frequencies expected from the known ratio of the quadrupole moments.1)

Table I. Resonance frequencies of $Cl^{35}$ at 294°K.

| Compound | Frequency |
|---|---|
|  | mc/sec<br>27.80<br>27.58 |
|  | mc/sec<br>28.14<br>28.02 |

The crystal structure of $(PNCl_2)_4$ has been investigated by Ketelaar and de Vries.2) Their results show that this compound has octagonal type ring structure and for P-Cl distances the two different values of 1.975 A and 2.015 A are given. The above obtained two quadrupole resonance frequencies of this compound will correspond to the two P-Cl distances.

The molecular structure of $(PNCl_2)_3$ has been studied by Brockway and Bright.3) Their results show that this compound has planer benzene-like ring structure and all P–Cl distances have equal value of 1.97 A. However, the quadrupole resonance of this compound has two frequencies and their seperations is larger than in $(PNCl_2)_4$. This suggests that there are two different P–Cl distances in this crystal.

The average value of the two resonance frequencies of $(PNCl_2)_4$ is near the average frequency of $OPCl_3$ quadrupole resonances4) considering the temperature dependence of resonance frequency and P–Cl distances of 1.99 A in $OPCl_3$ is almost equal to the average of the two P–Cl distances in $(PNCl_2)_4$. Also the bond angle Cl–P–Cl is 103.6° in $OPCl_3$5) and 105°30′ in $(PNCl_2)_4$.

Comparing the two average values of the resonance frequencies of $(PNCl_2)_3$ and $(PNCl_2)_4$, the lower value of former compound corresponds the shorter P–Cl distances in the former, and the difference between them is perhaps due to the difference of their ring structures.

The auther expresses his sincere thanks for preparing the sample crystals to Mr. S. Fujii at Tokyo Institute of Technology and to Mr. H. Hamano for his helpfull discussions.

## Sub-microwave Absorptions in Potassium Bromate

By Yasaburo YOKOZAWA and Itaru TATSUZAKI

*Research Institute of Applied Electricity, Hokkaido University, Sapporo*

(Received October 18, 1955)

We have found many absorption lines in potassium bromate powder by the use of a super-regenerative detector with a transmission line tuned circuit in the frequency range of 120 Mc/s to 270 Mc/s.

The absorption appears weakly at the dry ice temperature and very strongly at the liquid nitrogen temperature. At room temperature such absorptions do not appear. For precise frequency measurement, the autodyne detector is used to exclude the beat frequencies acompanied inherently with the super-regenerative detector. The spectra consist of a great number of lines, the intervals of which vary from about 30 Kc/s to 40 Kc/s at the liquid nitrogen temperature, and the widths of these lines are very sharp as seen in Fig. 1. By lowering temperature these lines shift toward the higher frequency side.

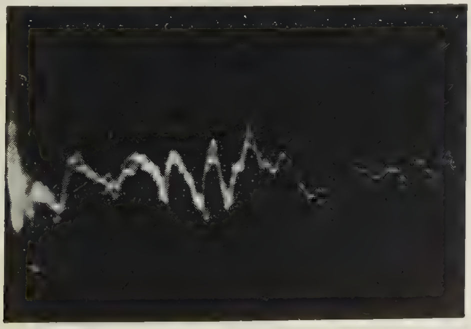

Fig. 1. Pattern for the absorption lines of potassium bromate powder using the autodyne detector. The frequency was swept from the left to the right between 180.21 Mc/s and 179.78 Mc/s.

The potassium bromate is a piezoelectric substance. The similar results were obtained for silver iodine, rochelle salt, zinc sulphide and quartz by S. Kojima and co-researchers1)2) and for levo-chloramphenical by J. Duchesne and A. Monfils3).

The origin of these spectra was considered due to the lattice imperfection by S. Kojima. On the other hand J. Duchesnse and A. Monfils attributed its origin to the lattice vibration in the crystal. However, as pointed above, we could not detect any absorption at room temperature. Furthermore, in spite of quenching at the room temperature after the sample had been heated to 170°C, it showed no absorption at room temperature.

Although there are some new features in potassium bromate different from that of the substances studied by other researchers, the absorption lines seem to be caused by the lattice imperfection as well as the lattice vibration.

In order to clarify the origin of the absorption, further experiments are now planned in broader frequency range.

## An Analysis of Two τ-Meson Decays

By Kuni IMAEDA and Mitsuko KAZUNO

*Department of Physics, Faculty of Liberal Arts and Education, Yamanashi University*

(Received August 15, 1955. Revised October 12, 1955)

In the course of the general scanning of Ilford G5 emulsion 600 microns thick exposed at the altitude of 70,000 ft about four hours in England 1954, we have observed two τ-mesons decaying in the emulsion.

τ–1 had the track length of 33.7 mm in 32 emulsion sheets and decayed into three particles. One of the three secondaries showed a typical π-μ-e decay after a total track length of 8.6 mm in 5 emulsion sheets. The track was produced by a positive π-meson. Another secondary left the emulsion stack, after the track length of 9.0 mm

Table I. For $\tau$-1, the energies of the $\pi$-2 and the $\pi$-3 are obtained by the calculation using the observed values of the energy of the $\pi$-1 meson, the angles between $\pi$-1, $\pi$-2 and $\pi$-3 and the momentum balance assuming that $\pi$-2 and $\pi$-3 tracks are produced by $\pi$-mesons.

$R_0$: Observed range in the emulsion.
$R_p$: Range corresponding to the path length in paper.
$N$: Number of the emulsion sheets.

* $\theta$, $\phi$ is the spherical polar coordinates of the direction of emission of the $\tau$-meson from the parent star or the incident direction of the $\tau$-meson onto the emulsion stack, where in the polar coordinate system $x$ and $y$ axis are taken the direction of emission of the negative $\pi$-meson and the direction of the normal to the $3\pi$-decay plane, respectively.

in 9 emulsion sheets. The length was enough to decide from the grain density and the scattering that the track was produced by a L-meson.

The third secondary could be followed 3.3 mm in 5 emulsion sheets, but the track was missed at the entrance of the adjoint emulsion sheet.

$\tau$-2 was in a better geometrical configuration than $\tau$-1. (See Fig. I.) It came from the star of type $5+1n$ and had the track length of 40.0 mm in 8 emulsion sheets. All the decay products were stopped in the emulsion stack and it was assured that $\tau$-2 was a positive $\tau$-meson. One of the three secondaries showed a typical $\pi$-$\mu$-e decay after a total track length of 3.51 mm in the same emulsion sheet in which the $\tau$-decay occurred. Another secondary produced a two pronged $\sigma$-star after a total track length of 5.97 mm in 5 emulsion sheets. It was decided that the secondary was a negative $\pi$-meson. One of the two prongs of the star was produced by an $\alpha$-particle of the energy of 17 Mev, and the other of the prongs was produced by a slow electron. It is concluded that the star was the disintegration produced by the absorption of a negative $\pi$-meson by a nucleus in the emulsion. The third secondary showed a typical $\pi$-$\mu$-e decay after a total track length of 27.0 mm in 20 emulsion sheets. All track length measurements in the emulsion plane were made using the Olympus' Ramsden ocular micrometer which was able to measure a length of 1/100 mm in the field of the microscope.

The shrinkage factor was checked by the measurement of the length of the tracks of the $\mu$-mesons of $\pi$–$\mu$–e decay which were nearly vertical to the emulsion plane. The stopping power of the emulsion at the time of the exposure was obtained from the mean track length $\bar{R}_\mu$ of nine flat $\mu$-meson tracks of $\pi$–$\mu$–e decays. The calibration of the range-energy relation was made as follows: we calculated the range of the $\mu$-meson of the energy of 4.12 Mev, by the following range-energy relation,

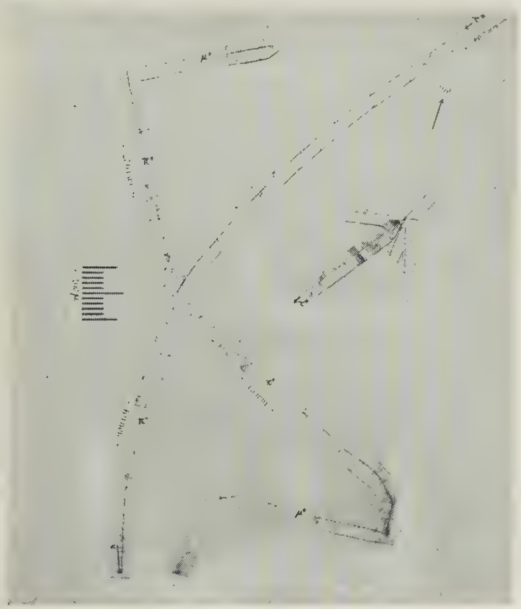

Fig. 1. Microphotograph of the $\tau$–2.

$$4.12\,\mathrm{Mev}=0.276(M_\mu/M_n)^{0\cdot432}(R)^{0\cdot568}\ ,$$

where $M_\mu/M_n=207/1837$ is the ratio of the mass of $\mu$-meson to that of nucleon, and then we have decide the numerical factor $f$ from the mean length $\bar{R}_\mu=590\pm10$ microns of the nine flat $\mu$-meson tracks by the following relation:

$$\bar{R}=fR_\mu\ .$$

The energy of the $\pi$-mesons were calculated using the following range-energy relations according to their length of the $\pi$-meson tracks:

(1) for $fR=0\sim6(M_\pi/M_n)$ mm,
$$E\text{–}1=0.276(M_\pi/M_n)^{0\cdot432}(fR)^{0\cdot568},$$
(2) for $fR=50\sim250(M_\pi/M_n)$ mm,
$$E\text{–}2=0.1605(M_\pi/M_n)^{0\cdot382}(fR)^{0\cdot618},$$
(3) for $fR=6\sim250(M_\pi/M_n)$ mm,
$$E\text{–}3=0.2303(M_\pi/M_n)^{0\cdot411}(fR)^{0\cdot589},$$

where $R$ is the observed length of the $\pi$-meson track, and took the mean of $E$–1 and $E$–3 or $E$–2 and $E$–3.

The results obtained are shown in the following tables:

In the Tables I and II, ( )* are the values obtained from without taking into consideration of the stopping power of the thin sheets of tissue paper between the emulsion sheets[2].

The $Q$-values obtained for $\tau$–1 and $\tau$–2 show rather a good agreement with the values obtained in the other laboratories[1]. The values of $p/\sin(\pi,\pi)$ in the Table II are not in good agreement, but agree within the experimental errors of the energies and the angles.

The authors are grateful to Professor C. F. Powell, Dr. Y. Fujimoto and Professor S. Nakagawa for the supply of the emulsion plates. They are also thanks to the emulsion group of Rikkyō University, who gave us the facility for the measurements, and Mr. T. Ogata, the assistance for the microphotograph and Assistant Professor H. Mōri the constant interest in this work.

This experiment was supported by the Scientific Research Expenditure of Ministry of Education.

# On the Image of Phase Microscope in Metastable Region

By Shigenori Nawata

*Research Institute for Scientific Measurements, Tōhoku University, Sendai*

(Received November 18, 1955)

Intensity distribution of the image of the phase microscope was calculated. Let $\chi=\beta\exp(-i\varphi)$ for $-a<x_0<0$ and $\chi=\alpha\exp(i\varphi)$ for $0<x_0<a$ as the object and $h\exp(i\delta)$ for the coated function of phase strip, complex amplitude in the neighbourhood $x_0=0$ (metastable region) is given by

$$F=\frac{(\alpha+\beta)}{2}h\cos\delta\cos\varphi-\frac{(\alpha-\beta)}{2}h\sin\delta\sin\varphi$$
$$-\frac{Si(\theta_2)}{\pi}\Big[(\alpha-\beta)\cos\varphi-h\{\alpha\cos(\varphi+\delta)$$
$$-\beta\cos(\varphi-\delta)\}\Big]\pm\frac{(\alpha-\beta)}{2}\cos\varphi$$
$$+i\Big[\Big[\frac{(\alpha-\beta)}{2}h\cos\delta\sin\varphi+\frac{(\alpha+\beta)}{2}h\sin\delta\cos\varphi$$

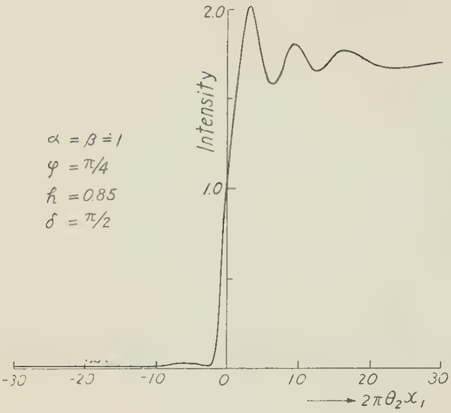

Fig. 1.

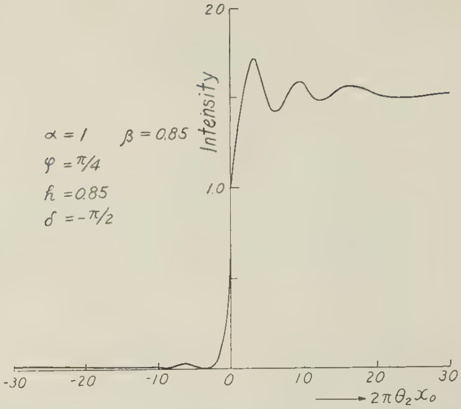

Fig. 2.

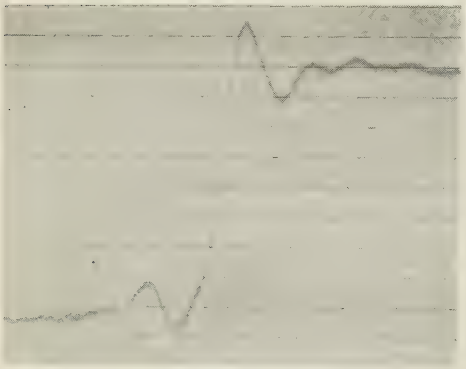

Photo. 1.

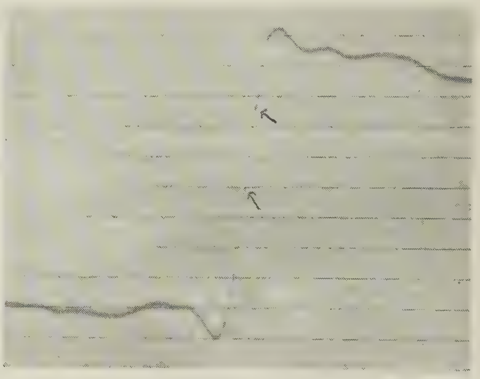

Photo. 2.

$$-\frac{Si(\theta_2)}{\pi}\Big[(\alpha+\beta)\sin\varphi-h\{\alpha\sin(\varphi+\delta)$$

$$+\beta\sin(\varphi-\delta)\}\Big]\pm\frac{(\alpha+\beta)}{2}\sin\varphi\Big]\Big],$$

where $$Si(\theta_2)\equiv\int_0^{2\pi\theta 2x_0}\sin\mu/\mu d\mu\ .$$

In this calculation, the geometrical image of the point of the light source under consideration (hereafter, refered as pinpoint) is formed on the line of center of the phase strip and the diffraction patten about this point crosses the edges of the phase strip at $\pm\theta_2$ (the direction cosines of the diffracted wave normal at the edges of the phase strip). Intensity distribution is given by $FF^*$. When $\alpha=\beta=1$ the results are the same as that of the phase annulus[1].

The author is especially interested in the continuity of the intensity at $x_0=0$, which were concluded from above equation as follows:

i) when $h=0$, the curve is continuous independent of the absorption of the object $\alpha$, $\beta$ and also $\varphi$,

ii) when $\varphi=\pm\pi/2$, the curve is continuous independent of $\alpha, \beta$ and also independent of the $h$, $\delta$ of the phase strip,

iii) when $h\doteqdot 0$, $\varphi=\pm\pi/2$, and moreover

   (1) if $\alpha=\beta$, the curve is continuous only in the case of $\delta=\pm\pi$,

   (2) if $\alpha\doteqdot\beta$, the curve is usually discontinuous.

Now if, point corresponds to the pinpoint in the phase strip is not coated, that is $h=1$, it causes the change of the brightness of back ground of the image. In this case, the first and second terms of real and imaginary parts of the equation change their form, which give the conclusion as follows:

i) when $\alpha=\beta$, the curve is usually continuous at $x_0=0$ independent of $\varphi, h$ and $\delta$ of phase strip except pinpoint,

ii) when $\alpha\doteqdot\beta$, the curve is always discontinuous independent of $\varphi$, $h$, $\delta$.

Some examples calculated are shown in Fig. 1, and 2 together with the results of experiments shown in Photo. 1 and 2. In Photo. 2, the discontinuities which were not observed in Photo. 1 can be seen as are indicated by arrows. Details will be given in the paper which will be published soon in Sci. Rep. Res. Insts. Tōhoku Univ. A. Vol. 8, No. 1, 1956.

# The Measurement of the Galvanomagnetic Tensors of Bismuth

By Toshihiro Okada

*Department of Physics, Faculty of Science, Kyushu University, Fukuoka*

(Received October 10, 1955)

According to the phenomenological theory, the galvanomagnetic effect of a single crystal could be expressed by the following tensor-equation¹⁾:

$$E_i=\rho_{ij}I_j+\rho_{ij,mn}I_jH_mH_n+\cdots$$
$$+\varepsilon_{ijk}I_j(R_{k,m}H_m+R_{k,mno}H_mH_nH_o+\cdots)\ ,$$

where $E_i$ $(i=1,2,3)$ are the components of the electric field which is applied to the crystal, $I_j$ $(j=1,2,3)$ the components of the electric current flowing through the crystal, $H_m$, $H_n$, $H_o$ $(m,n,o=1,2,3)$ the components of the applied magnetic field, and $\varepsilon_{ijk}$ is a tensor of the third rank which is equal to zero when $i=j$ or $k$, or $j=k$, but equal to 1 when $ijk=123$, 231 or 312, and equal to $-1$ when $ijk=213$, 321 or 132.

For bismuth crystal, which has the symmetry $D_{3d}{}^5=R\bar{3}m$, the non-zero components of the resistivity tensor are

$$\rho_{11}\quad\text{and}\quad\rho_{33}\ ,$$

if the binary axis is taken as the first axis and the principal axis as the third axis, and also the non-zero components of the magneto-resistance tensor are²⁾,³⁾,⁴⁾

$$\rho_{11,11}=\rho_{22,22},\ \ \rho_{11,22}=\rho_{22,11},\ \ \rho_{11,33}=\rho_{22,33},$$
$$\rho_{33,11}=\rho_{33,22},\ \ \rho_{33,33},$$
$$\rho_{11,23}=\rho_{12,13}=-\rho_{22,23},\ \ \rho_{23,11}=\rho_{13,12}=-\rho_{23,22},$$
$$\rho_{23,23}=\rho_{13,13},\ \text{and}\ \rho_{12,12}=\tfrac{1}{2}(\rho_{11,11}-\rho_{11,22})\ ,$$

and those of the Hall teosor are²⁾,³⁾

$$R_{1,1}\quad\text{and}\quad R_{3,3}\ ,$$

and those of the higher order Hall tensor (the third order galvanomagnetic effect) are⁴⁾

$$R_{1,111}=R_{2,222}=3R_{1,122}=3R_{2,112},$$
$$R=_{1,123}=R_{2,113}=-R_{2,223},$$
$$R_{1,133}=R_{2,233},\ \ R_{3,112}=-R_{3,222},\ \ R_{3,113}=R_{3,223},$$
$$\text{and}\ R_{3,333}.$$

As for a single crystal of pure bismuth, the writer carried out the measurement of the above given tensor components for the temperature range $-160°\sim+45°$C by the method described in the previous paper⁴⁾. Results are shown in the following table.

The detail of this research will be published in near future.

Table I.

# Change of Photocurrent of CdS Single Crystal in a Magnetic Field

By Shōji TANAKA, Taizō MASUMI
and Sigeru IIJIMA

*Department of Applied Physics,*
*University of Tokyo, Tokyo, Japan*

(Received November 19, 1955)

The photoelectromagnetic effects in semiconductors have been investigated recently.[1)-5)]. These effects are closely related to the surface properties of semiconductors.

The experiments reported here concern the changes of photocurrents of CdS single crystals in magnetic fields, and the obtained results seem to be different from the other effects which may be expected in the ordinary galvanomagnetic effects.

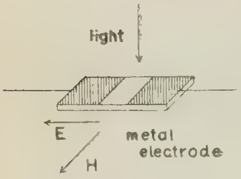

Fig. 1 (a).

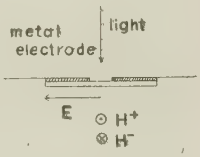

Fig. 1 (b).

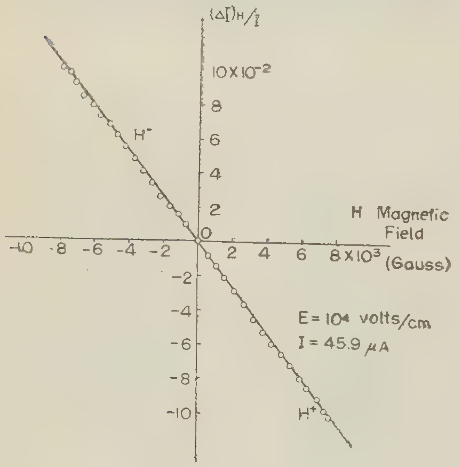

Fig. 2.

With application of magnetic field, the photocurrents of CdS single crystals increase or decrease according to the directions of the field. The experimental arrangement is shown in Fig. 1 schematically.

The specimens are thin flakes of CdS single crystals which were prepared by the Frerichs' method.[6)] The samples are illuminated on one face by the light. The applied electric and magnetic fields are parallel to this face and perpendicular to each other. The low potential end of the sample is connected to ground through a low impedance resistor, the voltage across which was measured with the differential amplifier. The distance of the metal electrodes is 0.2 mm and the applied voltage between them is 200 volts at most. For illumination, the monochromatic blue light (436 m$\mu$ in wavelength) and green light (548 m$\mu$ in wavelength) are used, the former lies in the strong absorption region and the latter in the long wavelength tail of the absorption edge.

The changes of the photocurrents induced by the illumination of the blue light with magnetic fields increase or decrease proportional to the strength of the magnetic field $H$ as shown in Fig. 2.

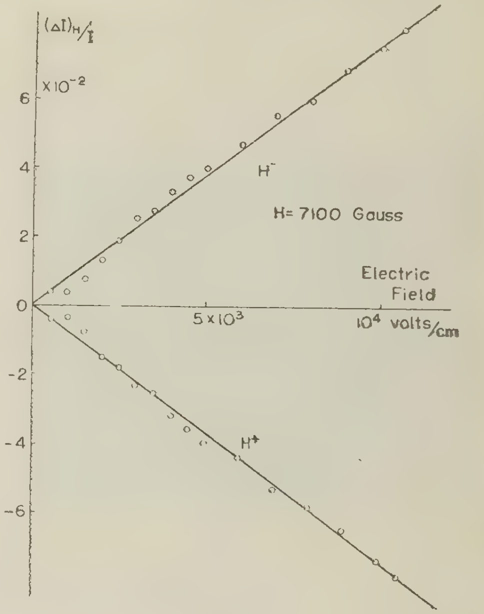

Fig. 3.

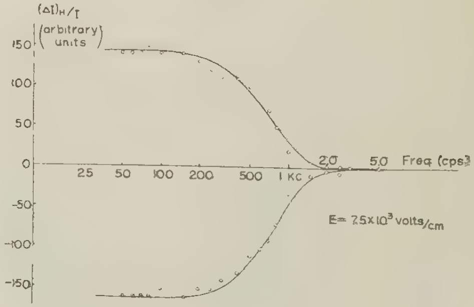

under the illumination of the blue light
Fig. 4.

In this figure, $I$ is the photocurrent in the absence of the magnetic field, while $(\Delta I)_H$ is its change due to the application of the magnetic field, and the positive direction of the magnetic field $H$ is such that the flowing current carriers in the crystal are deflected towards the illuminated surface.

Under a constant magnetic field, the absolute value of the ratio $(\Delta I)_H/I$ increases linearly with the applied electric field $E$ in both directions of the magnetic field (Fig. 3), and when the direction of the electric field is reversed, the reversal sign of $(\Delta I)_H/I$ is also observed. That is, for our observations the following expression may be probable,

$$(\Delta I)_H/I=\pm C\cdot EH \qquad (1)$$

where $C$ is a constant, independent of the intensity of illumination in the range of the present experiments in which the photocurrent is at most 70 $\mu$A with the electric field of about 8000 volts/cm.

These effects, however, have considerable fluctuations from sample to sample, and these fluctuations might be caused by some sensitive properties which are included in the constant $C$ in the Eq. (1).

When the sample is illuminated by the green light, general features of the results are similiar to the case of the blue light, while the value $(\Delta I)_H/I$ is smaller by a factor of ten although the photocurrent is the same order in both cases.

The experiments above mentioned are the static case. The further experiments in which the alternating electric field and the static magnetic field are used indicate that the relaxation effects are observed under relatively low frequencies. In the present experiments the alternating electric fields are sinusoidal and their amplitudes are kept at a constant value over the frequency range from 25 cps to 5 kc/s.

The measurements of the changes of the alternating photocurrents are made by reading the change of the positive peak voltage across the connecting resistor.

A typical example of the experimental results illustrated in Fig. 4 indicates that the relaxation effects appear even below 300 cps and in the frequency range above 2 kc/s the effects of the static magnetic fields are not observed, while the photocurrent is nearly independent of the frequency of the electric fields.

It might be considered that the behaviour of the excited current carriers near the illuminated surface of CdS single crystals contributes to these phenomena as the internal behaviours of the carriers, i.e. the surface recombination of excited carriers discussed by R. H. Bube[7] in CdS or the decrease of the effective carrier mobility in the space charge layer discussed by J. R. Schrieffer[8] in Germanium.

# On the Transition Temperatures of Superlatties $Au_3Cu$ and $AuCu_3$

By M. SHIMOJI

*Dept. of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Japan*

(Received October 7, 1955)

It is interesting that solid alloys $Au_3Cu$ and $AuCu_3$ have different transition temperatures of order-disorder[1], while the usual theory predicts the same transition temperatures for them. This discrepancy is evidently related to the simplicity of the theoretical model for the system, just as described in Guggenheim's text book. In the usual statistical theory of order-disorder the atomic structure of the system is quite ignored in the view of taking into account only combinatory factor and the concentration-independent interaction energy between a pair of the binary components, i.e., ($W_s$ = const.) Accordingly, theory must be improved by the reexamination of the model. Of course, the difference of electronic structure of the alloys should give the asymmetric behaviour.

However, another improvement is presented here. This is based upon the fact that the atoms of Au and Cu have different atomic sizes respectively. The molar volume of the gold-copper alloys is given by

$$V_m=x_{Cu}v_{Cu}+x_{Au}v_{Au}\,, \qquad (1)$$

where $x_{Cu}$ and $x_{Au}$ are the mole fractions of Cu and Au, $v_{Cu}$ and $v_{Au}$ are the molar volumes of pure components respectively. On the other hand, the energies between each pair are functions of the volume of the assembly. The "interchange energy" $W_s$ is determined by the "volume". The general relation between $W_s$ and volume is complicated. However, we take a simple assignment, putting

$$W_s=W_c/V_m\,, \qquad (2)$$

where $W_c$ is a constant independent of the concentration. This choice coincides with the Hildebrand-Scatchard relation[2] in regular solution. The statistical thermodynamics of the mixtures of atoms with slightly different sizes[3] shows that the equation (1) is approximately the reasonable expression in the lattice model of liquid alloy. The evaluation of the partition function for the order-disorder of the whole assembly is unaffected by any absolute magnitude of the interchange energy.

As $W_s$ is given by (2), we have the relations

$$W_s(\mathrm{Au_3Cu}) = 0.10\, W_c\,, \tag{3}$$

and

$$W_s(\mathrm{AuCu_3}) = 0.12\, W_c\,. \tag{4}$$

The theoretical transition temperature of these alloys is

$$T_t = \frac{W_s}{14.593\,k} \tag{5}$$

in the first approximation of quadruplets[1]. Thus we see that

$$\frac{T_t(\mathrm{Au_3Cu})}{T_t(\mathrm{AuCu_3})} = \frac{0.10}{0.12} \approx 0.83 \quad \text{(calc.)} \tag{6}$$

from equation (3), (4) and (5). The present theoretical ratio agrees with the experimental results, i.e.,

$$\frac{T_t(\mathrm{Au_3Cu})}{T_t(\mathrm{AuCu_3})} = \frac{516^\circ}{664^\circ} \approx 0.78 \quad \text{(obs.)}. \tag{7}$$

Taking into account the degree of the approximation, the similar tendancy between (6) and (7) is quite to be surprised. The transition temperature of AuCu is outside of the present theoretical application, because the change in spacing which accompanies the disorder-order transition is ignored in the usual statistical theory.

The author is grateful to Prof. E. A. Guggenheim for making communications about this problem.

# Theory of the Ortho-Para Conversion in Solid Hydrogen

By Kazuko Motizuki and Takeo Nagamiya
*Department of Physics, Osaka University*

(Received September 14, 1955)

The rate of ortho-para conversion in solid hydrogen ($H_2$) is calculated taking two kinds of interactions between ortho-molecules into consideration: interaction between the nuclear spins of one molecule and those of the other molecule and interaction between the rotational magnetic moment of one molecule and the nuclear spins of the other molecule. When an ortho-molecule converts into a para molecule, the rotational energy of the former is emitted as lattice phonons; we take the Debye model for the lattice vibrations and find that the dominant process is the emission of two phonons. The result for the rate of conversion (including a small effect arising from the emission of three phonons) is 1.94 percent per hour, which is comparable with the observed value of 1.75 percent per hour due to Cremer and of 0.9 percent per hour obtained recently by Hill. Further, the effect of a small amount of oxygen dissolved in solid hydrogen is treated and curves for the increase in average concentration as functions of time are plotted for various values of the oxygen concentration and of the initial ortho concentration. They are compared with preliminary measurements made in Tōhoku University.

## § 1. Introduction

The problem of ortho-para conversion of hydrogen molecule dates from old days: the conversion rate in gaseous hydrogen was calculated by Bonhoeffer and Harteck (1929)[1] for the case where the gas is pure and by Wigner (1933)[2] for the case where gas contains a catalytic substance. The rate of conversion is enhanced by introducing paramagnetic ions or molecules, since the inhomogeneous magnetic field produced at an ortho-hydrogen molecule by these paramagnetic ions or molecules decouples the parallel spins of the two protons of that molecule. Kalckar and Teller (1935)[3] calculated the ratio of the conversion rates in $H_2$ and $D_2$ when oxygen molecules were used as catalysers and pointed out that the interaction between the inhomogenous electric field and the quadrupole moment of the nuclei is important in the case of $D_2$. Farkas and Sandler (1939)[4] confirmed this point experimentally. Further, Casimir (1940)[5] discussed in detail the interaction between such inhomogeneous electric field and the quadrupole moment of heavy hydrogen and explained successfully the experimental results. An ingeneous point in Casimir's treatment is that he avoided the complicacy of the motion of hydrogen molecules by taking the ratio between the effect of the magnetic field and that of the electric field.

The rate of conversion from ortho to para in solid hydrogen presents another interesting problem. No theoretical treatment of it appears to have been made so far. It is known that hydrogen molecules in solid hydrogen are rotating freely (to a good approximation) as in gaseous hydrogen, so long as the temperature is not lower than about 2°K, which a lambda transition is observed for the crystal of high enough ortho concentration[6]. When an ortho-molecule converts into a para-molecule, the rotational state of this molecule changes from $J=1$ to $J=0$, and the difference of the energies of these states must be taken up by the lattice vibrations. Measurements of the natural ortho-para conversion in solid $H_2$ (also liquid $H_2$) have been made by Cremer and Polanyi (1932, 1933)[7] and by Cremer (1935, 1938)[8] who found that the rate is proportional to the square of ortho-concentration, independent of temperature from 4°K to 14°K, and has a value of about 2% per hour for virtually 100% ortho hydrogen. More recently, Hill and Ricketson (1954)[6], in their precise measurements of the thermal properties of solid hydrogen of various ortho-concentrations down to 1.15°K, resumed the measurements of the conversion rate, and they used the heat liberated by conversion to warm up the specimens; they confirmed that the rate is independent of temperature between 1.8°K and 4.5°K and assumed this constant value for lower temperatures. The value was, however, about one half of that given by Cremer. Kanda, Sugawara and Kobayashi[9] at Tohoku University are doing similar experiments and are obtaining similar results. They are also investigating the effect of a trace of oxygen molecules mixed in hydrogen.

We report in this paper our calculation of the rate of conversion in solid hydrogen ($H_2$) with the use of the Debye approximation for the lattice vibrations. We treat the natural ortho-para conversion as well as the effect of dissolved small amount of oxygen molecules. It can be expected that the Debye approximation is poor since large zero-point motion of the molecules must exist in solid hydrogen. However, it can be conceived that, for long waves, phonons are superimposed on this zero-point motion and that, by taking the average of the matrix elements of the transition over this zero-point motion, one would obtain a reasonable result for the conversion rate. In our actual calculation, we did not carry out this averaging procedure. More serious errors might arise from the circumstance that for short waves, which are actually important for our calculation, the assumption of the separability of phonons from the zero-point motion would be a poor approximation, and, even if an appropriate approximate separation could be made in a reasonable way, the phonon spectrum would be much different from that given by Debye's continuum model. At present, however, we have no rigorous treatment of the lattice vibrations in solid hydrogen, so that we have no other ways than to resort to the Debye approximation. That the result obtained (2% per hour) is in reasonable agreement with experiment seems, however, to support the validity of this approximation.

The programme of our calculation is as follows. We first write down the interaction between two ortho-hydrogen molecules which gives rise to the conversion; this consists of magnetic interactions between the nuclear spins of one molecule and those of the other molecule and the magnetic interactions between the magnetic moment of one molecule produced by its rotation and the nuclear spins of the other molecule. Taking these interactions as perturbations, we calculate the matrix elements which connect the ortho-state to para-state of one of the two molecules. The matrix elements are given as functions of the mutual distance between the two molecules. They are expanded in powers of the mutual displacement measured from the mean distance of the neighbouring molecules in the actual crystal. This displacement is expressed in terms of the normal modes of vibrations of the lattice. Finally, the probability of the ortho-para transition with the simultaneous emission of phonons to balance the energy change due to change in the rotational state is calculated. Emission of only one phonon is impossible because of the conservation of energy. Emission of two phonons turns out to be most effective for the conversion. The probability of the emission of three phonons is also calculated, but this probability is small. In the final section, the effect of oxygen molecules dissolved in solid hydrogen is discussed for the case where no diffusion of hydrogen molecules is taking place.

## § 2. Wave Functions and Interactions

The ortho-hydrogen molecule has a resultant nuclear spin of magnitude one and its rotational state has an odd quantum number; the para-hydrogen molecule has zero resultant nuclear spin and its rotational quantum number is even. Since the difference of the rotational energies of $J=1$ and $J=0$ amounts to 172°K in temperature scale, the ortho and para molecules in solid hydrogen, whose melting point is 14°K, are practically in the rotational state of $J=1$ and that of $J=0$, respectively. Thus the spin and rotational wave functions of the ortho-molecule are given by

$$\left.\begin{aligned} \varphi_{1,1}&=\alpha(1)\alpha(2)\,, \\ \varphi_{1,0}&=(1/\sqrt{2})[\alpha(1)\beta(2)+\alpha(2)\beta(1)]\,, \\ \varphi_{1,-1}&=\beta(1)\beta(2); \end{aligned}\right\} \tag{2.1}$$

$$\left.\begin{aligned} \psi_{1,1}&=-(1/2)(3/2\pi)^{1/2}\sin\theta\, e^{i\varphi}\,, \\ \psi_{1,0}&=(3/4\pi)^{1/2}\cos\theta\,, \\ \psi_{1,-1}&=(1/2)(3/2\pi)^{1/2}\sin\theta e^{-i\varphi} \end{aligned}\right\} \tag{2.2}$$

and those of the para-molecule by

$$\varphi_0=(1/\sqrt{2})[\alpha(1)\beta(2)-\alpha(2)\beta(1)]\,, \tag{2.3}$$

$$\psi_0=1/(2\sqrt{\pi})\,, \tag{2.4}$$

where $\alpha$, $\beta$ are Pauli's spin functions, 1, 2 represent two protons in the molecule, and $\theta$, $\varphi$ denote the polar and azimuthal angles of the molecular axis. The polar axis can be taken arbitrarily in the space.

The interaction between two molecules which causes the ortho-para conversion consists of two parts: 1. interaction between the proton spin moments of one molecule and those of the other molecule, 2. interaction between the proton spin moments of one molecule and the magnetic moment due to rotation of the other molecule. We shall denote these two interactions by $H_{ss}$ and $H_{rs}$, respectively. We shall further denote by $a$ and $b$ the two molecules and by $a1$, $a2$, etc. the first and second protons of the molecule $a$, etc. of one of the two molecules is para, the matrix elements of $H_{ss}$ and $H_{rs}$ connecting the ortho and para states of the other molecule vanish when averaged over the rotational motion of the para molecule, so that we have only to consider pairs of ortho-molecules. The $rs$-interaction between two ortho-molecules $a$ and $b$, which converts the molecule $b$ into para, can be written

$$H_{rs}=H_{rs}(a,b1)+H_{rs}(a,b2) \tag{2.5}$$

where

$$\begin{aligned} H_{rs}(a,b1)=(\mu_r\mu_p/R^5_{a,b1}|\boldsymbol{i}|)(A+B+C&\\ +D+E+F)\,,& \end{aligned}$$

$$\left.\begin{aligned}
A&=\boldsymbol{J}_{aZ}\boldsymbol{i}_{b1,Z}(R^2_{a,b1}-3Z^2_{a,b1})\,,\\
B&=-\frac{1}{4}[(\boldsymbol{J}_{aX}-i\boldsymbol{J}_{aY})(\boldsymbol{i}_{b1,X}+i\boldsymbol{i}_{b1,Y})\\
&\qquad+(\boldsymbol{J}_{aX}+i\boldsymbol{J}_{aY})(\boldsymbol{i}_{b1,X}-i\boldsymbol{i}_{b1,Y})]\\
&\qquad\times(R^2_{a,b1}-3Z^2_{a,b1})\,,\\
C&=-\frac{3}{2}[(\boldsymbol{J}_{aX}+i\boldsymbol{J}_{aY})\boldsymbol{i}_{b1,Z}+\boldsymbol{J}_{aZ}(\boldsymbol{i}_{b1,X}+i\boldsymbol{i}_{b1,Y})]\\
&\qquad\times Z_{a,b1}(X_{a,b1}-iY_{a,b1})\,,\\
D&=-\frac{3}{2}[(\boldsymbol{J}_{aX}-i\boldsymbol{J}_{aY})\boldsymbol{i}_{b1,Z}+\boldsymbol{J}_{aZ}(\boldsymbol{i}_{b1,X}-i\boldsymbol{i}_{b1,Y})]\\
&\qquad\times Z_{a,b1}(X_{a,b1}+iY_{a,b1})\\
E&=-\frac{3}{4}(\boldsymbol{J}_{aX}+i\boldsymbol{J}_{aY})(\boldsymbol{i}_{b1,X}+i\boldsymbol{i}_{b1,Y})\\
&\qquad\times(X_{a,b1}-iY_{a,b1})^2\,,\\
F&=-\frac{3}{4}(\boldsymbol{J}_{aX}-i\boldsymbol{J}_{aY})(\boldsymbol{i}_{b1,X}-i\boldsymbol{i}_{b1,Y})\\
&\qquad\times(X_{a,b1}+iY_{a,b1})^2\,.
\end{aligned}\right\} \tag{2.6}$$

Here $\mu_r$ and $\mu_p$ are the rotational and proton magnetic moments, $\boldsymbol{J}$ and $\boldsymbol{i}$ the rotational and proton angular momenta in units of $(|\boldsymbol{i}|=1/2)$ ($i$ appearing in brackets being $\sqrt{1}$), $R_{a,b1}$ the magnitude of the vector joining the centre of gravity of molecule $a$ to the first proton of molecule $b$ and $X_{a,b1}$, $Y_{a,b1}$, $Z_{a,b1}$ its components. The $ss$-interaction which converts the molecule $b$ into para can be written

$$\begin{aligned} H_{ss}=H_{ss}(a1,b1)+H_{ss}(a1,b2)&\\ +H_{ss}(a2,b1)+H_{ss}(a2,b2)& \end{aligned} \tag{2.7}$$

where for instance $H_{ss}(a1,b1)$ represents the interaction between proton $a1$ and proton $b1$ and can be written in a similar form as (2.6), the first factor in the right-hand side of (2.6) being replaced by $(\mu_p{}^2/R^5_{a1,b1}|\boldsymbol{i}|^2)$ and $\boldsymbol{J}_{az}$, $R_{a,b1}$, $Z_{a,b1}$, etc. in $A, B,\cdots, F$ by $\boldsymbol{i}_{a1,z}$, $R_{a1,b1}$, $Z_{a1,b1}$, etc.

We look for the matrix elements of $H_{ss}+H_{rs}$ between the state $a$=ortho and $b$=ortho and the state $a$=ortho but $b$=para. These matrix elements can be grouped into two: one is of such a property that the initial and final states of molecule $a$ are the same, both with respect to its rotational state and spin state, and the other is such that either the rotational state or the spin state, or both, of molecule $a$ change. When only the latter group is concerned, we are allowed to calculate the transition probability due to the interaction $H_{ss}+H_{rs}$ between $a$ and $b$ and then sum up this probability over the molecules $a$ which surround the molecule $b$. However, when the former group is concerned, we must, in principle, first sum $H_{ss}+H_{rs}$ over the molecules $a$ surrounding the molecule $b$ and then calculate the transition probability; this introduces a great complicacy of calculation since the state of each ortho-molecule is ninefold degenerate. We therefore treat the first group in the same way as the second group, hoping that the interference effect among the interactions coming from different $a$ molecules is negligible. Thus we calculate the transition probability from the interaction Hamiltonian between neighbouring two ortho-molecules and then multiply it by the average number of ortho-molecules surrounding each ortho-molecule. This simplification introduces a further simplification of the calculation when we adopt the Debye approximation of lattice vibration: namely, we can take the axis of quantization ($z$-axis) to be the line joining the equilibrium positions of the molecules $a$ and $b$, since in the Debye approximation the lattice is treated as isotropic, though actually the lattice of molecular hydrogen is hexagonal close-packed.

All the mathematical details of the calculation of the transition probability will be given in Appendices $A$ and $B$, and we shall proceed directly to the result.

## § 3. Numerical Result and Comparison with Experiment

The crystal of hydrogen molecules is hexagonal close-packed with $R_0=3.75$ Å[12) for the intermolecular distance of any of the neighbouring pair. The corresponding density is $\rho=0.0897$ gr/cm$^3$. Other necessary data for our calculation are as follows:

Difference in rotational energy between $J=1$ and $J=0$ (in temperature scale): $E_r=172°$K

Debye temperature: $\Theta_D=91°$K

Sound velocity: $v=\left(\frac{4\pi}{3}\right)^{1/3}\frac{V}{N}\frac{k\Theta_D}{h}$
$=1.021\times10^5$ cm/sec

Internuclear distance[12): $2r=0.74$ Å

Proton magnetic moment:
$\mu_p=1.403\times10^{-23}$ erg/gauss

Rotational magnetic moment[13):
$\mu_r=0.316\times\mu_p$

The integrations of (B. 11) and (B. 12), which give the probability of ortho-para transition with the emission of two and three phonons, respectively, were carried out graphically. The results are:

$$\left.\begin{aligned}12W(2)&=1.74\times10^{-2}\text{ per hour,}\\12W(3)&=0.20\times10^{-2}\text{ per hour,}\end{aligned}\right\}$$

total: $1.94\times10^{-2}$ per hour.

Thus, the three-phonon process yields a probabiltiy about one tenth as large as the two-phonon process and the total calculated probability is 1.94% or roughly 2% per hour.

Polanyi and Cremer[7),8) found that the ortho-concentration $c$ changes with time according to the equation

$$\frac{dc}{dt}=-kc^2 \tag{3.1}$$

with

$$k=1.75\times10^{-2}\text{ per hour,} \tag{3.2}$$

which they found to be independent of temperature between 4°K and 14°K. This value of $k$ should be compared with our result given above. The agreement is apparently perfect, but it must be somewhat fortuitous for the following reasons.

From the theoretical point of view, we cannot expect more than the correct order of magnitude of $k$, since we assumed small vibrations of the lattice, which should be inadequate for such a light molecule as hydrogen, and moreover the Debye approximation for the high frequency part of the vibration spectrum, which is efficient for the two-phonon process, is most poor (possibly it gives too large level densities there). Further we assumed that each interacting pairs of ortho-molecules contributes independently to the conversion rate; actually, as each ortho-molecule is surrounded by a number of ortho-molecules, we must in principle first take the sum of all the interactions between the former and the latter, calculate the matrix elements of the sum and then square it, whereas we first calculated the square of the matrix elements or each interaction and then took their sum (actually multiplied by $12c$). One may hope, however, that the errors caused by such a procedure are cancelled out after taking the average of the total conversion rate over all the possible initial states of the surrounding molecules and, when the ortho-concentration is not 100%, over all the possible distributions of the surrounding ortho-molecules. Should this conjecture be incorrect, we have no more the bi-molecular law (3.1).

One more point overlooked by the present calculation, which, however, seems to be unimportant when the time of measurements is not too long and the ortho-concentration is not too low, is this: when an ortho-molecule becomes isolated because all the surrounding ortho-molecules happened to change to para, it can no more change to para. This effect was investigated theoretically and experimentally by Cremer[8), who found that the effect is noticeable only after 60 hours, starting with the normal concentration of ortho. If diffusion of hydrogen molecules is taking place rapidly enough, we should have no effect of this isolation, but actually the diffusion seems to be practically negligible according to Cremer, though his estimation of the effect of isolation is crude and consequently his value of the diffusion constant deduced by comparing his theory with his experiment cannot be claimed to be accurate*.

Also from the experimental point of view, it seems that Polanyi-Cremer's value of $k$ is not the ultimate one. Recent measurements by Hill[14)] (also by Kanda, Sugawara and Kobayashi[9)]) give a value of $k$ of 0.9% per hour. Further, oxygen molecules contaminated in solid hydrogen will greatly enhance the conversion rate, as we shall see in the next section.

## § 4. Effect of Oxygen Molecules Contained in Solid Hydrogen

Oxygen molecule in its ground state has a spin of magnitude one, the corresponding magnetic moment being two Bohr magnetons, so that even a small amount of oxygen contained in the crystal of hydrogen can influence the rate of conversion to a great extent. Ortho-molecules in the neighbourhood of an oxygen molecule will change to para in a short time, so that the initial increase of para-concentration will be great. Since the rate of conversion due to an oxygen molecule is proportional to the inverse twelvth power of the distance between the oxygen molecule and the hydrogen molecule, as we shall see below, a small sphere of complete para-molecules is formed instantaneously around the oxygen molecule and this sphere subsequently expands slowly.

We shall assume that the effect of diffusion of hydrogen molecules is entirely negligible, as suggested by Cremer's[8)] experiment. If diffusion takes place, ortho-hydrogen molecules at distances from the oxygen molecules will migrate into the action spheres of the oxygen molecules, change to para, and then leave the spheres. Therefore, the rate of conversion is increased. (Measurements of this increase might provide a mean of determining the self-diffusion constant if the latter depends significantly on temperature.)

The spin of each oxygen molecule changes its orientation with time. The relaxation time associated with this change of orientation may depend on the oxygen concentration as well as the thermal agitation of the surrounding hydrogen atoms; the former governs the spin-spin relaxation and the latter the spin-lattice relaxation. At high concentrations of oxygen, say 0.1 atomic percent, thes pin-spin relaxation might predominate but the relaxation time might still be as long as $10^{-6}$ or $10^{-7}$ sec, which is very long compared with $\hbar/E_r \approx 10^{-13}$ sec, where $E_r$ is, as before, the difference in rotational energy of the ortho and para molecules. We can therefore safely assume that oxygen spins are at rest when considering the ortho-para conversion.

We first calculate the rate of conversion into para of an ortho-molecule at a distance $R$ from an oxygen molecule which has substituted a hydrogen molecule in the lattice of solid hydrogen ($R$ measures the distance between the centres of these molecules). The possible distortion of the lattice and the change of the lattice vibrations due to this substitution will be neglected. The oxygen molecule is assumed to be at rest (so that certain modes of lattice vibrations are eliminated and a smaller conversion rate should result). The oxygen molecule produces an inhomogeneous static magnetic field around itself and the nuclear spins of the hydrogen molecule couple with it. The interaction Hamiltonian is the same as (2.6) except that the rotational magnetic moment of molecule $a$ is now replaced by the magnetic moment of the oxygen molecule. The calculation of the transition probability proceeds in quite a similar manner as before, so that we shall motion only its essential points:

First, the matrix elements connecting the ortho state to para stste are calculated, taking account of only the spin and rotational states of the hydrogen molecule. Then, they are expanded in powers of the displacement of the hydrogen molecule, measured from its equilibrium position, as in § 4. The displacement of the oxygen molecule is taken to be zero. Terms corresponding to the emission of two phonons are considered, others neglected. All the final matrix elements are squared and summed up, then divided by 9, the number of the initial states. The result is the same as (B. 6) with $W_i(2)$ given by (B. 11(, except that we now have different values to the coefficients $C_i$ and that the factor 81 in the denominator of (B. 11) is replaced by 9; the present $C_i$'s are as follows:

---

* Recent measurements by Rollin and Watson (B. V. Rollin and E. Watson, Conference de Physique des Basses Températures, Paris, Sept. 1955) by the method of proton magnetic resonance show also that the diffusion rate is very small below about 8°K.

$$\left.\begin{aligned} C_0 \qquad &= 12\mu_p{}^2\mu^{p}{}_2{}^2 \\ C_1+C_2 &= 24\mu_p{}^2\mu_{o2}{}^2 \\ C_3+C_4 &= 15\mu_p{}^2\mu_{o2}{}^2 \\ C_5 \qquad &= 36\mu_p{}^2\mu_{o2}{}^2 \end{aligned}\right\} \tag{4.1}$$

Further, we average the result with respect to isotropic orientation of the oxygen spin.

In this way we finally obtain the rate of conversion of the hydrogen molecule at distance $R$ as:

$$k_{oxy.} \equiv W_{owy.}(2) = 250(R_0/R)^{12} \text{ per hour} \tag{4.2}$$

where $R_0 = 3.75\text{A}$ is the interatomic distance in hydrogen crystal. Comparing this result with $k$ given by (3.2), we find that the distance at which $k_{oxy.}$ equals $k$ is $R = 2.7R_0$.

Fig. 1 respresents the number of para molecules produced around an oxygen molecule as a function of time; curve $A$ is obtained by calculating the same

$$n_{para}(t) = \sum_i [1-\exp(-k_{oxy.})\boldsymbol{R}_i)t_0 \tag{4.3}$$

over all the surrounding hydrogen atoms $i$, and curve $B$ by replacing this sum by an integral. assuminig that the hydrogen atoms are distributed continuously and uniformly around the oxygen molecule with the density of the actual solid hydrogen, and subracting 1 from it because the oxygen molecule has replaced one hydrogen molecule. That is, (4.3) is replaced by

$$n_{para}(t) = n_{H2}\int_0^\infty [1-\exp(-k_{oxy.}(r)t)]4\pi r^2 dr - 1 \ , \tag{4.4}$$

where $n_{H2}$ is the number of hydrogen molecule per unit volume. Both correspond to the case of 100% ortho. We see that the difference between these two curves is smell, particularly after a long time. So we proceed below with this continuum model. (Curves $C$ will be explained later.)

We seek the number of para-molecules produced in time $t$ by the action of the oxygen molecules and simultaneously by the action of ortho-ortho interactions. Let the concentration of ortho-molecules at distance $r$ from an oxygen molecule at time $t$ be $c(r, t)$. The time rate of change of this quantity can be obtained from the equation

$$\frac{dc(r,t)}{dt} = -k_{oxy.}(r)c(r,t) - h_{hybr.}c(r,t)\bar{c}(r,t) \ , \tag{4.5}$$

where $k_{hydr.}$ is the previous $k$ and $\bar{c}(r, t)$ means the average of the concentration over the sphere of radius $R_0$ which encircles the point under consideration; to a good approximation, this average concentration may be put equal to $c(r, t)$, because $\bar{c}$ differ significantly from $c$ only near the boundary of the small region within which all the ortho-molecules have converted to para molecules by the action of the oxygen molecule and which expands with time mainly due to this action, while the dominant effect of the last term in (6.6) if found in the larger outer region. So, putting $\bar{c} = c$, and integrating, we have

$$c(r,t) = \frac{c_0 k_{oxy.}(r)}{[k_{oxy.}(r) + c_0 k_{hydr.}]\exp[k_{oxy.}(r)t] - c_0 k_{hydr.}} \tag{4.6}$$

which reduces to the solution of (3.1)

$$c(t) = \frac{c_0}{1 + c_0 k_{hydr.} t} \tag{4.7}$$

when $k_{oxy.}$ is neglected. Here $c_0$ is the initial concentration.

The excess number of para-molecules, $\Delta n_p$, produced in time $t$ when one oxygen molecule is present is calculated by integrating the difference between (4.6) and (4,7) over the whole volume, multiplying the result by $n_{H_2}$, the number of $H_2$ molecules per unit volume, and subtracting $c_0$ (the probability that the oxygen molecule replaces an ortho-molecule):

$$\Delta n_{para}(t) = n_{H_2}\int_0^\infty \left[\frac{c_0}{1 + c_0 k_{hydr.} t} - c(r,t)\right] 4\pi r^2 dr - c_0 \ . \tag{4.8}$$

This is not the number of para-molecules produced by the action of the oxygen molecule when there is simultaneously the action of the interactions among ortho-molecules; it is given by

$$n_{H_2}\int_0^\infty k_{oxy.}(r)\int_0^t c(r,t)dt 4\pi r^2 dr \ , \tag{4.9}$$

which, when calculated, comes close to the curve B of Fig. 1. To avoid confusion, however, we have given only curves of (4.8) in Fig. 1 (denoted as C). The increase of the average concentration of para-molecules at an arbitrary molar concentration of oxygen $\alpha$, is

$$\Delta c_{para}=\frac{c_0^2 k_{hydr.} t}{1+c_0 k_{hydr.} t}+\alpha \Delta n_{para}(t)\,. \qquad (4.1)$$

Full curves in Fig. 2 have been calculated with the use of (4.10) and broken curves with the use of the approximate formula

$$\Delta c_{para}=\frac{c_0^2 k_{hydr.} t}{1+c_0 k_{hydr.} t}+\alpha n_{para}(t)\,, \qquad (4.11)$$

$n_{para}(t)$ being given by (4.4). The value of $k_{hydr.}$ used in these curves is the calculated one.

In the above derivation, we have tacitly assumed that each oxygen molecule contributes to the conversion independently of one another. If oxygen concentration is so high that action spheres of the oxygen molecules come close together, this assumption is no longer valid. In such a case, we may take the following approximation. Oxygen molecules are first supposed to form, for convenience, a simple cubic lattice with a unit cell volume equal to the total volume divided by the number of the oxygen molecules. Then, forming a sphere around each oxygen molecule whose radius is equal to the lattice constant, and distributing six oxygen molecules on each such spherical surface, with a uniform probability, and putting an oxygen molecule at its centre, we calculate the central-symmetric field of conversion with the use of (4.2). Finally, a smaller sphere with the same centre and with a volume equal to the volume per oxygen molecule is described and equation (4.5) is applied within this sphere. Possibly, $\bar{c}$ cannot be approximated by $c$ in this case, but then we encounter a great mathematical difficulty, so we put $\bar{c}=c$. The solution obtained in this way for the case of 75% initial ortho and 0.5 molar percent of oxygen is shown by a dotted curve in Fig. 2. It does not differ much from the corresponding curve obtained with the use of (4.10). Comparison with preliminary measurements made in Tōhoku University reveals that the specimen used might have contained about 0.2 molar percent of oxygen. Measurements with intentively mixed oxygen are desirable for a further verification of the present theory.

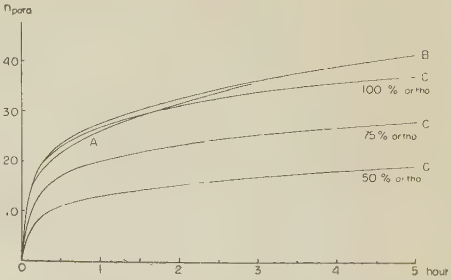

Fig. 1. Number of para-molecules produced around an oxygen molecule, as a function of time; Curve A is obtained with the use of Eq. (4.4), Curve C Eq. (4.9).

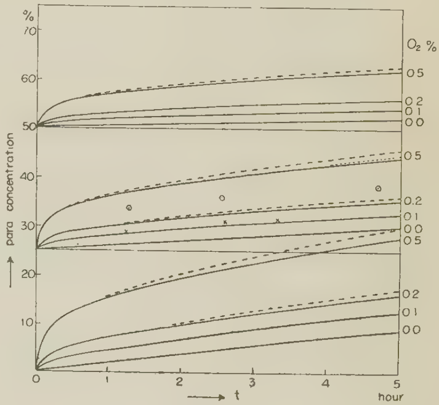

Fig. 2. Increase of the average concentration of para-molecules as a function of time for various values of the molar oxygen concentration and of the initial ortho-concentration. Full curves ware calculated with the use of Eq. (4.10) and broken curves with the use of Eq. (5.11). A dotted curve for 0.5 molar percent of oxygen and 75% initial ortho-concentration was calculated taking account of the simultaneous effect of neighbouring oxygen molecules.
⊙ and × represent experimental values obtained at Tōhoku University.

We are indebted to Professor E. Kanda, Dr. C. Sugawara and Miss H. Kobayashi of Tōhoku University for kind communications of their results and to Dr. Yoshida and other members of our laboratory for helpful discussions.

## Appendix A. The matrix elements of $H_{rs}$ and $H_{ss}$ with respect to the spin and rotational states.

This and the next appendices fill the gap between § 2 and § 3.

(a) The matrix elements of $H_{rs}$. $H_{rs}$ does not contain the spin operators of molecule $a$, so that we have only diagonal elements of it with respect to the spin states of $a$. The non-vanishing matrix elements of the spin operators of molecule $b$ with respect to the spin states of molecule $b$ are as follows:

$$\left.\begin{array}{ll}
\langle\varphi_{1,0}(b)|i_{b1,z}|\varphi_0(b)\rangle=\dfrac{1}{2} & \langle\varphi_{1,0}(b)|i_{b2,z}|\varphi_0(b)\rangle=-\dfrac{1}{2} \\
\langle\varphi_{1,1}(b)|i_{b1,x}+ii_{b1,y}|\varphi_0(b)\rangle=-\dfrac{1}{\sqrt{2}} & \langle\varphi_{1,1}(b)|i_{b2,x}+ii_{b2,y}|\varphi(b)\rangle=\dfrac{1}{\sqrt{2}} \\
\langle\varphi_{1,-1}(b)|i_{b1,x}-ii_{b1,y}|\varphi_0(b)\rangle=\dfrac{1}{\sqrt{2}} & \langle\varphi_{1,1}(b)|i_{b2,x}-ii_{b2,y}|\varphi_0(b)\rangle=-\dfrac{1}{\sqrt{2}}
\end{array}\right\} \tag{A. 1}$$

The non-vanishing matrix elements of the angular momentum operator of molecule $a$ are:

$$\left.\begin{array}{l}
\langle\psi_{1,1}(a)|J_{az}|\psi_{1,1}(a)\rangle=1 \\
\langle\psi_{1,-1}(a)|J_{az}|\psi_{1,-1}(a)\rangle=-1 \\
\langle\psi_{1,0}(a)|J_{ax}+iJ_{ay}|\psi_{1,-1}(a)\rangle=\langle\psi_{1,1}(a)|J_{ax}+iJ_{ay}|\psi_{1,0}(a)\rangle=\sqrt{2} \\
\langle\psi_{1,0}(a)|J_{ax}-iJ_{ay}|\psi_{1,1}(a)\rangle=\langle\psi_{1,-1}(a)|J_{ax}-iJ_{ay}|\psi_{1,0}(a)\rangle=\sqrt{2}\,.
\end{array}\right\} \tag{A. 2}$$

In taking the matix elements of $H_{rs}$ with respect to the rotational states of molecule $b$, we have to calculate those of $(R^2_{a,b1}-3Z^2_{a,b1})/R^5_{a,b1}$, etc. We expand the latter quantities in powers of $r/R$, where $r$ is half the internuclear distance of each molecule and $R$ the distance between the centres of the two molecules; $r/R \fallingdotseq 1/10 \ll 1$ if we take for $R$ the mean distance in the actual crystal. Since $H_{rs}$ is the sum of $H_{rs}(a, b1)$ and $H_{rs}(a, b2)$, and is invariant against the inversion of molecule $b$ with respect to its centre, and since the matrix elements of $i_{b1}$ have opposite sign to those of $i_{b2}$, as seen from (A. 1), we have only to retain those terms of the expansion which change sign under the inversion of molecule $b$. The first terms of the expansion are discarded by this reason, the second terms adopted, and the higher order terms neglected. Then we have the following results:

$$\left.\begin{array}{ll}
\text{$A$ and $B$ terms:} & \left\langle\psi_{1,1}(b)\left|\dfrac{R^2_{a,b1}-3Z^2_{a,b1}}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=\sqrt{\dfrac{3}{2}}\,f_1 \\
 & \left\langle\psi_{1,0}(b)\left|\dfrac{R^2_{a,b1}-3Z^2_{a,b1}}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-\sqrt{3}\,f_0 \\
 & \left\langle\psi_{1,-1}(b)\left|\dfrac{R^2_{a,b1}-3Z^2_{a,b1}}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-\sqrt{\dfrac{3}{2}}\,f_2 \\
\text{$C$ term} & \left\langle\psi_{1,1}(b)\left|\dfrac{Z_{a,b1}(X_{a,b1}-iY_{a,b1})}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=\dfrac{5}{\sqrt{6}}f_3 \\
 & \left\langle\psi_{1,0}(b)\left|\dfrac{Z_{a,b1}(X_{a,b1}-iY_{a,b1})}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=\dfrac{1}{\sqrt{3}}f_1 \\
 & \left\langle\psi_{1,-1}(b)\left|\dfrac{Z_{a,b1}(X_{a,b1}-iY_{a,b1})}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=f_5 \\
\text{$D$ term:} & \left\langle\psi_{1,1}(b)\left|\dfrac{Z_{a,b1}(X_{a,b1}+iY_{a,b1})}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-f_5 \\
 & \left\langle\psi_{1,0}(b)\left|\dfrac{Z_{a,b1}(X_{a,b1}+iY_{a,b1})}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=\dfrac{1}{\sqrt{3}}f_2 \\
 & \left\langle\psi_{1,-1}(b)\left|\dfrac{Z_{a,b1}(X_{a,b1}+iY_{a,b1})}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-\dfrac{5}{\sqrt{6}}f_4 \\
\text{$E$ term:} & \left\langle\psi_{1,1}(b)\left|\dfrac{(X_{a,b1}-iY_{a,b1})^2}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=\dfrac{5}{\sqrt{6}}f_6 \\
 & \left\langle\psi_{1,0}(b)\left|\dfrac{(Y_{a,b1}-iY_{a,b1})^2}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-\dfrac{5}{\sqrt{3}}f_3
\end{array}\right\} \tag{A. 3}$$

$$\left\langle \psi_{1,-1}(b)\left|\frac{(X_{a,b1}-iY_{a,b1})^2}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=2f_8$$

F term:

$$\left\langle \psi_{1,1}(b)\left|\frac{(X_{a,b1}+iY_{a,b1})^2}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-2f_9$$

$$\left\langle \psi_{1,0}(b)\left|\frac{(X_{a,b1}+iY_{a,b1})^2}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-\frac{5}{\sqrt{3}}f_4$$

$$\left\langle \psi_{1,-1}(b)\left|\frac{(X_{a,b1}+iY_{a,b1})^2}{R^5_{a,b1}}\right|\psi_0(b)\right\rangle=-\frac{5}{\sqrt{6}}f_7$$

where $f_0, f_1, \cdots, f_9$ are functions of the relative coordinates $X, Y, Z\,(X^2+Y^2+Z^2=R^2)$ of the centres of molecules $a$ and $b$ and are given as follows:

$$f_0=Z\{3(X^2+Y^2)-2Z^2\}\frac{r}{R^7}$$

$$f_1=(R^2-5Z^2)(X-iY)\frac{r}{R^7}$$

$$f_2=(R^2-5Z^2)(X+iY)\frac{r}{R^7}$$

$$f_3=Z(X-iY)^2\frac{r}{R^7}$$

$$f_4=Z(X+iY)^2\frac{r}{R^7}$$

$$f_5=\frac{1}{\sqrt{6}}Z\{2R^2-5(X^2+Y^2)\}\frac{r}{R^7}$$

$$f_6=\{(X^3-3XY^2)-i(3X^2Y-Y^3)\}\frac{r}{R^7}$$

$$f_7=\{(X^3-3XY^2)+i(3X^2Y-Y^3)\}\frac{r}{R^7}$$

$$f_8=\frac{1}{2\sqrt{6}}\{4R^2-5(X^2+Y^2)\}(X-iY)\frac{r}{R^7}$$

$$f_9=\frac{1}{2\sqrt{6}}\{4R^2-5(X^2+Y^2)\}(X+iY)\frac{r}{R^7} \tag{A. 4}$$

The same formulas apply when $b1$ is replaced by $b2$. Combining all the above formulas, we can calculate the required matrix elements of $H_{rs}$.

(b) The matrix elements of $H_{ss}$. In calculating the matrix elements of e.g. the product of $i_{a1,z}$ and $i_{b1,z}$, we can apply the formulas (A. 1) separately for molecules $a$ and $b$; the results may not need be reproduced here. In calculating the matrix elements with respect to the rotational states of $a$ and $b$, we again expand $H_{ss}$ in powers of $r/R$. A little consideration will show that we have only to calculate those terms of $H_{ss}(a1, b1)$ which are invariant againt the inversion of molecule $a$ and change sign against the inversion of molecule $b$, and then to multiply the result by 4 in order to take account of $H_{ss}(a1, b2)$, $H_{ss}(a2, b1)$ and $H_{ss}(a2, b2)$. The leading terms of the expansion of $H_{ss}(a1, b1)$ which satisfy these conditions are the same as those which we considered above in (a) in the expansion of $H_{rs}(a,b1)$, so that we can utilize the results (A. 3) and (A. 4) for each of the three rotational states of molecule $a$.

Now we can proceed further. We have initially an ortho-molecule $a$ and an ortho-molecule $b$ and finally an ortho-molecule $a$ and a para-molecule $b$. Each ortho-state is nine-fold degenerate, so that the initial state is 81-fold degenerate. The final state is 9-fold degenerate. As we are interested in the probability of transition from one of the 81 initial states to any one of the 9 final states, we sum up the probabilities of all the possible transitions between these sets of states and then divide the sum by 81.

The change in energy of the rotational state of molecule $b$, which has converted into para, must be balanced by an emission of phonons. We shall denote by $\psi_T$ and $\psi_{T'}$ the wave functions of the initial and final vibrational states of the lattice. Then the ortho-para transition probability is proportional to

$$\frac{1}{81}\sum\left|\langle\psi^a_{1m_a}\varphi^a_{1n_a}\psi^b_{1m_b}\varphi^b_{1n_b}\psi_T|H_{rs}+H_{ss}|\psi^a_{1m_a'}\varphi^a_{1n_a'}\psi_0^b\varphi_0^b\psi_{T'}\rangle\right|^2 \tag{A. 5}$$

where $m, m'$ and $n, n'$ with suffixes $a$ or $b$ are magnetic quantum numbers of rotational and spin angular momenta of molecules $a$ or $b$, and suffixes 1 and 0 refer, as before, to ortho and para states. The summation in (A. 5) runs over the initial 81 and final 9 states. The matrix elements of the Hamiltonian with respect to rotational and spin states have been calculated as sketched above, and the result was expressed in terms of $f_i$ ($i=0, 1, 2, \cdots 9$), (A. 4), which are functions of the relative coordinates of molecules $a$ and $b$. So, (A. 5) can be expressed as

$$\frac{1}{81}\sum_{i=0}^{9} C_i\,|\langle\psi_T|f_i|\psi_{T'}\rangle|^2 \tag{A. 6}$$

where $C_i$ are

$$\left.\begin{aligned} C_0 &= 108\mu_p{}^4[4+(\mu_R/\mu_p)^2] \\ C_1+C_2 &= 252\mu_p{}^4[4+(\mu_R/\mu_p)^2] \\ C_3+C_4 &= 2700\mu_p{}^4[4+(\mu_R/\mu_p)^2] \\ C_5 &= 432\mu_p{}^4[4+(\mu_R/\mu_p)^2] \\ C_6+C_7 &= 450\mu_p{}^4[4+(\mu_R/\mu_p)^2] \\ C_8+C_9 &= 432\mu_p{}^4[4+(\mu_R/\mu_p)^2] \end{aligned}\right\} \tag{A. 7}$$

In Appendix $B$, we express $f_i$ in terms of the lattice vibrations.

## Appendix B. Emission of phonons

We shall adopt the Debye approximation for the lattice vibrations, as mentioned in § 1. The Debye temperature $\Theta_D$ is 91°K[10], while the difference of the rotational energy of ortho-molecule and that of para-molecule is 172°K[11], so that at least two phonons must be emitted.

We now denote the two molecules $a$ and $b$ by $k$ and $l$, these numbers running over the lattice points, and write small displacements of the centres of these molecules from their respective equilibrium positions as $x_k$, $y_k$, $z_k$ and $x_l$, $y_l$, $z_l$. We expand the functions $f_i$ in powers of the relative displacement

$$x=x_k-x_l\,,\quad y=y_k-y_l\,,\quad z=z_k-z_l \tag{B. 1}$$

as

$$f=f_0+\sum_x\left(\frac{\partial f}{\partial x}\right)_0 x+\frac{1}{2!}\sum_{x,y}\left(\frac{\partial^2 f}{\partial x\partial y}\right)_0 xy+\frac{1}{3!}\sum_{x,y,z}\left(\frac{\partial^3 f}{\partial x\partial y\partial z}\right)_0 xyz+\cdots\,, \tag{B. 2}$$

where the suffix 0 means the equilibrium position. In calculating the process of emission of two phonons, the second order terms of the above expansion are to be considered, for the emission of three phonons the third order terms, and so on. The displacement of molecule $k$ and that of molecule $l$ can be written in the Debye approximation as

$$x_k=\sum_\sigma\sum_{j=1}^{3}(a_{\sigma j}\cos\boldsymbol{\sigma}\cdot\boldsymbol{k}+b_{\sigma j}\sin\boldsymbol{\sigma}\cdot\boldsymbol{k})x_{\sigma j}\,,\quad\text{etc.}, \tag{B. 3}$$

$$x_l=\sum_\sigma\sum_{j=1}^{3}(a_{\sigma j}\cos\boldsymbol{\sigma}\cdot\boldsymbol{l}+b_{\sigma j}\sin\boldsymbol{\sigma}\cdot\boldsymbol{l})x_{\sigma j}\,,\qquad\text{etc.} \tag{B. 4}$$

where $\boldsymbol{\sigma}$ is $a$ wave vector, $\boldsymbol{k}$ and $\boldsymbol{l}$ vectors representing the lattice points $k$ and $l$, $j$ the three components of polarization, and $x_{\sigma j}$, $y_{\sigma j}$, $z_{\sigma j}$ the Cartesian components of the unit vector which represents polarization $j$ of wave $\sigma$. The amplitude operators $a_{\sigma j}$ and $b_{\sigma j}$ are independent of each other and have matrix elements between those states in which the number of phonons differs by one:

$$\left.\begin{aligned} \langle m_{\sigma j}|a_{\sigma j}|m_{\sigma j}+1\rangle &= (\hbar/2M)^{1/2}(m_{\sigma j}+1)^{1/2}\omega_{\sigma j}{}^{-1/2}\,, \\ \langle n_{\sigma j}|a_{\sigma j}|n_{\sigma j}+1\rangle &= (\hbar/2M)^{1/2}(n_{\sigma j}+1)^{1/2}\omega_{\sigma j}{}^{-1/2}\,. \end{aligned}\right\} \tag{B. 5}$$

$M$ is the total mass of the crystal. We assume, for the sake of simplicity, that $\omega_{\sigma j}$ does not depend on $j$, and denote it simply as $\omega_\sigma$. Further we assume the relation $|\sigma|=\omega_\sigma/v$, where $v$ is the sound velocity.

For the process of emission of two phonons, we are interested in the transition probability:

$$W(2)=\sum_i W_i(2)\,, \tag{B. 6}$$

$$\begin{aligned} W_i(2)=\frac{1}{81}\frac{2\pi}{\hbar}C_i\int\sum_{j,j'}\Bigg[&\left|\left\langle m_{\sigma j}, m_{\sigma' j'}\right|\frac{1}{2}\sum_{x,y,z}\left(\frac{\partial^2 f_i}{\partial x\partial y}\right)_0 xy\left|m_{\sigma j}+1,\ m_{\sigma' j'}+1\right\rangle\right|^2 \\ &+\left|\left\langle m_{\sigma j}, n_{\sigma' j'}\right|\frac{1}{2}\sum_{x,y,z}\left(\frac{\partial^2 f_i}{\partial x\partial y}\right)_0 xy\left|m_{\sigma j}+1,\ n_{\sigma' j'}+1\right\rangle\right|^2 \\ &+\left|\left\langle n_{\sigma j}, m_{\sigma' j'}\right|\frac{1}{2}\sum_{x,y,z}\left(\frac{\partial^2 f_i}{\partial x\partial y}\right)_0 xy\left|n_{\sigma j}+1,\ m_{\sigma' j'}+1\right\rangle\right|^2 \\ &+\left|\left\langle n_{\sigma j}, n_{\sigma' j'}\right|\frac{1}{2}\sum_{x,y,z}\left(\frac{\partial^2 f_i}{\partial x\partial y}\right)_0 xy\left|n_{\sigma j}+1,\ n_{\sigma' j'}+1\right\rangle\right|^2\Bigg] \\ &\times\delta(\hbar\omega_{\sigma'}+\hbar\omega_\sigma-E_r), \end{aligned} \tag{B. 7}$$

where the integration is carried out with respect to the states of the phonons and $E_r$ is the difference in rotational energy for states $J=1$ and $J=0$. The numbers of phonons appearing in the above expression are replaced by their thermal average values;

$$m_{\sigma j}=n_{\sigma j}=\frac{1}{e^{\hbar\omega_\sigma/kT}-1}, \qquad m_{\sigma j'}=n_{\sigma j'}=\frac{1}{e^{\hbar\omega_\sigma/kT}-1}. \tag{B. 8}$$

The number of states of phonons within frequency range $(\omega_\sigma, \omega_\sigma+d\omega_\sigma)$ and within solid angle $d\Omega_\sigma$ is

$$\frac{V}{(2\pi)^3}\sigma^2 d\sigma d\Omega_\sigma=\frac{V}{(2\pi)^3}\frac{\omega_\sigma^2}{v^3}d\omega_\sigma d\Omega_\sigma\,, \tag{B. 9}$$

where $V$ is the volume of the crystal; $V$ and $M$ appear in a combined form $\rho=M/V$, which is the density. So $W_i$ can be written

$$W_i(2)=\frac{1}{81(2\pi)^5V^6\rho^2}C_i\left[\sum_{x,y,z}\left|\left(\frac{\partial^2 f_2}{\partial x\partial y}\right)_0\right|^2\right]\iiint d\omega d\Omega d\Omega'\frac{e^{\hbar\omega/kT}}{e^{\hbar\omega/kT}-1}\frac{e^{\hbar(E_r/\hbar-\omega)/kT}}{e^{\hbar(E_r/\hbar-\omega)kT}-1}$$
$$\times\,\omega(E_r/\hbar-\omega)\sin^2\left(\frac{\boldsymbol{k}-\boldsymbol{l}}{2}\cdot\sigma\right)\sin^2\left(\frac{\boldsymbol{k}-\boldsymbol{l}}{2}\cdot\sigma'\right). \tag{B. 10}$$

We may put the first two factors of the integrand equal to one, since, we are interested in the temperature region much lower than the Debye temperature and since the frequencies of phonons under consideration cannot be much lower than the maximum Debye characteristic frequency by virtue of the energy conservation. This approximation leads to a temperature independent conversion rate. Integrations with respect to solid angles can be carried out easily and the result is

$$\mathrm{W}_i(2)=\frac{1}{81(2\pi)^3v^6\rho^2}C_i\left[\sum_{x,y,z}\left|\left(\frac{\partial^2 f_i}{\partial x\partial y}\right)_0\right|^2\right]\int_{\omega_r-\omega_D}^{\omega_D}\left[\frac{\sin(R_0\omega/v)}{R_0\omega/v}\right]\cdot\left[1-\frac{\sin\{R_0(\omega_r-\omega)/v\}}{R_0(\omega_r-\omega)/v}\right]$$
$$\times\,\omega(\omega_r-\omega)d\omega\,, \tag{B. 11}$$

where $\omega_r=E_r/\hbar$, $\omega_D=k\Theta_D/\hbar$ and $R_0$ is the equilibrium distance between neighbouring molecules. The above integration can be carried out numerically or graphically.

Since there are twelve neighbours for each molecule, we must multiply $W(2)$ by 12 for 100% ortho hydrogen and $12c^2$ for hydrogen with ortho concentration $c$.

Similar calculation can be performed for the probability of emission of three phonons. In order to avoid unnecessary complicacies of the calculation, we assume for $h\omega_r/k$ a value higher by 10 degrees than its actual value, thus making $\omega_r=2\omega_D$; the result for the probability should be somewhat greater than the actual one. The probability is given by

$$W(3)=\frac{2\hbar}{81\times9\times(2\pi)^5v^9\rho^3}\sum_i C_i\left[\sum_{x,y,z}\left|\left(\frac{\partial^3 f_i}{\partial x\partial y\partial z}\right)_0\right|^2\right]\int_0^{\omega_D}d\omega'\int_{\omega_r-\omega_D-\omega'}^{\omega_D}\omega\omega'(\omega_r-\omega-\omega')$$
$$\times\left[1-\frac{\sin(R_0\omega/v)}{(R_0\omega/v)}\right]\cdot\left[1-\frac{\sin(R_0\omega'/v)}{(R_0\omega'/v)}\right]\cdot\left[1-\frac{\sin\{R_0(\omega_r-\omega-\omega')/v\}}{R_0(\omega_r-\omega-\omega')/v}\right]d\omega\,. \tag{B. 12}$$

We must again multiply this by $12c^2$ in order to obtain the ortho-para conversion probability per molecule.

It is shown that the three-phonon process is much less important than the two-phonon process. In the above calculation of the three-phonon process we made the same assumption as that in the two-phonon process, i.e. we assumed that the number of phonons in thermal equilibrium is zero; actually, phonons in the neighbourhood of zero frequency play some role in the three-phonon process, and for these phonons the assumption is not valid. But the correction due to this circumstance will not appreciably change the magnitude of $W(3)$ and, since $W(3)$ is much less $W(2)$, this correction is not important.

There are many other processes: absorption of one phonon and emission of two phonons, emission of four phonons, absorption of one or two phonons and emission of three or two phonons, etc. All these processes are expected to give much less contributions to the ortho-para conversion rate than the two-phonon emission process.

# On Ferroelectric Barkhausen Pulses of Rochelle Salt

By Ryuji ABE

*Faculty of Science, Nagoya, University, Nagoya, Japan*

(Received July 19, 1955)

Ferroelectric Barkhausen pulses were observed when an electric field was applied on a rochelle salt crystal. The volume corresponding to a pulse and the dependence of the number of the pulse on temperature, humidity and strength of applied electric field were studied. It is found in the present experiment that the volume is the order of $10^{-9}$ cm$^3$ which is in accordance with Kojima and Kato's result. It is also found that the critical field at which pulses begin to take place is proportional to the $n$'th power of spontaneous polarization. The value of $n$ determined from the experiment is $2.7 \pm 0.5$. This result can be explained satisfactorily assuming that walls are stabilized at hollows in a crystal before a field is applied on the crystal.

## § 1. Introduction

Recently the domain structure and the movement of domain walls of rochelle salt were observed through the crossed nicols¹⁾. The direction of the spontaneous polarization is normal to $a$-plane and two neighboring domains have polarization of opposite sense, resulting in 180° boundary walls parallel to $b$- or $c$-planes. When an electric field is applied normal to $a$-plane, the walls parallel to $c$- and $b$-plane move in the directions of $b$- and $c$-axis, respectively. The movement of wall may cause a phenomenon similar to Barkhausen effect in ferromagnetic substances.

In 1933 M. Kluge and von H. Schönfeld²⁾ reported that they observed pulses similar to the ferromagnetic Barkhausen pulse when an electric field was applied on rochelle salt crystal. In 1935, however, Schönfeld assured³⁾ that these pulses were not Barkhausen pulse but they were caused by electric discharges through the gap between the crystal surface and the electrode. According to him the discharge began to take place at a certain voltage independent of the thickness of the crystal. The voltage estimated from his figure[2)]′ is about 100 volts for rochelle salt.

The true ferroelectric Barkhausen effect was reported by Newton, Ahearn and Mckey[4)] for barium titanate, and by Takahashi, Hara and Nakamura[5)] and Kojima and Kato[6)] for rochelle salt. They observed pulses quite different from Schönfeld noise. According to Kojima and Kato the volume corresponding to a pulse, i. e. the volume in which the polarization is reversed to produce a Barkhausen pulse, is the order of $10^{-8}$ cm$^3$. This volume is much smaller than the volume of a domain observed through the crossed nicols.

The present investigation was undertaken to clarify the cause of the ferroelectric Barkhausen pulse. The volume corresponding to a pulse and the dependence of the number of the pulse on temperature, humidity and strength of applied electric field were studied. From the analysis of the experimental results it is concluded that a pulse is not produced by an uniform motion of a boundary wall but it is produced by a jerky motion which occurs when a wall passes across a hollow in a crystal.

## § 2. Experimental

*Specimen* Crystals used in the present experiment are thin slabs normal to *a*-axis. Their thickness is 1 mm and their area is 1.2 × 1.2 cm$^2$. Silver electrodes were made by evaporation in vacuum on both sides of the slab. The thickness of the electrodes was about 500 Å and the area was about 1 × 1 cm$^2$. Since there is no gap between the electrodes and the slab, the evaporated electrodes are advantageous to avoid Schönfeld noise.

*Specimen chamber* To keep the temperature and the humidity constant during an experiment a crystal was set in a closed chamber in a thermostat (Fig. 1 (b)). The constancy of temperature was about ±0.1°C. The humidity in the chamber was controlled by changing concentration of sulfuric acid. Although humidity was not measured, fluctuation was inferred from the experimental results to be about 2%. To obtain more constant temperatures the other specimen chamber (Fig. 1(a)) was used although it could be used only at room temperatures.

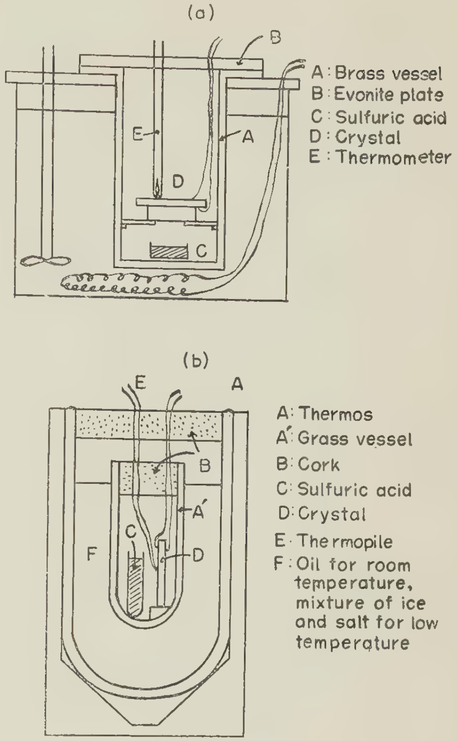

Fig. 1.

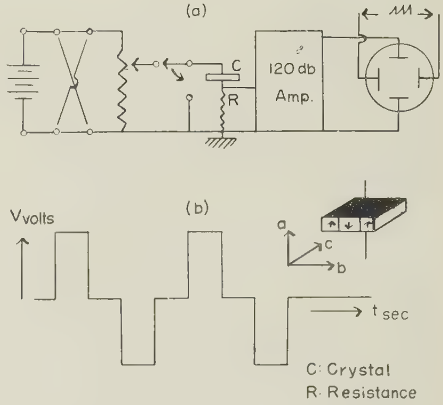

Fig. 2.

*Circuit* Since the pulse is very small, 120 db voltage amplifier was used. To remove the noises of external origins all instruments were shielded perfectly. The block diagram of the circuit is shown in Fig. 2 (a). The pulses produced in the crystal were introduced into the amplifier through the resistance *R* and the amplified pulses were applied to the longitudinal axis of C. R. O.. The horizontal axis was scanned by 1000 c. p. s. sawed pulses. To eliminate the fluctuation of line voltage the power was supplied into C. R. O. and the amplifier through a voltage stabilizer.

*Observation of pulses* The electric field applied to the crystal was raised step by step, for example 5 volts/cm for each step. The pulses begin to take place when the field is raised to about 30 volts/cm. The pulses take place also when the electrodes are shortcircuited after the application of a field. These pulses are smooth and generally separated one by one (Fig. 3), although sometimes a little more complicated pulses were observed (Fig. 3(d)). The figures 3(a) and 3(c) show the pulses observed when an electric field is applied, and 3(b) shows the pulses when the electrodes are shortcircuited. A pulse in 3(c) has a tail below the holizontal line. This tail was frequently observed when the pulse was high.

The pulses were not observed in paraelectric regions even when a considerably high field (about 100 volts/cm) was applied.

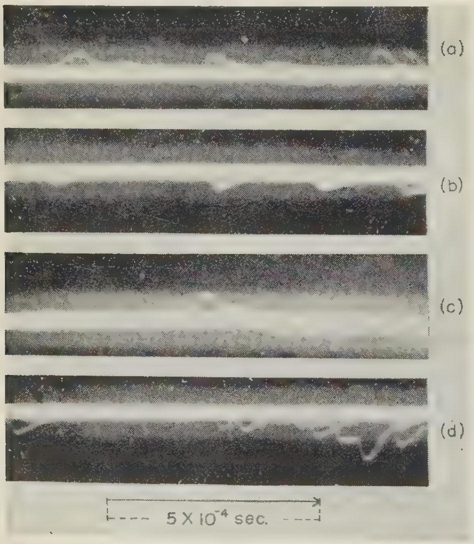

Fig. 3.

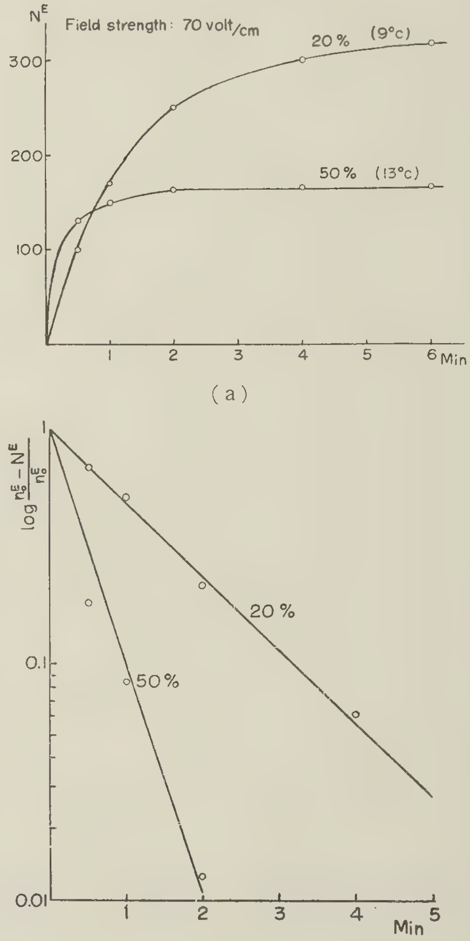
*Counting method* The number of pulses was counted by the naked eye. In the present experiment the number of pulses observed during 2 minutes was used as an indication of the total number of pulses under a certain field, since the frequency of the pulses decreases so rapidly after the application of the field that only a few pulses are observed after 2 or 3 minutes. To avoid irreversible results the alternative field as shown in Fig. 2(b) was applied. The mean value of the total number of pulses for both directions of a field was used as the final value, since the numbers of pulses appearing in these directions were not exactly equal.



(a)

(b)

Fig. 4.

## § 3. Behaviors of Pulses

*Total number of pulses* The total number of the pulses saturates exponentially with the lapse of time under a constant field (Fig. 4 (a)). This relation may be explained as follows:

Let us assume sources that produce pulses in a crystal and let the total number of the sources under a certain field $E$ be $n_0^E$. If we assume that a source disappears when a pulse is produced, then we get the relation

$$dn=nPdt$$

where $n$ is the number of the sources at the time $t$ and $P$ is the probability that a pulse appears in unit time under the field. If $P$ is independent of $n$, we get

$$n = n_0^E \exp(-Pt)\ .$$

Then the total number of pulses appearing during a period of time $t$ is

$$N_0^E = n_0^E(1-\exp(-Pt))\ .$$

This relation indicates that the total number saturates exponentially with time.

The experimental results in Fig. 4(a) are replotted in Fig. 4(b), the ordinate being log $(n_0^E - N^E)/n_0^E$ and the abscissa $t$. From the inclination of the lines the value of $P$ is determined. This value is about 3 $\sec^{-1}$ for 20% relative humidity and about 1 $\sec^{-1}$ for 50% relative humidity. Thus almost all the pulses appear within 2 minutes after the application of the field.

*Volume corresponding to a pulse* From the area of a pulse observed in C. R. O., the volume in which the polarization is revesed can be calculated as follows:[*]

The order of magnitude of the charge $q$ corresponding to a pulse is given as

$$q \sim (V/RA)\tau$$

where $V$ is the maximum voltage of a pulse in the C. R. O., $\tau$ the duration of the pulse, $A$ the amplification factor and $R$ the grid resistance of the first stage. If the thickness of the crystal is denoted by $L$ and the surface area by $S$, then the volume corresponding to a pulse is given by

$$v = q/q' \times L \times S$$

where $q' = S \times 2P_0$ and $P_0$ is the spontaneous polarization. Using the experimental values, $V \doteqdot 10$ volts, $A \doteqdot 10^6$, $R = 2.5 \times 10^5 \Omega$, $t \doteqdot 1/1000 \times 1/10$ sec, $L \doteqdot 0.1$ cm and $P_0 = 2.5 \times 10^{-7}$ coulomb /cm$^2$, the volume turns out

$$8 \times 10^{-10}\ \text{cm}^3 \sim 1 \times 10^{-9}\ \text{cm}^3\ .$$

This is much smaller than the volume of a domain which is the order of $10^{-5}$ cm$^3$.

*Relation between total number and applied field* Pulses are not observed at very low fields. They begin to take place at a certain field, e. g. about 30 volts/cm. The total number of pulses $n_0^E$ increases with the increase of the field and it begins to saturate at about 70 volts/cm (Fig. 5). Since the relation between $n_0^E$ and the field is almost linear at lower fields, the intersection of the line with the holizontal axis is called in this paper the critical field for the pulse.

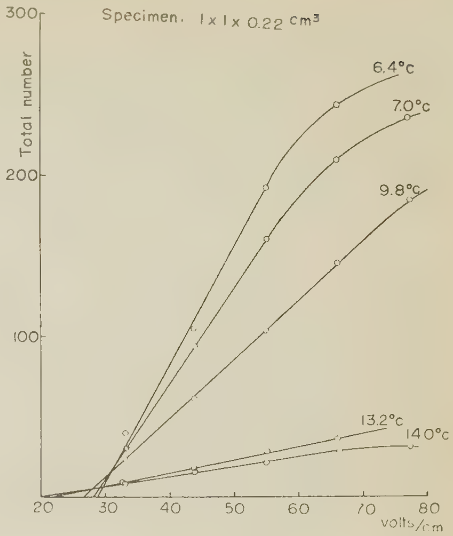


Fig. 5.

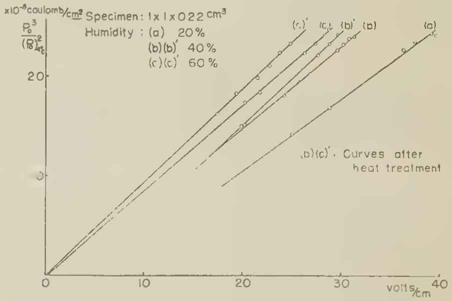

Fig. 6.

*Influence of humidity on the critical field* The dielectric constant and the piezo-electric modulus of rochelle salt change with humidity as reported by Kawai7). The critical field for the pulse also changes with humidity. It becomes lower with the increase of humidity under a constant temperature (Fig. 6).

*Influence of temperature on total number* It is recognized in Fig. 5 that the total number of pulses at higher fields decreases with the rise of temperature. This relation is reversed at temperatures lower than 0°C (Fig. 7). This behavior suggests that the total

---

[*] In the present experiment the time constant of the circuit containing the crystal is about $4 \times 10^{-5} \sim 8 \times 10^{-5}$ sec, if the dielectric constant of the crystal is assumed as 200～400. This is the same order as the period of time in which the pulse rises and falls (Fig. 3). This indicates that the time constant is really the same order as the duration in which the polarization is reversed abruptly.

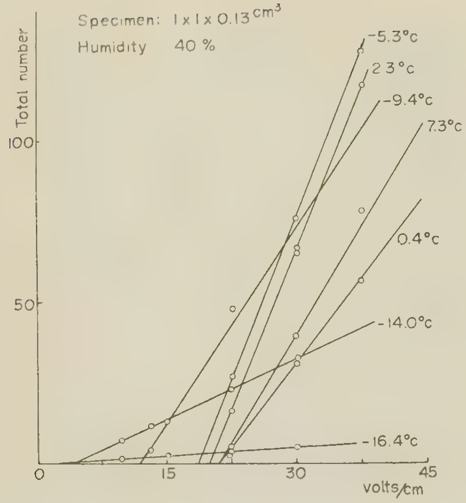

Fig. 7.

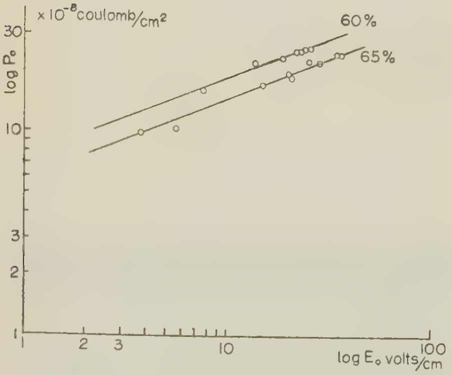

Fig. 8.

Table I.

| Experimental arrangement | Humidity | $n$ |
|---|---|---|
| Fig. 1 (a) | 60% | 2.7 |
| Fig. 1 (b) | 60% | 2.6 |
| | 65% | 2.5 |

number of pulses under a certain field is dependent upon the spontaneous polarization.

*Influence of temperature on the critical field* The critical field of the pulse $E_0$ is dependent upon temperature under a constant humidity (Fig. 6). If $\log E_0$ is plotted against $\log P_0$, a linear relation is found between them provided the humidity is higher than 60% (Fig. 8). This mean that there holds a relation $E_0=\text{constant}\times P_0^n$. The value of $n$ can be determined from the inclination of the line. A few examples of the value are given in Table I. The mean value of Table I is $\bar{n}=2.6$.

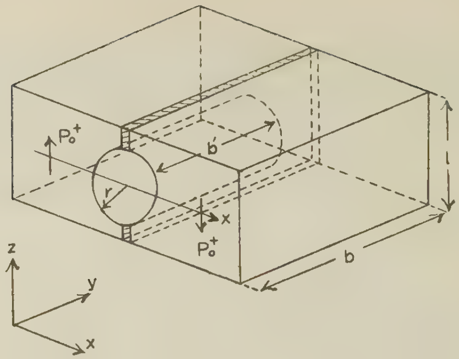

Fig. 9.

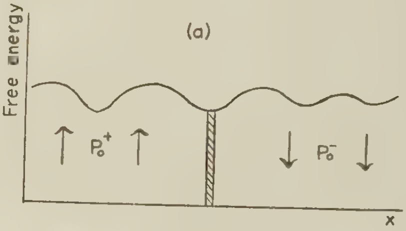
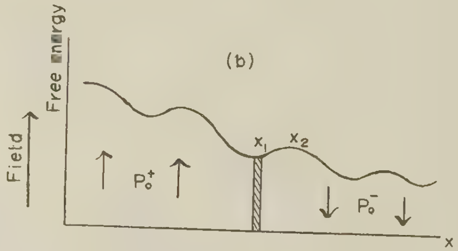


Before the application of a field



After the application of a field

Fig. 10.

It was observed that the critical field becomes lower soon after the crystal is heat-treated (see curve (b)′ and (c)′ in Fig. 6).

## § 4. Explanation of the Experimental Results

I) It is well known that there are many hollows in a rochelle salt crystal[8]. The hollow is generally cylindrical, having the radius of $10^{-4}\sim10^{-5}$ cm and the length of 1 mm$\sim10^{-4}$ cm and it is mostly extending to the direction of $c$-axis. If a boundary wall parallel to $c$-plane moves across a hollow by the application of a field, a pulse is caused with its movement because the potential energy of the wall is changed abruptly by the hollow. The volume corresponding to such a pulse can be roughly estimated by both the radius of a hollow and the surface area of a wall which moves cooperatively. If the value for the surface area obtained by the calculation in the next section is used, the volume turns out $10^{-8}\sim10^{-9}$ cm$^3$, which is the same order with the volume obtained from the experimental result. Thus the experimental result for the volume corresponding to a pulse can be explained favourably on the assumption that a pulse is caused when a wall passes across a hollow by the application of a field.

II) As known by the observation through the crossed nicols, there are many boundary walls in a crystal before the application of a field. These walls are generally arranged parallel to *c*-plane or *b*-plane with a little different intervals. If one of the walls passes through a hollow, it is stabilized at this hollow (Fig. 9) because the hollow cuts off a certain volume of the wall and therefore it decreases the potential energy of the wall (Fig. 10(a)). When a field is applied on the crystal, the potential energy changes and the wall moves as shown in Fig. 10(b). If the field becomes a certain strength, the wall can just leave the hollow and moves freely getting over other hollows. This motion of the wall results in pulses as explained before. Therefore the critical field for the pulse is identified with such a field that a wall can just leave a hollow first of all if it is assumed that all the walls are stabilized at hollows before the application of the field. Taking this assumption into consideration the relation between the critical field and the spontaneous polarization can be explained as given in the next section.

III) If a wall stays at a hollow before the application of a field, there are two causes which prevent the wall from its movement to leave the hollow by the application of the field. One of the causes is the increase of the wall energy and the other is the increase of the depolarizing field due to the charge produced on the hollow surface. The former is not influenced by humidity, but the latter is influenced severely because the higher humidity is, the faster the surface charge is neutralized by floating charges. Thus the increase of humidity facilitates the movement of a wall to leave a hollow by the application of a field. This tendency is in accordance with the one obtained from the experimental result. Therefore the experimental result can be explained qualitatively on a further assumption that the conductivity of the hollow surface is increased with the increase of humidity as well as the one of the crystal surface. In the calculation of the next section it is assumed that the critical field is not influenced by the surface charge. This assumption seems to be satisfied from the experimental result if humidity is higher than 60%.

Now let us summarize the assumptions necessary to explain all the experimental results.

1) All the walls in a crystal are stabilized at hollows before the application of a field.

2) A pulse is caused by the jerky motion of a wall passing across a hollow.

3) The critical field for the pulse is such a field that a wall can just leave a hollow first of all.

4) The conductivity of a hollow surface is increased with the increase of humidity as well as one of the crystal surface.

## § 5. Theoretical Treatment of the Relation between the Critical Field and the Spontaneous Polarization

For convenience of calculation let us assume only one wall and only one hollow in a crystal. The wall passes through the center of the hollow (Fig. 9) before the application of a field. Then the change of the free energy for a movement of the wall by a distance $x$ under a field $E$ is given by

$$F=2\sigma b'\left[\int_{-\Delta/2}^{\Delta/2}\sqrt{r^2-(x-r)^2}\,dx-\int_{x-\Delta/2}^{X}\sqrt{r^2-(x-r)^2}\,dx\right]-2EP_0\left(blx-2b'\int_{-\Delta/2}^{x-\Delta/2}\sqrt{r^2-(x-r)^2}\,dx\right) \tag{1}$$

where $r$ and $b'$ are the radius and the length of the hollow respectively; $b$, $l$ and $\Delta$ are the length, the thickness and the breadth of the wall respectively; $\sigma$ is the wall energy per volume. The value $X$ is $x+\Delta/2$ for $2r-\Delta/2\geq x>r$ and $r$ for $2r+\Delta/2\geq x>2r-\Delta/2$. The first bracketed term gives the increase of the wall energy and the second bracketed term the derease of the interaction energy between the polarization and the field. Since the relation $l\gg r$ ($\sim10^{-5}$ cm) is generally satisfied, the last term of the equation can be neglected. This equation has a minimum at $x_1$ for

$2r-(\varDelta/2)\geqq x>r$ and has a maximum at $x_2$ for $2r+(\varDelta/2)\geqq x>2r-\varDelta/2$ provided $E$ is constant. Thus the difference between the free energies at $x_1$ and $x_2$, $\varDelta F$, is the potential barrier for the wall. The value of $x_1^0$ and $x_2^0$ can be obtained by the following equations:

$$\sqrt{r^2-(x_1^0-r-\varDelta/2)^2}-\sqrt{r^2-(x_1^0-r+\varDelta/2)^2}=(E_0P_0bl)/(\sigma b') \quad (2)$$

$$\sqrt{r^2-(x_2^0-r-\varDelta/2)^2}=(E_0P_0bl)/(\sigma b') \quad (3)$$

where $x_1^0$ and $x_2^0$ is the values of $x_1$ and $x_2$ when $E$ is equal to the critical field $E_0$. If $\varDelta F$ becomes the same order of $kT$, the wall can get over the barrier in a few minutes. By putting $\varDelta F=kT$, we can get the critical field $E_0$:

$$kT=-2E_0P_0bl(x_2^0-x_1^0)+2\sigma b'\left[\int_{x_1^0-\Delta/2}^{x_1^0+\Delta/2}\sqrt{r^2-(x-r)^2}\,dx-\int_{x_2^0-\Delta/2}^{r}\sqrt{r^2-(x-r)^2}\,dx\right]. \quad (4)$$

It may be inferred that the $x_1^0$ and $x_2^0$ have the values nearly equal to $r$ because $kT$ is much smaller than the other terms in eq. (4).

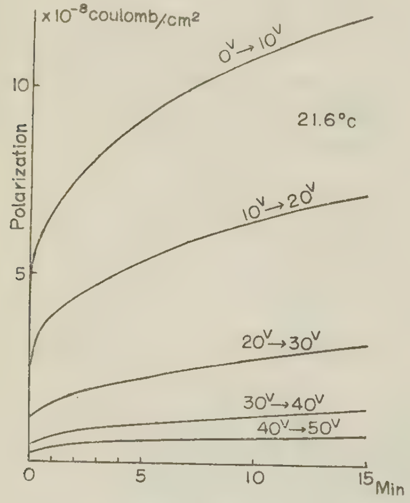


Fig. 11.

Putting $x_1^0=2r-\xi$, $x_2^0=2r-\eta$ and assuming $r\gg\xi$, $\eta$ and $\varDelta$, from eqs. (2), (3) and (4) we get

$$\xi=\varDelta/2+kT/(E_0P_0bl) \quad (5)$$

$$\eta=[(E_0P_0bl)/(\sigma b')-r\varDelta]/2r \quad (6)$$

and

$$[(E_0P_0bl)^2/((\sigma b')^2/2r)-\varDelta]^2-(2kTE_0P_0bl)/(r(\sigma b')^2)=0\,. \quad (7)$$

Since $\varDelta\geqq\left(\frac{E_0P_0bl}{\sigma b'}\right)^2\Big/2r$ from eq. (6), the second term in eq. (7) is smaller than $3\times10^{-22}/bl$ using the values $\varDelta=2\times10^{-7}$ cm, $r=10^{-5}$cm, $V\fallingdotseq1/10$ e. s. u., $P_0=760$ e. s. u. about at 4°C and $kT\sim10^{-13}$ e. s. u.. This value is much smaller than the value $\varDelta^2$ because $bl$ is much larger than $10^{-8}\,\text{cm}^2$ as proved later. Thus from eq. (7) we get approximate relation

$$\varDelta=\left(\frac{E_0P_0bl}{\sigma b'}\right)^2\Big/2r \quad (8)$$

Substituting the relation $r=\frac{8}{3}P_0^3\sqrt{cd}$ and $\varDelta=\frac{2}{P_0}\sqrt{\frac{c}{d}}$ obtained by Mitui and Furuichi[9)] into (8), the wall energy per volume comes out

$$\sigma=\gamma/\varDelta=4/3\,d\,P_0^4$$

where $c$ and $d$ are certain constants. Using this $\sigma$ and $\varDelta$, eq. (8) becomes

$$E_0bl=\frac{4}{3}\,dP_0^3b'\sqrt{2r\varDelta}=\frac{8}{3}\sqrt{r}\,d^{3/4}c^{1/4}b'P_0^{2\cdot5}\,.$$

Assuming that $c$, $d$ and $b'$ are independent of temperature, $E_0$ changes proportional to $p_0^{2\cdot5}$. This agrees with the experimental result within the error. Using $d\fallingdotseq6\times10^{-7}$ and the previous values, we get

$$bl\fallingdotseq6\times10^{-3}b'\,.$$

If we assume that $b'=0.1$ cm and $b=0.5$ cm, then $l\fallingdotseq10^{-3}$ cm which satisfies the condition $l\gg r$. The area $bl$ may be considered as the area which moves cooperatively under a constant field.

## § 6. Discussion

1) As calculated in § 3, a volume corresponding to a pulse is the order of $10^{-9}\,\text{cm}^3$. This is much smaller than the volume of a domain which is the order of $10^{-5}\,\text{cm}^3$. Kojima and Kato reported that a volume corresponding to a largest pulse is the order of $10^{-8}\,\text{cm}^3$. This value is in good accordance with the value obtained in this experiment.

2) According to the assumption described in § 4, a close relation is expected between the polarization charge and the number of pulses because both the charge and the pulses are caused by the movement of walls. Although the polarization charge is not studied in the present experiment, its variation with time was already studied by Takahashi and Hara[10)] (Fig.

11). This curve agrees qualitatively with the curve of the total number of pulses which is shown in Fig. 4(a). This indicates that our assumption is correct.

## § 7. Summary

1) When a field is applied on a crystal of rochelle salt, the pulses different from Schönfeld noise are observed.

2) The volume corresponding to such a pulse is the order of $10^{-9}$ cm$^3$.

3) With the increase of the applied field the total number of pulses increases but begins to saturate at about 70 volts/cm. This indicates that the source of the pulse is finite. The maximum number observed on C. R. O. is about 400 for the crystal the volume of which is about $1\times1\times0.1$ cm$^3$.

4) The critical field for the pulse decreases with the increase of humidity. This effect can be explained taking account of the influence of humidity on the conductivity of the hollow surface.

5) The relation between the critical field $E_0$ and the spontaneous polarization $P_0$ is given by $E_0=\alpha P_0{}^n$ where $\alpha$ is a constant and $n=2.7\pm0.5$. This result can be explained on the assumption that all the walls are stabilized at the hollows before the application of a field.

6) A pulse observed in the present experiment may take place by the jerky motion of a wall when it passes across a hollow.

7) The critical field changes a little by the heat-treatment for the same crystal, for example a few volts/cm at 4°C.

Finally the author wishes to express his appreciation to Professor Ryozi Uyeda for his encouragement and to Mr. H. Yoshioka for his helpful discussions. This work was supported partly by the Scientific Research Fund of the Ministry of Education.

# Experimental Evidence for the Collective Nature of the Characteristic Energy Loss of Electrons in Solids

## —Studies on the Dispersion Relation of Plasma Frequency—

By Hiroshi WATANABE

*Hitachi Central Research Laboratory, Kokubunji, Tokyo, Japan*

(Received September 17, 1955)

The energy loss of 25 kv. electrons was studied by a modified velocity analyzer of Möllenstedt type. By means of the analyzer we obtained the diagram which shows the variation of energy loss with the scattering angle. The specimens studied were Be, Mg, Al, Ge and C (graphite).

In the diagram we classified six types of patterns in which two are of the fundamental importance: (1) The first type is the sharp energy loss lines such as first discovered for Al and Be by Ruthemann. In the present experiment it was found that the value of energy loss of these lines increases with the scattering angle. To represent this relation an emprical formula was established. On the other hand, a theoretical formula was derived from the dispersion relation in Bohm-Pines' plasma oscillation theory. These two formulas are in good agreement for the lines of Be (19 ev), Mg (10.3 ev) and Al (14.8 ev). This agreement proves most decisively that the sharp lines are caused by the excitation of the collective plasma oscillation. For Ge (16.4 ev) and C (7.3 ev) the agreement is less perfect. (2) The lines of second type are observed at 23 ev for Al and 25 ev for C. They are rather diffuse and their energy losses do not vary with the scattering angle. The author attributes them to the excitation of individual electrons in energy bands. The value 23 ev for Al is in agreement with the energy difference between the large peaks in the fine structure of L-absorption edge.

According to the theory the curving and the position of the patterns in the first type are insensitive to the temperature of the specimen, being in agreement with the experiment.

## § 1. Introduction

Experiments on the energy analysis of electrons which have passed through thin foils were originally carried out by Ruthemann[1] and Lang[2]. They observed several equally spaced sharp lines in the energy spectrum from Be and Al, which lines indicate that incident electrons lose their energy in integral multiples of a sharply defined basic unit. Comparing the observed energy losses with the fine structures of $K$-absorption edge, Cauchois[3] suggested that such losses might be caused by the excitation of metal electrons from the occupied band to unoccupied ones. Although her suggestion seemed to be reasonable at first, the sharpness of the lines can hardly be explained because the unoccupied bands in metals are much broader than the observed breadth (3 or 4 ev) of lines. On the other hand Bohm and Pines[4][5] proposed that such an energy loss is caused by the excitation of a collective plasma oscillation of electron gas in metals, the angular frequency of which is $\omega_p$. They noted that the calculated values of the fundamental quantum of energy loss ($\hbar\omega_p$) are in remarkably good agreement with the observed values. Following this interpretation we can easily understand the sharpness of the lines which is difficult to be explained by Cauchois' suggestion.

Utilizing the high chromatic aberration of an electrostatic lens Möllenstedt[6] devised a new velocity analyzer of extremely high resolution. Using the analyzer of his type energy losses in numerous substances have been studied in detail by several authors[7][8][9]. Based upon these studies the substances can be classified into two groups. In the first group loss values are in good agreement with $\hbar\omega_p$ which is given by Bohm-Pines' theory, and in the second they are in no agreement. Elements Be, Mg, Al, Ta and Mo belong to

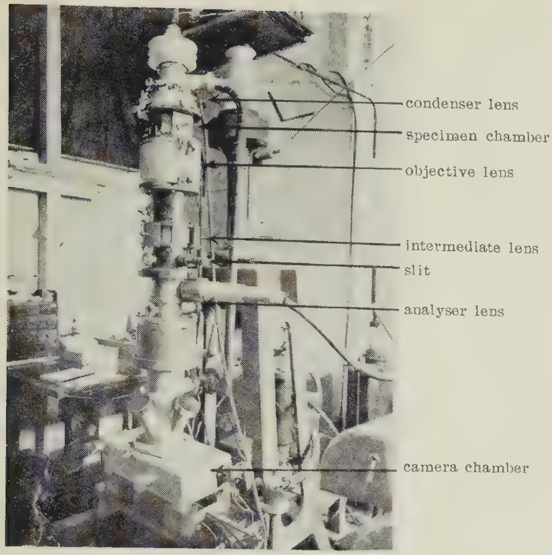

Fig. 1 a. A photograph of the velocity analyzer used in this experiment.

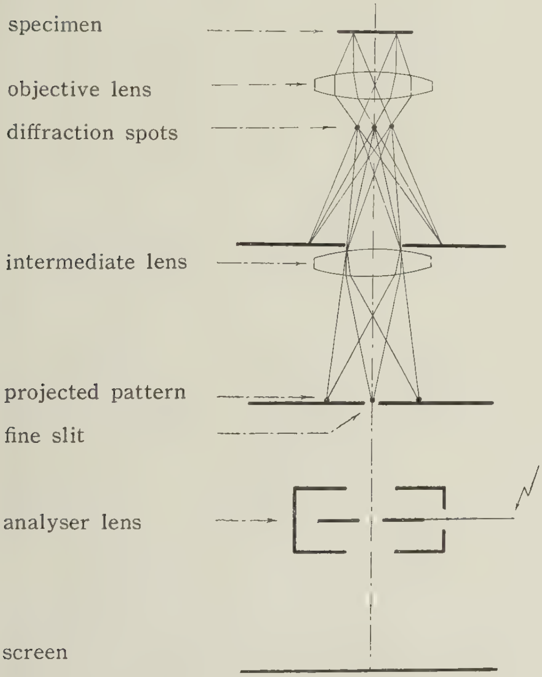

Fig. 1 b. A schematic diagram of the electron optical system.

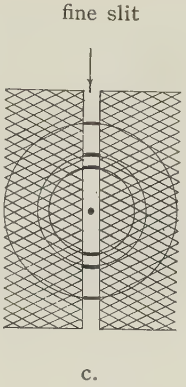
the first, and noble metals and transition metals to the second. In this classification $\hbar\omega_p$ is calculated under the assumption that the valence electrons are all free. Since this assmption is not always adequate, it cannot be decided whether the plasma oscillation is actually the caused of the energy loss or not.



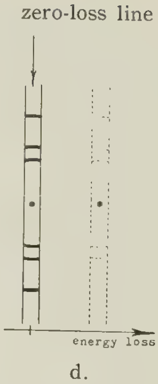


Fig. 1 c. A diffraction pattern on the fine slit plane.

Fig. 1 d. The energy loss spectrum. Rings drawn by dotted lines are due to the inelastically scattered electrons losing a certain discrete energy.

In the experiments mentioned above, the energy loss was measured for electrons which are scattered in a small angle of ca. $10^{-2}$ rad. Recently Leonhard[10] and the present author[11] studied the angular dependence of the energy loss up to $10^{-1}$ rad., using a modified velocity analyzer of Möllenstedt type. The author found that the energy loss increases with the scattering angle for the sharp lines which were originally found by Ruthemann and Lang. Kanazawa[12] has pointed out to the author that such dependence can be interpreted by the dispersion relation in Bohm-Pines' theory (see eq. (67) in reference (5),).

In this paper the author describes in detail the angular dependence of energy loss of the sharp lines, and comparing the experimental results with Bohm-Pines' theory he concludes that the sharp lines are caused by the excitation of plasma oscillation.

## § 2. Experimental Procedure

Figure 1a shows a photograph of the velocity analyzer used in this experiment and Fig. 1b a schematic diagram of its electron optical system. A diffraction pattern on the back focal plane of the objective lens is imaged by an intermediate lens on a plane with a fine slit. The electrons forming the pattern have various energy values owing to the inelastic collisons in the specimen. The velocity of the electrons which have passed through the slit is analyzed by an analyzer lens. The analyzer lens is a cylidrical unipotential electrostatic lens with rectangular electrode apertures, the same as that original-

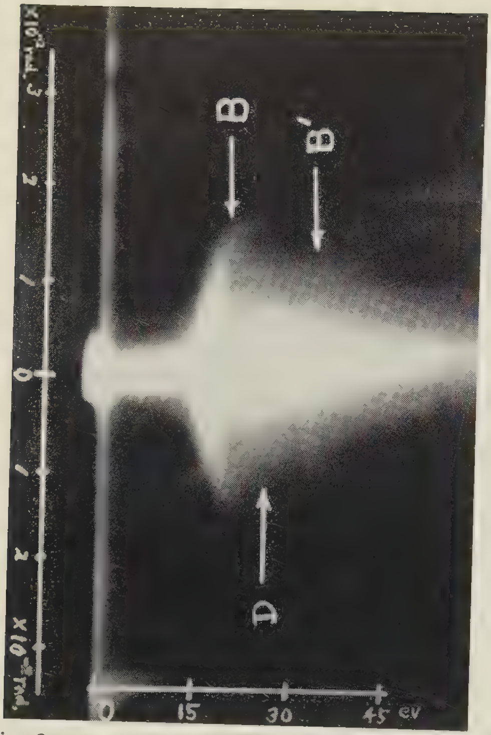

Fig. 2 a. An energy loss spectrum from Al corresponding to Fig. 1 d.

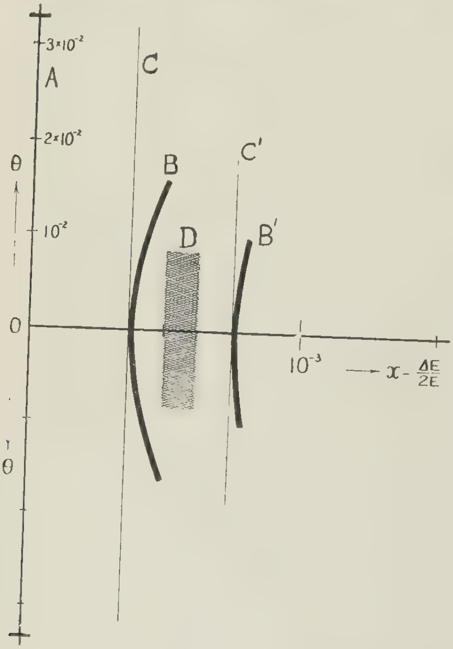

Fig. 2 b. The loss-angle diagram constructed from Fig. 2 a.

ly devised by Möllenstedt.

Figure 2a shows an example of energy spectra obtained in the energy analysis. From this photograph we make a diagram the abscissa of which is $x = \Delta E/2E$ and the ordinate the scattering angle $\theta$, where $\Delta E$ is energy loss and $E$ the accelerating voltage. In this paper we call this diagram a "loss-angle diagram". The energy loss is calibrated by a known accelerating voltage difference. The scattering angle is obtained from the radii of diffraction rings. The accelerating voltage used in this experiment was 25 kv, and the least detectable energy difference was ca. lev.

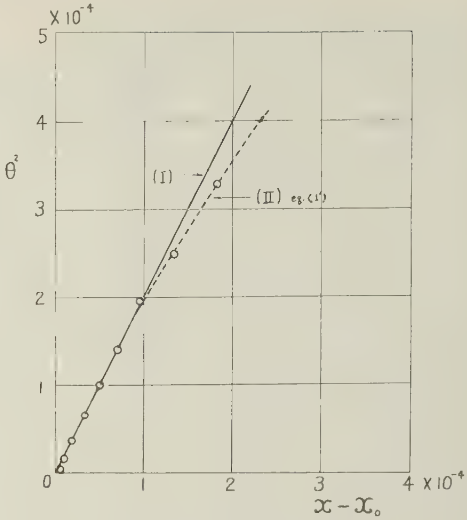

Fig. 2 c. Relation between $\theta^2$ and $(x - x_0)$. ○: experimental point.

Specimen examined were prepared by evaporation in vacuum higher than $10^{-4}$ mm Hg, as determined by an ionization gauge. The evaporated metal was condensed on a slide glass coated with collodion. To eliminate the effects of the collodion the slide was then immersed in 50% ether-alcohol to free the evaporated film from its backing. The unbacked metal foils were mounted on sheet meshes of copper. Thicknesses of the foils ranged from 150Å to 250Å. In the case of Mg we used very thick foils (ca. 500 Å) to avoid the influence of oxides covering the film. We examined each foil by the electron diffraction method and used only those foils which give few rings of the oxides.

Sometimes the electron optical system was changed as shown in Fig. 3 so that the specimens can be heated. In this system the diffraction pattern was reduced by the intermediate lens so that the electron beam enters into the analyzer with an angular

divergence as small as possible. The temperature of the specimen is measured by a Cu-Pt thermocouple attached to the copper mesh. The thermocouple was calibrated by the melting points of Sn and Pb which were placed at the position of the specimen.

## § 3. Experimental Results

Figure 2a is an example of photographs obtained from Al foil. Figure 2b is the loss-angle diagram obtained from Fig. 2a. In this diagram there are contained all of the typical patterns as denoted by A, B, B′, C, C′ and D.

The patterns B and B′ are of the fundamental importance in the following interpretation of the patterns. They indicate that the energy loss increases with the scattering angle. The discrete energy loss obtained in all the previous experiments is the energy loss of electrons averaged over the scattering angle of ca. $10^{-2}$ rad. The pattern $B'$ is a discrete energy loss which is about twice of loss of B, and the curvature at its vertex is smaller than that of B.

In order to treat quantitatively the relation between the energy loss and the scattering angle, we assume the empirical formula

$$(x-x_0)=a\cdot\theta^2+b\theta^4+\cdots\cdots \qquad (1)$$

where $x_0$ represents $x$-coordinate of the vertex of the pattern. To determine the coefficients $a$ and $b$, $\theta^2$-values are plotted against $(x-x_0)$-values. An example is shown in Fig. 2c which corresponds to the pattern B in Fig. 2b. A linear relation between $\theta^2$ and $(x-x_0)$ holds in the range of $(x-x_0)$ $<1.0\times10^{-4}$ (line (I) in Fig. 2c), the tangent of this line giving the value of $a$. The coefficient of $\theta^4$ term is determined by the magnitude of the deviation of the experimental points from the line (I). The curve (II) in Fig. 2c represents

$$(x-3.0\times10^{-4})=0.5\cdot\theta^2+3\times10^2\cdot\theta^4. \qquad (1')$$

The experimental points lie on curve (II) in the range of $(x-x_0)<2.0\times10^{-4}$. The pattern B fades out into the background at about $\theta$ $=1.5\sim1.8\times10^{-2}$ rad. Table I gives the value of $a$ and $b$ as well as $x_0$ for the patterns $B$ and $B'$ of Be, Mg, Al, Ge and C (graphite).

Table II gives the values of $a$ and $x_0$ for Al under various temperatures. It is easily concluded from this table that $a$ and $x_0$ do not depend on the temperature of the specimen.

The pattern D is an energy loss line which is distinguished from $B$ or $B'$ by its straightness and diffusedness. This straightness indicates the energy loss concerned is independent upon the scattering angle. For Al the energy loss of this type is 23 ev. Patterns of this type are observed also for collodion (21.2 ev), MgO (11.4 ev), MoS$_2$ (8.7, 22.8 ev), Ag(25 ev) and Au(25 ev).

## § 4. Interpretation of the Patterns

### *4·1* Pattern B

### *4·1·1* Theory

Let us assume that an incident electron of

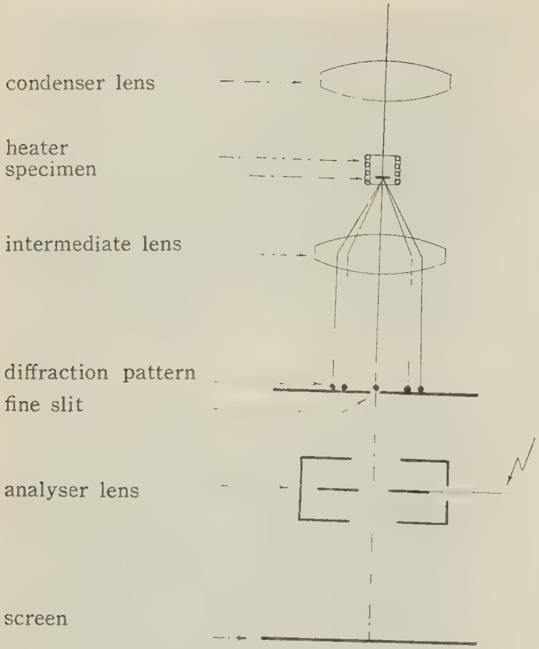

Fig. 3. A schematic diagram of the electron optical system in the arrangement for specimen heating. An electron diffraction specimen holder with a heater is inserted between the condenser and intermediate lenses.

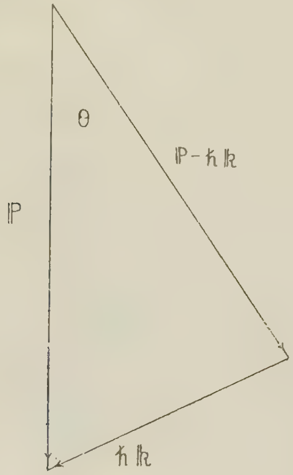

Fig. 4. Illustration of the momentum relation of the electron before and after the collision.

energy $E$ excites a plasma oscillation of frequency $\omega$ in the electron gas, thus it loses energy quantum of $\hbar\omega$ and is scattered into a direction $\theta$ from the incident direction. We will derive a relation between the scattering angle $\theta$ and the energy loss $\hbar\omega$ from the law of momentum conservation. When the momentum of the incident electron $p$ is large compared with $\hbar k$ we have the relation

$$p\theta=\hbar k \tag{2}$$

where $k$ is the wave number of the excited plasma wave. The dispersion relation of the plasma frequency is given by Bohm and Pines (see eq. (67) in reference (5)) as follows,

$$\omega=\omega_p+\frac{k^2}{m\omega_p}\cdot\frac{1}{n}\sum_i\frac{P_i^2}{2m}+\frac{\hbar^2k^4}{8m^2\omega_p} \tag{3}$$

where

$$\omega_p=\sqrt{4\pi ne^2/m}$$

$n$: density of free electrons
$P_i$: momentum of $i$-th electron
$e, m$: charge and mass of the free electron.

Substituting $k$ from eq. (2) into (3) we have

$$\hbar\omega=\hbar\omega_p+\alpha\frac{p^2}{m}\theta^2+\frac{p^4\theta^4}{8m^2\hbar\omega_p} \tag{4}$$

where

$$\alpha=\frac{1}{n}\sum_i\frac{P_i^2}{2m}\Big/\hbar\omega_p\,. \tag{5}$$

Introducing a dimensionless variable

$$x=\frac{m\hbar\omega}{p^2}=\frac{\hbar\omega}{2E}\quad\left(E=\frac{p^2}{2m}\right) \tag{6}$$

and a dimensionless constant

$$x_0=\frac{m\hbar\omega_p}{p^2}=\frac{\hbar\omega_p}{2E} \tag{7}$$

we have

$$x-x_0=\alpha\theta^2+\frac{\theta^4}{8x_0}\,. \tag{8}$$

Adopting the free electron model of metal, we can easily calculate the numerator of the expression of $\alpha$[13],

$$\frac{1}{n}\sum_i\frac{P_i^2}{2m}=\frac{3}{5}\varepsilon_0'\left[1+\frac{5}{12}\pi^2\left(\frac{kT}{\varepsilon_0'}\right)^2\right], \tag{9}$$

where

$$\varepsilon_0'=\frac{1}{2}\frac{\hbar^2}{m}\left(\frac{3n}{8\pi}\right)^{2/3}. \tag{9'}$$

### *4·1·2* Comparison with experiment

Equation (8) has the same form as the empirical formula (1). In Table I the theoretical values of $\alpha$, $1/8x_0$ and $x_0$ are compared with the experimental values of $a, b$ and $x_0$, respectively. Agreements between these values are good enough for Be, Mg and Al to conclude that the pattern B is caused by the excitation of a plasma oscillation.

For Ge and C (graphite) the agreement is less perfect, especially the experimental value of $x_0$ for graphite is much smaller than theoretical value. This may be attributed to the inadequacy of the free electron model adopted.

### *4·1·3* Temperature dependence

As given in Table II the position and shape of the pattern $B$ in Fig. 2 are independent of the temperature of specimen. This temperature independence is easily understood when we refer to eqs. (5), (7), (8) and (9). Equation (7) and (3′) show that the position of the pattern depends upon the temperature only through $\sqrt{n}$, which decreases with increasing temperature,

$$\sqrt{n}=\sqrt{n_0}\cdot\left(1-\frac{3}{2}\alpha_l T\right) \qquad (10)$$

where $n_0$ means the electron density at 0°K and $\alpha_l$ the linear expansion coefficient. For Al ($\alpha_l=2.3\times10^{-5}$ deg.$^{-1}$) we have

$$\frac{3}{2}\alpha_l T=3\times10^{-2} \qquad (11)$$

at 1000°K. This is too small to be detected in our analysis.

The shape of the pattern is determined by the dispersion coefficient $\alpha$ which contains explicitly the temperature T (cf. eq. (9)). The temperature dependent term $\frac{5}{12}\pi^2\left(\frac{kT}{\mathcal{E}_0'}\right)^2$, however, is extremely small even at 1000°K for most metals. For example, with $\mathcal{E}_0'=11.7$ ev for Al, we have at 1000°K

$$\frac{5}{12}\pi^2\cdot\left(\frac{kT}{\mathcal{E}_0'}\right)^2=5\times10^{-4}\,. \qquad (12)$$

This is also beyond the resolution of our analyzer. Thus the temperature dependence of the position and the shape of the pattern are indetectable by means of our instrument, being in agreement with the experiment.

### *4·1·4* Maximum scattering angle

Ferrell[14] has pointed out that such a loss-angle diagram as Fig. 2a provides us with an information as to the critical wave number $k_c$ for collective plasma oscillation. Here, $k_c$ is defined as $2\pi/\lambda_c$, and the critical wave length $\lambda_c$ is nearly equal to Debye length $\lambda_D$. A plasma oscillation with the shorter wave length than $\lambda_c$ can not be excited in solids. Based upon eq. (2) we expect that the maximum scattering angle $\theta_c$ is

$$\theta_c=\frac{\hbar k_c}{p}\,. \qquad (13)$$

The maximum wave number $k_c$ is given by Bohm and Pines[15] as follows,

$$k_c=0.353\ (r_0/a_0)\cdot k_0 \qquad (14)$$

where $k_0$ is the wave number of an electron at the top of the Fermi distribution, $r_0$ is the interelectronic spacing defined by

$$n=(4\pi r_0^3/3)^{-1}, \qquad (15)$$

and $a_0$ is Bohr radius. For Al we calculate $\theta=1.1\times10^{-2}$rad. for 25 kv electrons. This is to be compared with the maximum angle at which the pattern $B$ fades away into background. As given in the preceeding section, the maximum scattering angle measured in Fig. 2a is 1.5∼1.8×10$^{-2}$ rad. which is somewhat larger than the theoretical value.

### *4·2* Pattern B′

It is evident that in passing through a solid an incident electron undergoes more than one collision unless the solid is very thin. As an electron scattered inelastically in a direction $\theta$ with an energy loss of $\hbar\omega$ proceeds through the specimen, the second chance of the electron surffering the similar process of inelastic scattering occurs. As illustrated in Fig. 5 the dependence of the energy loss upon the scattering angle in such double scattering process is represented approximately by a parabola similar to B, the vertex of which is situated on a parabola ($B''$ in Fig. 5)

$$(x-2x_0)=\alpha\theta^2\,. \qquad (16)$$

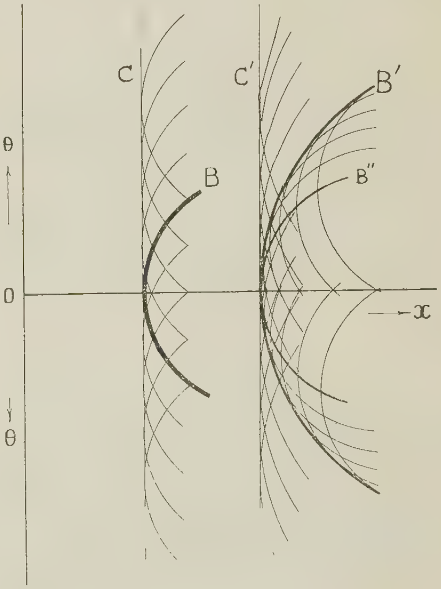

Fig. 5. Illustration of the arc $B'$ and lines $C$, $C'$.

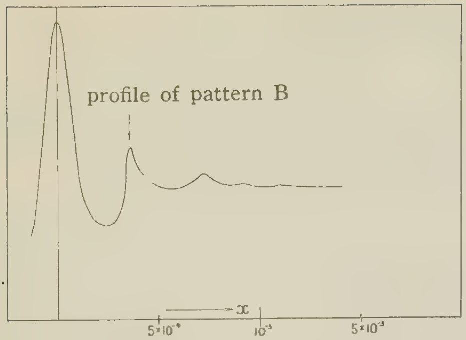

Fig. 6 a. An intensity distribution curve obtained along the $x$-axis in Fig. 2 a. The arrow indicates the position of arc $B$.

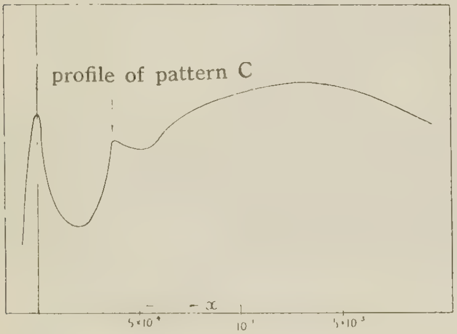

Fig. 6 b. An intensity distribution curve obtained along a straight line of $\theta=2\times10^{-2}$ rad. The arrow indicates the position of line $C$.

(We will neglect the small $\theta^4$ term in the following discussions.) If the envelop of a group of such parabolas is observed as the arc of $B'$ type, the equation representing the envelop becomes

$$(x-2x_0)=\frac{\alpha}{2}\theta^2 . \qquad (17)$$

Thus the coefficient $a$ for B patterns is twice that of $B'$. Since. however, the brightness of each parabola is largest at the vertex, we may observe an intermediate curve which lies between two parabolas of eqs. (16) and (17). In Table I we see that the ratio of the coefficients of $B$ and $B'$ is 1.6 for Al as well as for Mg.

### *4·3* Pattern *D*

The loss line of $D$ type is characterized by its straightness and diffusedness. This can be interpreted as due to the excitation of the conduction electrons to the allowed unoccupied levels. The fact that in the fine structure of the $L$-absorption edge of $X$-ray in Al there is a relatively large absorption peak at an energy distance of 23 ev[16) from the edge may support this explanation.

For Ag and Au we observed diffuse and straight patterns similar to D. It is, however, premature to conclude that they are caused by interband transitions because the plasma oscillation should be excited in these metals. The diffusedness may be due to some unknown factors and the curving is not observed because of the diffusedness.

### *4·4* Other Patterns

The line $A$ represents the angular distribution of scattered electrons the energy loss of which is less than 1 ev. The bright parts on this line give the positions of diffraction rings, by which we can determine the scattering angle.

For the interpretation of the parallel lines $C$ and $C'$ in Fig. 2b we have to take into account the double or triple scattering of the incident electrons. Electrons scattered onto a point $(0, \theta_1)$ on the line A in Fig. 2b undergo the secondary inelastic collision losing an energy quantum of $\hbar\omega$. Since the secondary inelastic collision process gives the similar angular distribution of scattered electrons as in the case of direct excitation of the plasma oscillation, the resulting angular dependence of the double scattering is obtained from eq. (8) to give

$$(x-x_0)=\alpha(\theta-\theta_1)^2 . \qquad (18)$$

As is illustrated in Fig. 5, the line $C$ is thought to be the envelop of a group of these parabolas

$$(x-x_0)=0 . \qquad (19)$$

The pattern $C'$ can be interpreted by the similar consideration. In this case, of course, one more inelastic collision process must be taken into account.

Although in the above consideration we took only elastic-inelastic process, the reverse inelastic-elastic process is also possible.

An experimental evidence in support of the above consideration is given by a comparison of relative intensity curves obtained along the $x$-axis with that along a straight line of $\theta=2\times10^{-2}$ rad. in Fig. 2a. The curves are reproduced in Fig. 6. The peak indicated by an arrow in Fig. 6a represents a profile of a section of pattern $B$ cut along $x$-axis and slopes to the larger $x$ side by a steeper des-cent in comparison with the case of the peak corresponding to *C* in Fig. 6b. Such a difference in the slopes of the two intensity curves can be easily explained by adopting the above interpretation for line *C*. (see Fig. 5).

## § 5. Discussions

As stated in the introduction two ways of explanation are proposed concerning the origin of energy losses of electrons. The one is that the losses are caused by the interband transitions and the other is that by the excitation of collective plasma oscillation. It was not yet decided which theory is adequate for the interpretation of a loss line.

Only by the coincidence of the observed values of the loss with the calculated values it is difficult to conclude that the energy loss is due to the plasma oscillation, because the assumption under which the calculation is carried out is not always adequate. And we can not derive a decisive conclusion from the breadth of the lines because of the lack of the knowledge about it. Wolff(17) has suggested that the breadth of plasma lines should increase from element to element as the 3d shell is filled in the transition metals Sc–Ni. This suggestion, however, was not supported by experiment(7)(13), and we failed to decide whether the lines are due to the plasma oscillation or not, by this suggestion.

In the present experiment the curving of the patterns *B* and *B'* is observed. Based upon the plasma oscillation theory we explained curving as described in § 4. It is difficult to see how an angular distribution like this can be reconciled with interband transitions, since it has its origin in the $k^2$ term in the dispersion relation, (3). Thus the sharp lines observed in Mg, Be, Al and etc. are without doubt caused by the excitation of plasma oscillation.

We observed also the diffuse and straight lines in the loss-angle diagrams. These lines are conceivable as due to the interband transitions, being in agreement with the observation of the fine structure of *L*-absorption edge.

## § 6. Acknowledgement

The author is indepted to Prof. H. Kanazawa of Tokyo University who kindly suggested the interpretation of the pattern *B* to the present author, and also to Dr. N. Kato of Kobayashi Institute of Physical Research and Prof. R. Uyeda of Nagoya University for the helpful discussions. It is a preasure of the author to express his appreciation to Drs. D. Pines and R. A. Ferrell for their kind criticism and encouragement. The author is grateful to Dr. B. Tadano and Mr. N. Morito for their encouragement throughout this study.

# Observation of Dislocations in Silver Halides
## Part I. Annealed Crystals

By Hiroshi KANZAKI

*Institute of Industrial Science, University of Tokyo, Chiba, Japan*

(Received August 5, 1955)

It has been concluded that the distribution of both the printed-out silver particles and the chemical etching pits reveals that of dislocations in annealed crystals of silver chloride. In the crystals with (110) surfaces, however, the existing dislocations do not contribute to the formation of silver particles and in those with (100) surfaces the existing dislocations do not produce etch pits. The necessary condition for the formation of silver has been concluded to be the existence of extra effective charge on the surface of the crystal.

## § 1. Introduction

Hedges and Mitchell[1] have found that the printed-out silver particles precipitate at the dislocations in polygonized crystals of AgBr and thus have succeeded in observing the distribution of dislocations inside the crystals for the first time.

On the other hand, several experimental results[2] have shown that the dislocations can produce "chemical etching pits" at the surface.

In this part of the article, the observation of both the printed-out silver particles and the etch pits is adopted for the direct examination of dislocation patterns in annealed crystals of AgCl. Special attention will be paid to the following problems:

(1) What is the mechanism which enables us to see the dislocations?

(2) What is the origin of existing dislocations?

## § 2. Experimental Procedures

### 2-1. Specimens

Powders of AgCl were specially prepared by Dr. Koseki of the Research Laboratory, Fuji Photo Film Co., Ltd..

The specimens were prepared by the gradual solidification from the melt. The procedures in making crystals are schematically shown in Fig. 1. and carried out in the following ways.

(1) Powders of AgCl have been melted in the crucible of Pyrex glass as shown in Fig. 1 (a).

(2) By reducing the temperature, the solid crystals are grown under considerable temperature gradient in 20 to 30 minutes (shown in Fig. 1(b) and (c)).

(3) Liquid AgCl is removed out from the crucible and solid crystals remain as attached to the wall of the crucible as shown in Fig. 1(d).

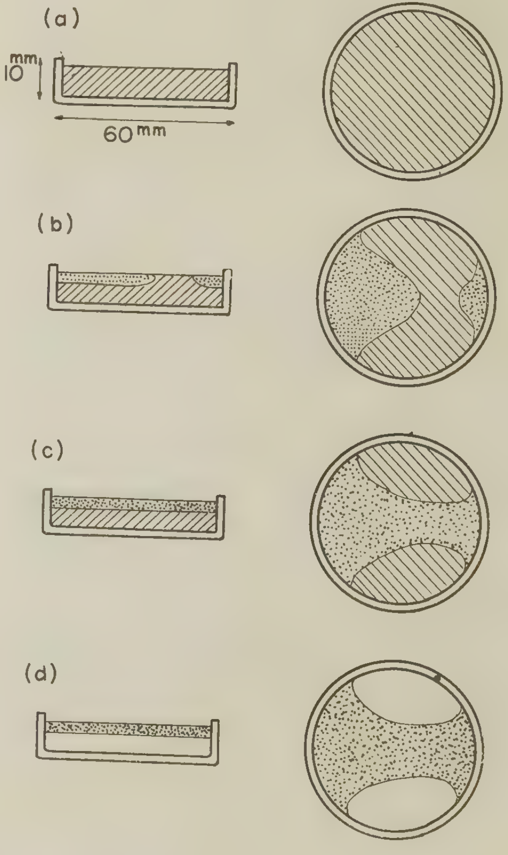

Fig. 1. Procedures of preparing the "usual crystals" of AgCl from the melt. Hatched areas; molten AgCl, dotted areas; solid AgCl.

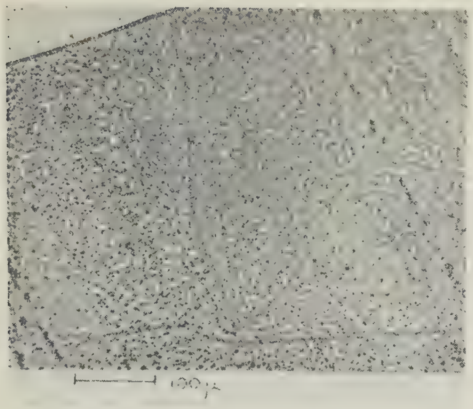

Photo. 1. Printing-out pattern of the "usual crystal" with (100) surface. Left-upper corner is the crystal with (110) surface.

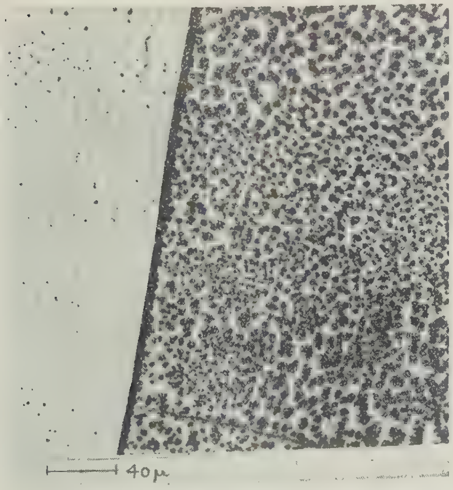

Photo. 3. Printing-out pattern near the grain boundary of the "usual crystal". The right-hand grain has (100) surface and the left-hand one has (110) surface.

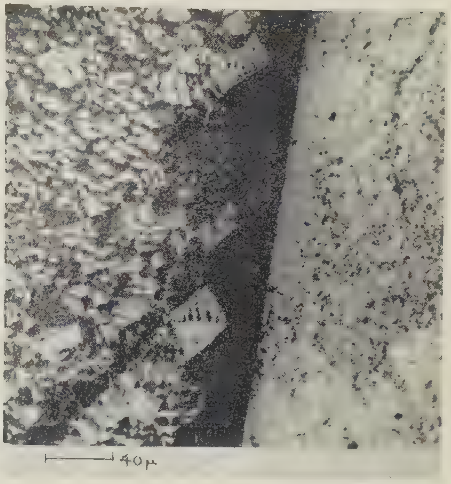

Photo. 4. Etching pattern of the same area with Photo. 3.

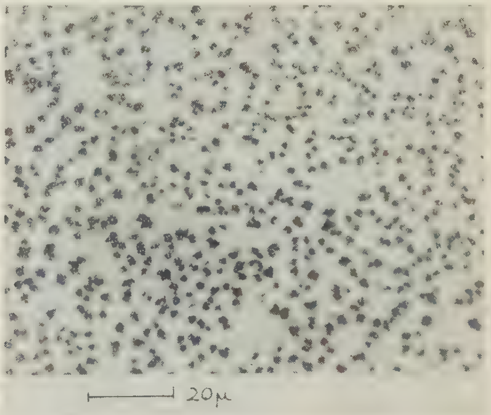

Photo. 5. Printing-out pattern of "perfectly annealed" crystal with (100) surface.

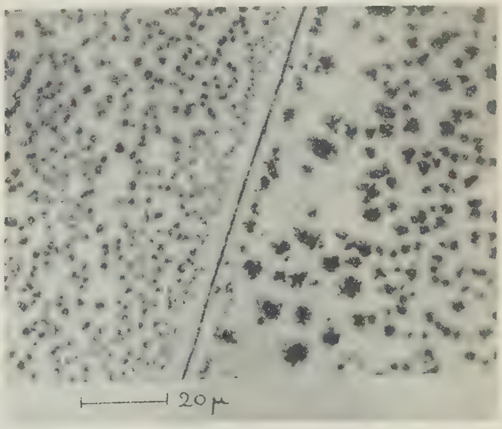

Photo. 6. Printing-out pattern of "perfectly annealed" crystals near the grain boundary.

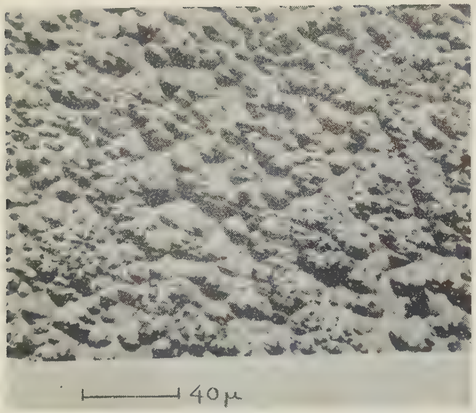

Photo. 7. Etching pattern of "perfectly annealed" crystal with (110) surface.

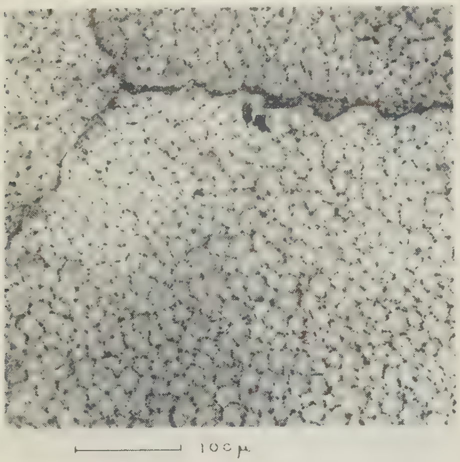

Photo. 8. General view of the printing-out pattern of the "special crystal No. 1".

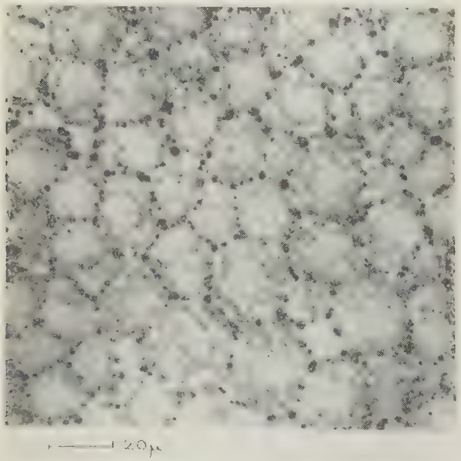

Photo. 9. Printing-out pattern at the surface of the "special crystal No. 1".

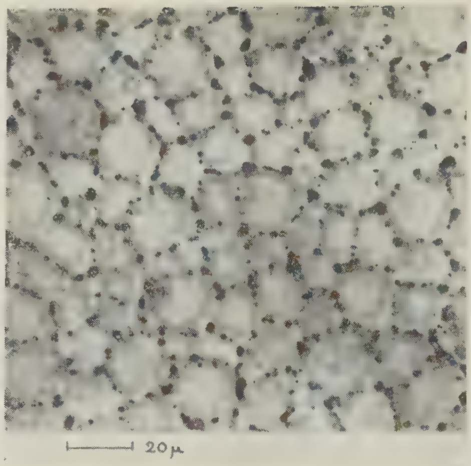

Photo. 10. Printing-out pattern in the interior of the "special crystal No. 1".

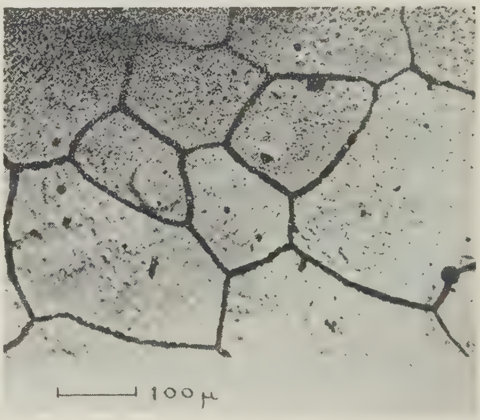

Photo. 11. General view of the surface of the "special crystal No. 2". Each of the "islands" of crystal is separated by the "valleys".

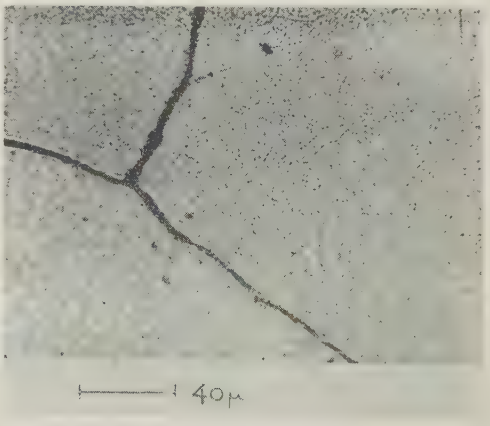

Photo. 12. Printing-out pattern of the "special crystal No. 2".

(4) The solid AgCl is annealed at 420 to 430°C for 2 hours and then slowly cooled to the room temperature in about 20 hours.

The specimens thus produced were made of several single crystals with dimensions of 5 to 10 mm. The central part of them may be reasonably identified as the strain-free crystals grown from the melt and was used in the main of the following experiments. They may be designated as the "usual crystals" in the following. Their surfaces were nearly parallel to either (100) or (110) face.

The special type of crystals used in some of the experiments were prepared in the following way.

One of them were thin crystals grown on the surface of the "usual crystals." They were produced by decanting the molten AgCl on the crystals which had been kept at the temperature slightly below the melting point. They may be designated as the "special crystals No. 1" in the following. Their surfaces were usually nearly parallel to (111) face.

The other special crystals were thin crystals grown on the surface of Pyrex glass plates, by decanting the melt in the simillar manner with the "special crystals No. 1". They may be designated as the "special crystals No. 2." The rate of solidification of these special crystals No. 1 and 2 was somewhat more rapid than that of the usual ones.

### 2-2. Printing-out

The crystals were exposed to the filtered radiation of 405 m$\mu$ (just in the long wavelength edge of the fundamental absorption band of AgCl) from the high pressure mercury lamp. After exposure of several hours under the photon intensities of $10^{14}$ quanta per sec. cm$^2$, the printed-out silver became visible under the microscope.

### 2-3. Chemical Etching

Etching was carried out by using the commercial photographic fixer* for a few minutes.

This etching procedure was also useful for the determination of crystal orientation. The crystals with (100) surface orientation showed hardly any pits and became glossy. Crystals with (110) and (111) surfaces showed etch pits on the entire surface and the pits took square and triangle form, respectively, according to the crystallographic symmetry.

## § 3 Results Obtained

### 3-1. Crystals with (100) or (110) Surface ("Usual Crystals")

In annealed crystals of AgCl, both the printing-out and the chemical etching revealed the grain boundaries and the sub-boundaries (boudaries with low angle of misfit inside the single crystals) at the surface of the specimens, as shown in Photos. 1 and 2. It may reasonably be concluded that the silver particles and the etch pits correspond to the existing dislocations. The results on strained crystals also support this conclusion and will be described in Part II.

The important experimental results are as follows:

(1) The silver particles appear in the crystals with (100) surface but do not appear in those with (110) surface, as seen in Photo. 1.

(2) The etch pits appear in the crystals with (110) surface but do not in those with (100) surface, as seen in Photo. 2.

Photos. 3 and 4 show the both types of patterns along the same grain boundary. They clearly show that the dislocations in (110) grains do not contribute to the printing-out and those in (100) ones do not to the formation of etch pits.

The sub-boundaries such as seen in Photos. 1 and 2 can be removed by the most careful annealing of specimens. Photos. 5,6 and 7 show the printing-out and etching patterns of these "perfectly annealed crystals".

The densities of dislocations are estimated as $5\times10^6$ per cm$^2$ from printing-out and $3\times10^6$ per cm$^2$ from etching.

### 3-2. Crystals with (111) Surface ("Special Crystals No. 1")

The printing-out of this type of crystals revealed the silver particles which outlined the somewhat regular hexagonal pattern both at the surface and in the interior of specimens. The general view of distribution of silver is shown in Photo. 8.

At the surface, the two groups of silver particles are observed as shown in Photo. 9. They are: (1) the larger particles which outline the hexagonal pattern and (2) the smaller particles which are distributed around the hexagonal pattern.

---

* FFH photographic fixer (Fuji-fix; Fuji Photo Film Co., Ltd. Kanagawa, Japan) was used in our experiments.

In the interior of the specimen, as shown in Photo. 10, the particles are distributed *discontinuously* upon the hexagonal cylindrical surfaces which were outlined by the particles of the group (1) at the surface as described above.

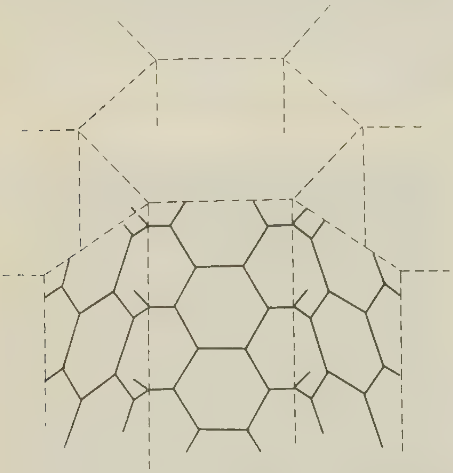

Fig. 2. The hexagonal columnar distribution of plane networks of dislocations in the "special crystal No. 1".

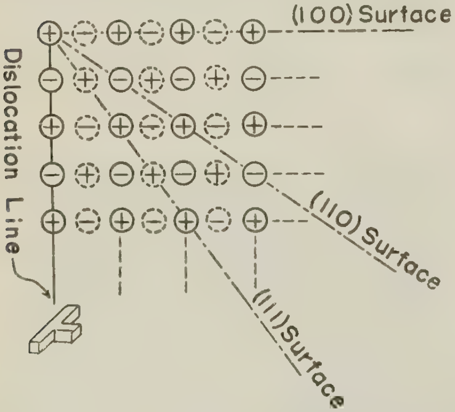

Fig. 3. Intersection of "extra-half-plane of edge dislocation" by the surfaces with various orientations. The plane of the full circles and the plane of the dotted circles are separated by on atomic spacing.

These results can be interpreted in the following manner. In this type of crystals, the silver particles are preferentially produced,

(a) at the emergence points of dislocations at the surface........the group (1) of Photo. 9.

(b) at the kink sites at the surface, that is to say, the defect sites at the surface ........the group (2) of Photo. 9.

(c) at the nodes in the dislocation networks inside the crystals........Photo. 10.

These interpretations will be further discussed later in § 4-1. When we assume their validity, the distribution of dislocations in these crystals may be supposed to be such as those shown schematically in Fig. 2. They may be described that the plane network of dislocations is extended upon the hexagonal cylindrical surfaces which are approximately perpendicular to the (111) plane.

The linear dimensions of plane-networks upon cylindrical surfaces could be estimated to be of the order of 10 microns from the vertical displacement of the objective lens of microscope.

The density of dislocations is found to be about $4\times10^6$ per $cm^2$ in these crystals.

### 3-3. Crystals Grown on the Glass Surface ("Special Crystals No. 2")

The general view of the surface of these crystals are quite similar to that of metal crystals prepared by the similar procedures³⁾, and is shown in Photo. 11. Each of the "islands" of crystals is separated by the "valleys" or "cracks".

Printing-out on the "free" surface of them revealed the existence of plentiful sub-boundaries inside the islands as shown in Photo. 12. The printing-out patterns of each island are quite similar to those of strained crystals to be discussed in Part II. The existence of internal strains in these islands is naturally expected from the existence of constraints at the contract surface of AgCl with glass.

The density of silver particles is found to be about $3\times10^7$ per $cm^2$ in these crystals.

## § 4. Discussions

### 4-1. Formation of Silver Particles

Several experimental evidences⁴⁾ are now available for trapping of photo-electrons along dislocations in AgCl. Seitz⁴⁾ proposed that the traps are incipient vacancies with an effective charge of $+e/2$ and his prediction has received further support in the work of Hedges and Mitchell¹⁾.

The writer⁵⁾ intends to propose that the following trapping centres in addition to the incipient vacancies must be effective in the case of annealed crystals;

(a) the kink sites at the surface,
(b) the emergence points of edge dislocations at the surface, and
(c) the nodes in the dislocation networks inside the crystal.

This proposal stands mainly on the observation described in § 3–2 and the mechanism of these preferential production of silver particles may be explained by the trapping of electrons due to the extra effective charge existing there.

In the case of trapping at the (b) sites, the extra half plane of (110) type accompanied with the edge dislocations may produce extra charge by intersecting the surface plane of (111) and (100), but may not at the surface plane of (110) as schematically shown in Fig. 3. This type of orientation dependence has been confirmed by the experimental results described in § 3–1, which show that the edge dislocations in the (110) grains (revealed by the etch pits) do not contribute to the formation of silver particles*.

The size of silver particles differs sometimes from grain to grain under the same amount of exposure (for example as seen in Photo. 6). It is naturally expected that their size is determined by the crystallographic orientation of their surface or, in other words, the orientation dependence of the effective range of the extra electric charge due to the intersection of edge dislocations with the surface.

This conclusion on the existence of extra charge on the surface due to dislocations may support the possibility of the extra charge at the nodes in the dislocation networks. This problem, however, merits further consideration.

### 4–2. Formation of Etch Pits

The etching experiments on annealed and strained crystals have been concluded not to contradict the generally accepted viewpoints that the impurity atmosphere around dislocations make dislocations visible to us by producing etch pits.

The most remarkable fact is the difficulty of revealing etch pits on the (100) surface**. The etched pattern of the crystal with (100) surface is usually very flat and the rate of chemical etching takes the minimum value in the crystal with (100) surface as seen in the photographs. It may be explained by the well-confirmed viewpoint that the value of the surface energy takes the minimum at (100) plane.

### 4–3. Origin of Dislocations

Seitz[7)] and Frank[8)] suggested the origin of dislocations by the condensation of thermal vacancies in the course of cooling from the melting point. The predominant defects of AgCl in equilibrium are, however, those of Frenkel type (Ag interstitials and Ag vacancies). It is not possible for them to produce the extra-half planes by their condensation.

On the other hand, the predominant defects in NaCl are those of Schottky type (Na and Cl vacancies) and thus have an ability to produce edge dislocations by their condensation.

The unpublished results by the present writer on the thermal etching patterns of NaCl single crystals revealed etch pits of the order of $10^5$ per cm$^2$ on their (100) surfaces†.

Comparing this value with that of AgCl of $10^6$ to $10^7$ per cm$^2$, we must conclude that some other origin of dislocations, in addition to the vacancy condensation, is important in these crystals.†† This another factor is supposed to be the misorientation of micro-crystals grown from different nuclei of solidification from the melt.

Next, the discussions will return to our crystals of AgCl prepared under various conditions of crystal growth.

How will become the dislocations which were produced during solidification process and are supposed to form the boundaries between neibouring micro-crystals?

In the case of the "usual crystals", there are little restrictions to their movement and they may move rather freely and thus become randomly distributed inside the crystals as seen in Photos. 5, 6 and 7.

---

* These results also show that the atmosphere of impurity atoms around dislocations, cannot, by itself, act as the nuclei for the precipitation of silver.

** Imura and Suzuki[6)] have experienced the similar kind of difficulty in the etching of Aluminium. The degree of anisotropy of the difficulty was, however, far less than our case, as expected reasonably.

† See also, W. Dekeyser: Proc. Defects in Solid, 134 (1955).

†† Of course, we cannot neglect the presence of small number of Schottky defects in AgCl. Their density at the malting point, however, can be estimated to be the order of $10^{-5}$. On the other hand, the density of Schottky defects in NaCl at the Melting point is $1 \times 10^{-4}$.

In the case of the "special crystals No. 2", the resistance to their movement is the largest and some of the grain boundaries change themselves into "valleys" or "cracks" as seen in Photo. 11.

In the case of the "special crystals No. 1", the restriction is the medium and the boundaries of micro-grains may remain in the form of hexagonal columnar patterns of dislocation networks as seen in Photos. 8, 9 and 10. The hexagonal patterns of this type of crystals are quite similar to those expected from the theory of T. Suzuki and H. Suzuki[9], but the mechanism of the appearance of such special arrangements seems to be not the same with that proposed by Suzuki and Suzuki; because, in our experiments as described above, they did appear only under special condition of crystal growth, rather than in the crystals annealed under ideal free and unrestricted circumstances.

# Observation of Dislocations in Silver Halides
## Part II. Strained Crystals

By Hiroshi KANZAKI
*Institute of Industrial Science, University of Tokyo, Chiba, Japan*

(Received August 5, 1955)

The appearance of sub-boundaries are revealed in the crystals of AgCl and AgBr deformed at room temperature, by the technique of printing-out and etching. The origin of sub-boundaries can be explained by the progress of polygonization during the deformation.

### § 1. Introduction

The main object of this Part of the article is to obtain the knowledge on the distribution of dislocations in deformed crystals by using the techniques described in the Part I.

### § 2. Experimental Procedures

Experiments were made on the crystals of AgBr and AgCl grown from the melt.

Specimens of AgBr were prepared by the method exactly the same with that adopted by Hedges and Mitchell[1]. Their original size was about 20 mm × 20 mm and 0.3 mm in thickness. Their surface was usually nearly parallel to (100). After being separated from Quartz plates, they were cut to the size of 5

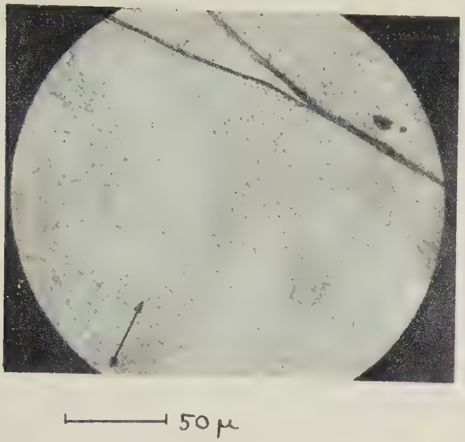

Photo. 1. Printing-out pattern of deformed crystal of AgBr. The arrow shows the direction of faint slip bands observed in the same area.

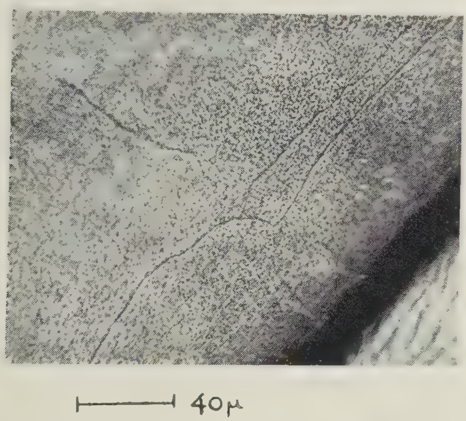

Photo. 2. Printing-out pattern of deformed crystal of AgCl with (100) surface. The grain of the right-lower corner has the (110) surface and its pattern is shown in Photo. 3.

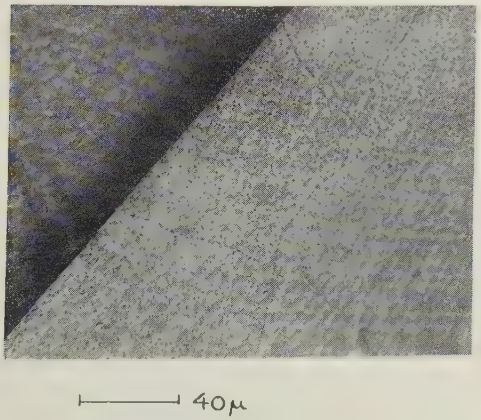

Photo. 3. Printing-out pattern of deformed crystal of AgCl with (110) surface (faint slip bands may also be seen). The left-hand grain is that shown in Photo. 2 and the slip bands in that area may be seen in this photograph.

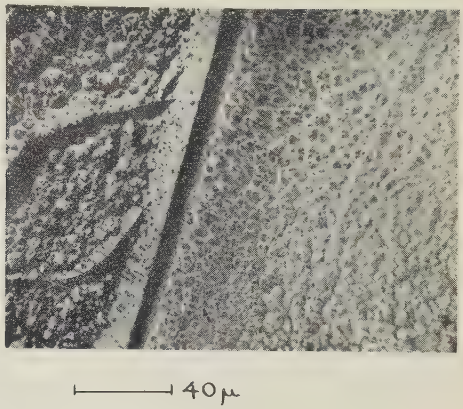

Photo. 4. Etching pattern of deformed crystal of AgCl near grain boundary.

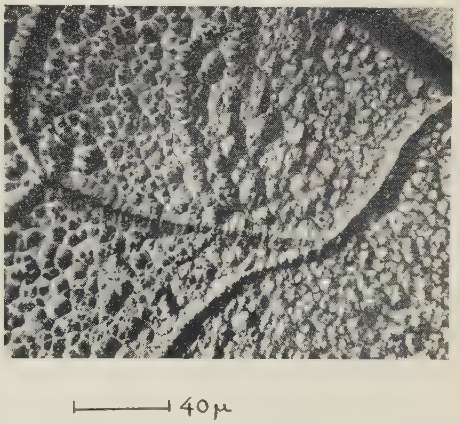

Photo. 5. Etching pattern of deformed crystal of AgCl. The polygon boundaries as well as grain boundaries have been revealed in Photos. 4 and 5.

mm × 20 mm and then annealed at 400 to 410°C. Deformation was given by plastic bending at room temperature. Exposure to light was given by the filtered radiation from the tungsten lamp with wavelengths at the long wave edge of the absorption band of AgBr.

Specimens of AgCl were prepared in the same manner as described in Part I. Deformation was given at room temperature by indentation on their free surfaces with the fine head (0.3 mm in diameter) of the Pyrex glass rods. The exposure and the etching were carried out in the same manner as in Part I.

## § 3. Results Obtained

### 3-1. AgBr

Printing-out of annealed crystals of AgBr revealed the random distribution of silver particles at the surface with the density of about $10^6$ per $cm^2$.

Printing-out of the deformed crystals revealed the existence of the sub-boundaries made of rows of silver particles in the interior of the crystals (about 10 micron below the surface) as shown in Photo. 1. These boundaries became clearly visible when the value of the surface strain exceeded over 0.5 percent.

These boundaries which appear in the strained crystals of both AgBr and AgCl are developed especially well near the grain boundaries and also at the places where the slip bands on the surface become "faint", and are approximately perpendicular to the slip bands.

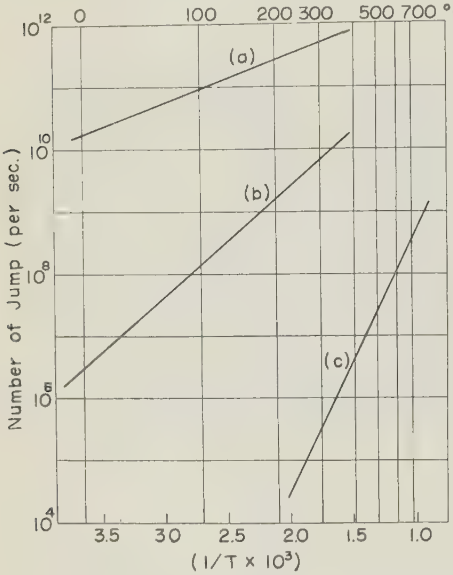

Fig. 1. Temperature dependence of the mobility of defects calculated from the conductivity data3)4).
(a) Ag interstitial ions in AgBr,
(b) Ag vacancies in AgBr,
(c) Na vacancies in NaCl.

From the experimental results on the relation between these boundaries and the slip bands, it has been concluded that the origin of these sub-boundaries is the polygonization accompanied by the deformation at room temperature and these boundaries are made of rows of dislocations with strong edge components.

### 3-2. AgCl

As stated above, the "polygon" boundaries were also observed in the interior of the deformed AgCl as well as in the case of AgBr.

Photos. 2 and 3 show some of the printed-out patterns of deformed AgCl in the interior of the crystal. It is also remarkable that the size of the silver particles has been decreased and the density of them has been increased by the deformation. The measured density is about $6\times10^7$ per $cm^2$ in the deformed crystals with (100) surface orientation (as seen in Photo. 2) and 1 to $2\times10^7$ per $cm^2$ in those with (110) surface (Photo. 3). Such orientation dependence of the particle densities may be explained in the same manner with that of annealed crystals shown in § 3-1 of Part. I. The degree of such anisotropy is, however, far less in deformed crystals than in annealed ones of § 3-1 of Part I. Actually, we could confirm one-to-one correspondence between silver particles and etch pits along the same polygonization boundaries in the crystals with (110) surface. In the case of annealed crystals, it was quite impossible to make this kind of experimental confirmation because of strong anisotropy in producing both silver particles and etching pits.

Chemical etching also revealed the polygonization boundaries in deformed crystals as shown in Photos. 4 and 5. The density of etch pits is calculated to be 1 to $2\times10^7$ per $cm^2$.

## § 4. Discussions

### 4-1. Formation of Silver Particles

The printed-out silver particles in deformed crystals of AgBr and AgCl appeared always below the surface of crystals. This fact is to be contrasted with the appearance of particles on the surface of annealed crystals. These results are consistent with those by Hedges and Mitchell1). In the case of strained crystals, a lot of jogs are expected along dislocation lines and they contribute effective traps for photo-electrons. Under these circumstances, the location of silver particles is determined by the density of jogs along dislocations as has been fully discussed by Hedges and Mitchell1).

### 4-2. Formation of Etch Pits

Experimental results have shown that the dislocations produced by deformation contribute fairly well to the formation of etch pits. We must then conclude that the impurity atmospheres are well formed around these dislocations. This conclusion may be reasonably accepted by considering the rather high values of defects mobilities in silver halides which are to be discussed in the next paragrahps.

### 4-3. Plastic Deformation of Silver Halides

It seems generally accepted[2] that the temperature dependence of plastic properties of solids is determined by the mobility of the atomic defects in the solids.

Fig. 1 shows the temperature dependence of the mobility of defects (number of jumps per unit time) calculated from the conductivity experiments of AgBr[3] and NaCl[4]. It may also be supposed[5] that the mobility of the neutral pair of vacancies is nearly the same with that of positive ion vacancies.

Assuming the value of $10^7$ to $10^8$ per sec for the jumping frequency of vacancy pair in AgBr, it may be well conceivable that the polygonization proceeds considerably during the course of deformation at room temperature.

From the results of Fig. 1, it is supposed that the deformation of AgBr at room temperature corresponds to that of NaCl at 500°C. The temperature dependence of the plastic properties of NaCl may be the most interesting from this point of view.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 11, No. 2, FEBRUARY, 1956

# Electron Diffraction and Microscope Study of the Surface Structure of Copper Single Crystals

By Susumu YOSHIDA

*The Government Mechanical Laboratory, Suginami-ku, Tokyo, Japan*

(Received March 31, 1955, and in revised form September 27, 1955)

The submicroscopic structure of electrolytically polished and etched surfaces of copper single crystals was studied by means of electron diffraction and electron microscope, supplemented by the method of light figures. Our results indicate that the etched surfaces are composed of submicroscopic facets which belong to [100] zone and the electropolished surfaces are smooth and undulating. Assuming a simple model for the undulation, the mean inner potential of copper crystal was determined. The mean value of the mean inner potential turned out to be 11 volts.

## §1. Introduction

Many authors studied the submicroscopic surface structure of metal single crystals by the method of electron diffraction. For example, Raether *et al*[1-3]. found that the electropolished surfaces of copper crystals were smooth and undulating. Pashley[4] studied the electrolytically etched and polished surfaces of silver crystals and found that fine structure effects, in the form of split spots or streaks, gave information concerning the surface structure of the various surfaces of the crystals. However, the origin of split spots and streaks in the electron diffraction pattern has not yet been fully elucidated. So it is often difficult to study in detail the submicroscopic surface topography of crystals only by electron diffraction and the observation by means of electron microscope is required.

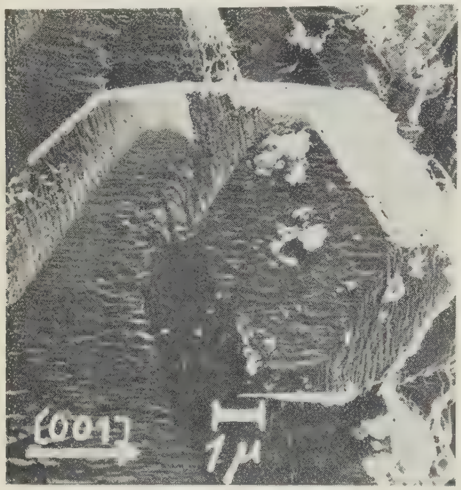

Fig. 1. {110} surface electrolytically etched for 15 minutes.

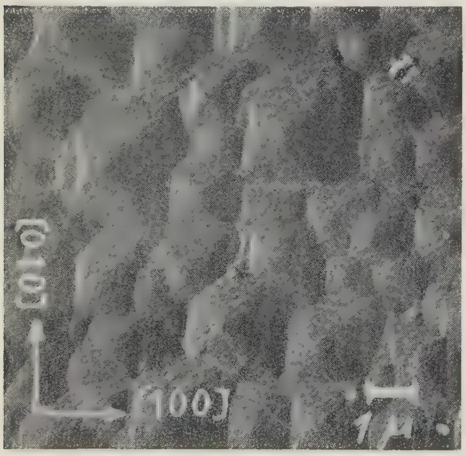

Fig. 2. {001} surface electrolytically etched for 15 minutes.

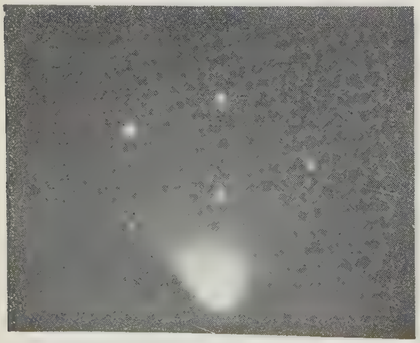

Fig. 3. {111} surface electrolytically etched for 15 minutes. [$\bar{1}$10] azimuth.

In the present work the electrolytically etched and polished copper single crystals were studied by electron diffraction and electron microscope, supplemented by the observation by the method of light figure. Our results indicate that the etched surfaces are composed of minute facets which belong to [100] zone, and the electropolished surfaces are smooth and undulating. Assuming a simple model for the undulation, we determined the mean inner potential of copper crystal and the mean angle of the undulation.

## § 2. Experimental

The copper single crystals used in this experiment were made from melted electrolytic copper by slow cooling. Surfaces of the crystals were polished mechanically and then etched. After determining the orientation of the crystal axes by electron diffraction, flat surfaces parallel to {100}, {110} and {111} planes were prepared by grinding and mechanical polishing. The surface layer distorted by mechanical working was removed by electropolishing.

The electrolytic solution used for polishing was a mixture containing 40 cc of water and 50 cc of orthophosphoric acid (90%). Electropolishing and etching were carried out at 15 ∼20°C with the specimen as the anode. The electrode potential applied was 0.4∼0.6 volt for electrolytic etching and 1.6∼1.8 volts for electropolishing. The oxide layer which was often formed on the surface in the process of electropolishing was removed by light etching in dilute solution of sulphuric acid. The lustre of the polished surface showed no change after this process. Specimens thus prepared were rinsed in distilled water, dried quickly in air flow and then examined by electron microscope and diffraction. For the electron microscope specimens the methyl-methacrylate aluminium replicas shadowed with germanium were used. The electrolytically etched surfaces were also studied by light figures, i.e., the figures produced by reflecting a narrow beam of light on the surface of a crystal.

## § 3. Results on the Surface Structure

### (a) Electrolytically etched surfaces

*Strongly etched surfaces.* When the electrolytic etching is continued for more than 10 minutes, the surface of the crystal becomes mat and reflects light strongly in certain definite directions. The electron micrograph shows that the surface is covered with etch pits which are 1 to several microns in size. They are of characteristic shapes which depend on the indices of the surfaces (Figs. 1 and 2). From the shape of the facets which compose the etch pits it can be concluded that they belong to [100] zone. Generally the facets are not smooth, but covered with submicroscopic projections. Only on a few specimens smooth facets are observed.

The electron diffraction spots are streaked from the centres into a few directions (Fig. 3). According to several authors[4)–6)] the streaks are caused by the refraction effect of electrons on submicroscopic facets and the indices of those facets can be determined by the direction of streaks*. In the present experiment the streaks indicate that the indices of submicroscopic facets are {100}, {110}, {210} and {310}, irrespective of the indices of the microscopic surfaces, although a few streaks cannot be attributed to any faces of simple indices.

When the electron micrograph of a surface shows many etch pits which have smooth facets, the streaks observed by electron diffraction is replaced by a subsidiary spot separated from the normal diffraction spot. In such a case the mean inner potential of copper crystal can be measured approximately. Using {110} surface a mean inner potential of 13~14 volts was obtained from (400) spot. This is con-

---

* Pashley[4)] observed for electrolytically etched silver surfaces several evidences which suggest that the observed streaks are not solely due to the refraction effect. We also observed the similar evidences.

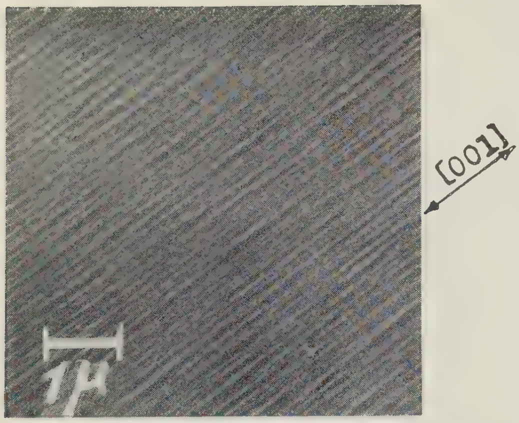

Fig. 7. {110} surface electropolished for 5 minutes and lightly etched for 30 seconds.

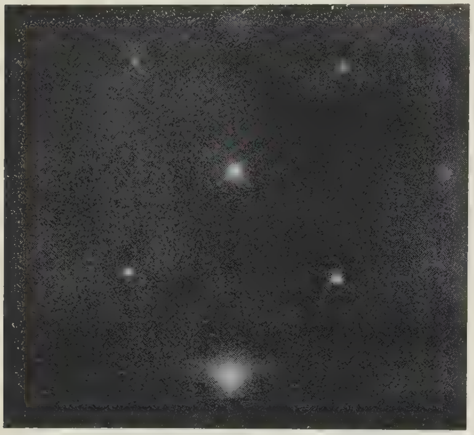

Fig. 8. {110} surface electropolished for 5 minutes and lightly etched for 30 seconds. [001] azimuth.

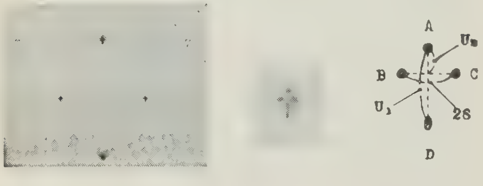

(a) (b) (c)

Fig. 9. (a) {110} surface electropolished for 5 minutes and lightly etched for 30 seconds. [$\bar{1}$10] azimuth.
(b) Enlargement of the (222) spot.
(c) Illustration os the distances given in Table 1.

sistent with the value (13.7 volts) calculated by Tull[7].

The indices of the microscopic facets of the etch pits are determined by analysing light figures. Although the recorded figures are diffuse and elongated, the direction of strong intensity correspond to {100}, {110} faces and a face intermediate between {210} and {310} (Fig. 4).

The indices observed by both methods, electron diffraction and light figure, are summarized in Fig. 5. Although the facets observed by different methods are not perfectly in accordance, all the observed facets belong to [100] zone. This is consistent with the observation by the electron microscope. No {111} facets were found in accordance with Pashley's result[4] for silver crystals. Fig. 6 represents a polyhedron which is bounded by the observed facets. The etch pits shown in the electron micrographs resemble some parts of this polyhedron.

*Lightly etched {110} surface.* When a {110} surface is electropolished and then electrolytically etched for a short time (30 sec.~1 minute), the electron micrograph of this surface shows stripes running along [001] direction (Fig. 7). The width of the stripes is from 500 to 2000 Å.

The electron diffraction pattern at [001] azimuth shows long, sharp streaks along [100] and [101] directions (Fig. 8). At [$\bar{1}$10] azimuth split spots are observed (Fig. 9). The split spots cannot be explained by the simple refraction effect. But the spot D is explained by assuming spikes in reciprocal lattice space

Table I. Comparison between observed and calculated positions of the split spots.
(The definitions of $U_1$, $U_2$ and $S$ are given in Fig. 9.)

| Split spot | $U_1$(mm) | | $U_2$(mm) | | $S$(mm) | |
|---|---|---|---|---|---|---|
| | Obs. | Calc. | Obs. | Calc. | Obs. | Calc. |
| (220) D | 0.7 | 0.78 | | | | |
| 〃 B, C | | | 0.3 | 0.33 | 0.2 | 0.21 |
| (440) D | 2.2 | 2.06 | | | | |
| 〃 B, C | | | 0.8 | 0.73 | 0.5 | 0.45 |
| (222) D | 1.9 | 1.70 | | | | |
| 〃 B, C | | | 0.4 | 0.35 | 0.3 | 0.25 |
| (311) D | 0.7 | 0.67 | | | | |
| 〃 B, C | | | 0.3 | 0.30 | 0.2 | 0.19 |
| (331) D | 1.4* | 1.4* | | | | |
| 〃 B, C | | | 0.6** | 0.6** | 0.38** | 0.38** |
| (442) D | 2.3 | 2.22 | | | | |

* The angle of incidence of the electron beam with the {110} crystal plane is calculated from Pashley's formulae[4] (1) and (2), assuming the split spot D for the (311) diffraction spot to be due to the [010] spike.

** The direction cosines for the spikes which cause split spots B, C are calculated from their positions for the (311) diffraction spot,

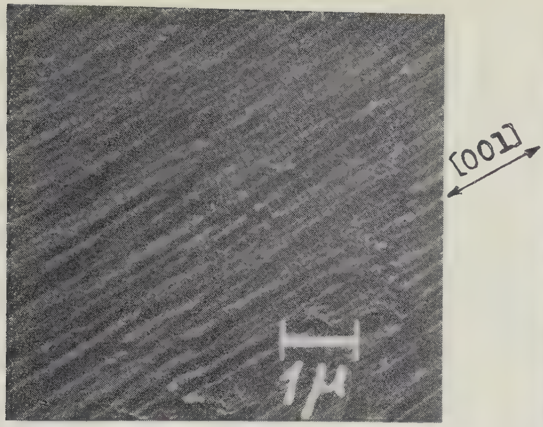

Fig. 10. {110} surfaces electrolytically etched for 5 minutes.

as considered by Pashley[4]. The result of analysis indicates that the spot D is due to a spike along [010] or [100] direction (Table 1). Therefore, the stripes observed by the electron microscope is concluded to be due to a furrow-like structure which is bounded by oblique {100} and {010} facets.

When the etching is continued further, the period of the furrow-like structure becomes larger (Fig. 10) and sometimes a step-like structure develops (Fig. 11). Finally etching pits of the type such as described in the previous section (Fig. 1) appear and gradually cover the surface. The characteristic furrow-like structure still remains as a fine structure on the facets of the pits even in this stage of etching.

(**b**) **Electropolished surfaces**

The surface of the specimen becomes lustrous by 3∼5 minutes' electropolishing. At this stage of polishing, the electron micrograph from {100} surface shows a very smooth surface structure (Fig. 12). {110} surface is also smooth, but generally faint streaks are observed along [001] direction (Fig. 13). When the electropolishing is continued for a longer time, the streaks gradually become distinct and the appearance of the surface becomes somewhat similar to that from the lightly etched {110} surface (Fig. 7).

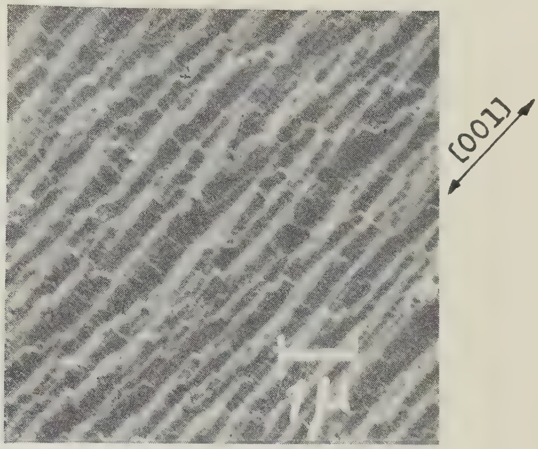

Fig. 11. {110} surface electrolytically etched for 10 minutes.

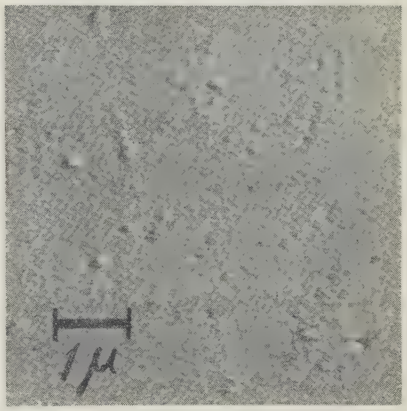

Fig. 12. {100} surface electropolished for 5 minutes.

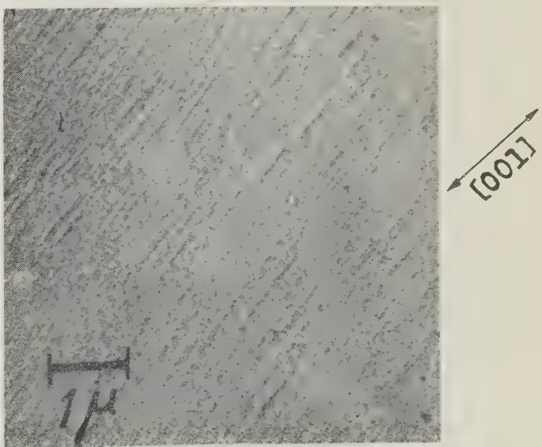

Fig. 13. {110} surface electropolished for 5 minutes.

Though slight changes in the condition of polishing result in variations in details of electron diffraction patterns, the general features of the patterns well correspond to the electron microscopic observation as given below. For {100} surface the diffraction spots elongate towards the shadow edge. The elongated streaks are sharp and show no difference when the azimuth of the incident beam is changed. This fact indicates that

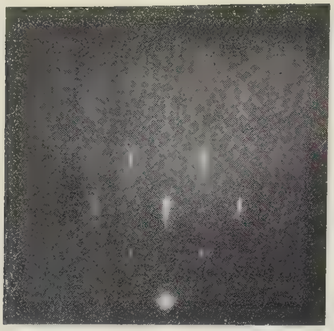

Fig. 14. {110} surface electropolished for 5 minutes. [$\bar{1}$10] azimuth.

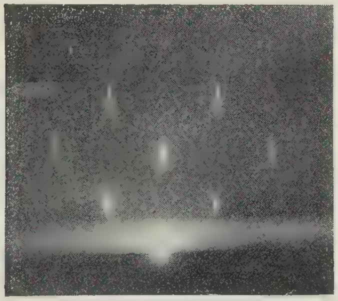

Fig. 15. {110} surface electropolished for 5 minutes. [001] azimuth.

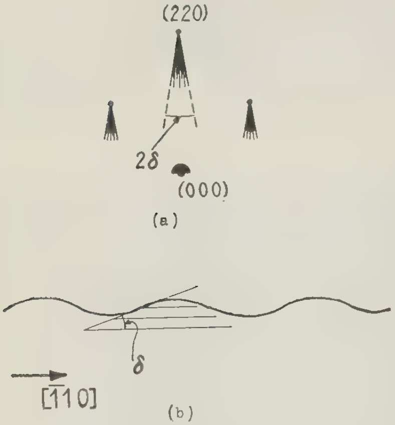

Fig. 16. (a) Illustration of the electron diffraction pattern from electropolished {110} surface at [001] azimuth (Fig. 15).
(b) Illustration of the submicroscopic profile of the surface corresponding to the pattern (a).

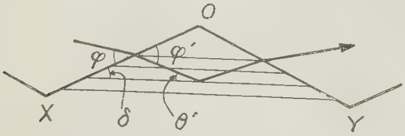

Fig. 17.

the surface is slightly undulated, though it appears very smooth in the electron micrograph, and that the undulation is not along any definite crystallographic direction. For {110} surface the diffraction spots also elongate towards the shadow edge at [$\bar{1}$10] azimuth, but they look like comets at [001] azimuth (Figs. 14 and 15). These patterns indicate that the streaks observed in the electron micrograph of {110} surface correspond to slight undulation along [$\bar{1}$10] direction. The mean angle of inclination of the undulation is given by half the angle ($\delta$) of the spread of the trail of the comet-like spot (Fig. 16). It comes out 3∼5° for a well polished surface*.

When the electropolishing of {110} surface is continued for a longer time, the appearance of the diffraction spots changes as follows. At [$\bar{1}$10] azimuth the elongated part of a diffraction spot splits from the normal spot and the normal spot tends to protrude on both sides parallel to the shadow edge. At [001] azimth the trail of the comet-like spot becomes smaller and the angle $\delta$ increases, often amounting to 60∼70°. Therefore the diffraction pattern becomes somewhat similar to that from the lightly etched surface (Fig. 8 and 9). This fact corresponds well to the change observed in the electron micrograph.

## § 4. Measurement of the Mean Inner Potential and Angle $\delta$[8)]

It was already found that an electropolished surface of a metal crystal is slightly undulated and the undulation forms a small angle with the macroscopic surface. By the electron diffraction method, Kranert, Leise and Raether[1)] formerly estimated the angle to be 1∼2° for a copper crystal. However, they had to assume the value of the mean inner potential. If we assume the undulating surface as represented in Fig. 17, we can determine both the mean inner potential and the angle $\delta$ by the following method. When an incident electron beam falls upon the facet OX, it is refracted on the facet and then reflected by the net plane when the Bragg condition is fulfilled. Since the Bragg angle $\theta'$ for the refracted beam is approximately equal to $\theta$ for the unrefracted beam the deviation of the beam due to refraction effect is calculated by Snell's law[9]:

---

* The mean angle $\delta$ of the inclination can be measured also by the method described in the later section (§ 4.). The measured value (Table II) is consistent with the value given here.

$$\phi'-\phi=\frac{\mu^2-1}{\phi'+\phi}\doteq\frac{\mu^2-1}{2\phi'}\doteq\frac{\mu^2-1}{2(\delta+\theta)}\,, \qquad (1)$$

where $\mu$ is the refractive index for electrons and $\phi$ and $\phi'$ are the angles shown in Fig. 17. The reflected beam departs from the crystal through another facet OY and the total deviation due to the effect of refraction is $2(\phi'-\phi)$. Using the familiar relation $\mu^2-1=V/E$ where $V$ is the mean inner potential and $E$ the accelerating voltage, we get the following equation:

$$\varDelta_n\equiv2(\phi_n'-\phi_n)=\frac{V}{E}\,\frac{1}{\delta+\theta_n}\,, \qquad (2)$$

where the suffix $n$ indicates the order of reflexion. This formula can be rewritten as

$$B_n=-\delta A_n+V\,, \qquad (3)$$

where $A_n=\varDelta_n E$ and $B_n=\varDelta_n\theta_n E$. Equation (3) is a linear relation between $A_n$ and $B_n$, both of which can be obtained by measuring $\varDelta_n$ and $\theta_n$ on a rotation photograph. Plotting $A_n$ and $B_n$ on a diagram for a series of reflexions, we can determine $V$ and $\delta$.

Electron diffraction rotation photographs were taken of electropolished {110} surface of copper crystals. Specimens were set in an azimuth where the incident electron beam was approximately parallel to [$\bar{1}$10] but the effect of simultaneous reflextion was avoided as far as possible[10]. The surface of real crystals always deviates from the ideal model (Fig. 17) and the angle $\delta$ is not unique but is distributed in a certain range. This results in diffraction spots elongated toward the shadow edge. We measured the point of maximum intensity of the elongated spot and applied equation (3). Thus we obtained the average value of $\delta$. A few examples are given in Fig. 18. Sometimes the plots don't lie on an exact straight line. This may be due in part to the fact that the effective angle $\delta$ depends upon $\theta_n$ and in part to the variation of apparent mean inner potential in low order reflexions[11]. The same method was applied also to {100} surface. In this case, however, physical meaning of $\delta$ is not so clear as for {110} surface, for the {100} surface is not undulated along a definite crystallographic direction (§ 3. (b)). The results are given in Table II. Our data agree inorder of magnitude with the value 13.7 volts which was theoretically calculated by Tull[7].

| (100) | | 11±4 | 10±4 |

## § 5. Discussions

We observed a furrow-like structure on the lightly etched {110} surface. Even when the etching was continued for a longer time, this characteristic structure was found accompanying the etching pits. Moreover, its traces still remained as undulation on an electropolished surface. Thus, it may be concluded that the furrow-like structure represents an elementary process in the electrolytic etching and polishing. The facets of the furrows ({100} planes) seem to be the most stable surface formed in the electrolytic dissolution of copper crystal.

A similar furrow-like structure was formerly observed on electropolished aluminium surfaces by Brown[12)13)] and Bucknell and Geach[14]. Brown called it the " micro-etch " structure. Although both are alike, the one for aluminium is different from that for copper in the following points: 1) The period of the former structure (400 A) is a little smaller than that of the latter. 2) The facets of the former are not {100} planes as for copper, but {111}. It is not yet clear whether both structures have the same origin or not.

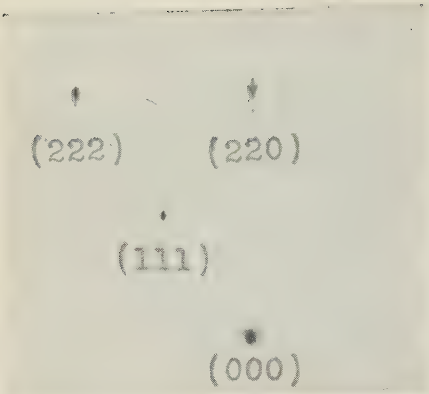

Fig. 19. {110} surface electropolished for 5 minutes and lightly etched for 30 seconds. Azimuth rotated 4° from $[\bar{1}10]$.

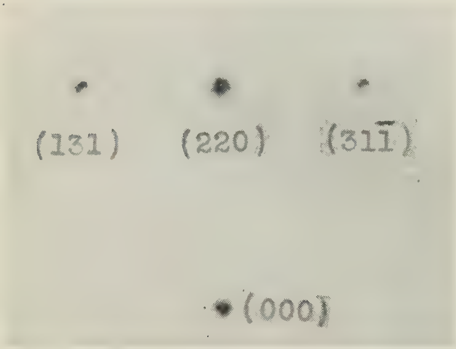

Fig. 20. {110} surface electropolished for 5 minutes and lightly etched for 30 seconds. $[\bar{1}11]$ azimuth.

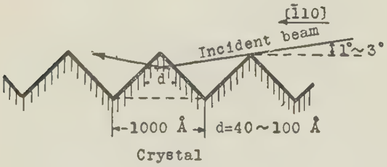

Fig. 21.

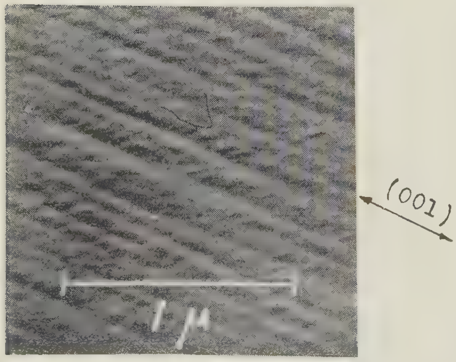

Fig. 22. {110} surface electropolished for 5 minutes and lightly etched for 30 seconds.

Electron diffraction patterns from a surface with the furrow-like structure, if closely examined, show complex appearance. They cannot be explained in several points by the simple refraction effect or reciprocal lattice spikes based on the kinematical theory. The points are as follows. (1) Among the splits spots observed with the incident beam parallel to $[\bar{1}10]$ (Fig. 9), the spot D was already explained. If the spots B and C were similarly caused by reciprocal lattice spikes, the direction cosines of the spikes would be 0.90:0.23:±0.37 (Table I). If the spot A were also caused by a spike, it would be $[\bar{1}10]$ spike parallel to the incident beam. Actually, however, the spikes corresponding to the spots A, B and C are not observed at other azimuths, while streaks corresponding to [201], [102] and [101] spikes are observed. (2) When the azimuth is a little rotated from $[\bar{1}10]$, the split spots take more complex appearance (Fig. 19). (3) Streaks which belong to one diffraction spot sometimes don't cross on the same point (Fig. 20).

As already shown, the mean period of the furrows is about 1000 Å. The size of crystals which diffract electrons are, therefore, about 50 Å for $[\bar{1}10]$ azimuth (Fig. 21). This size is of the order of magnitude where the application of the dynamical theory becomes gradually more adequate than that of the kinematical theory[15]. This seems to be the cause that makes the diffraction patterns complex and difficult to be explained. Moreover, we often observed in the electron micrograph of the furrow-like structure fine traces of lines lying obliquely to the ridge of the furrows (Fig. 22). The direction of the traces show that they are caused by {101} or {201} plane. Such a subsidiary structure of the furrows may also complicate the diffraction patterns.

In conclusion the author wishes to express his sincere thanks to Professor Ryozi Uyeda for his kind advices and criticisms. He is also indebted to Dr. T. Kawada of this laboratory for his continual encouragement during the course of this work.

# Paramagnetic Resonance Absorption in Copper Formate

By J. SHIMADA, H. ABE and K. ÔNO

*Institute of Science and Technology, University of Tokyo, Tokyo, Japan*

(Received September 17, 1955)

Paramagnetic resonance in single crystals of copper formate tetrahydrate and its dihydrate was investigated at room temperature with microwaves of $\lambda=11\sim5$ mm. Either crystal has only one absorption peak at any direction of static magnetic field. The line width of the tetrahydrate is 400 oer. in order and that of dihydrate is 200 oer. The shape of these lines is Lorentzian.

## § 1. Introduction

Paramagnetic resonance absorption in single crystals of copper formate tetrahydrate $Cu(HCOO)_2 \cdot 4H_2O$ and its dihydrate $Cu(HCOO)_2 \cdot 2H_2O$ have been investigated at room temperature and with 3 wave-lengths (11∼5.4 mm). Experiments on the same crystals have been performed by Itoh et al at Ôsaka University with a longer wave-length (3 cm)[1]. The anomaly in paramagnetic resonance absorption as in copper acetate $Cu(CH_3COO)_2 \cdot H_2O$[2,3] and copper propionate $Cu(CH_3CH_2COO)_2 \cdot H_2O$[4] is not observed in these crystals but a single peak is observed in any direction of static magnetic field.

The X-ray analysis of these salts was performed in Kiriyama's laboratory at Ôsaka University[5]. Both crystals are monoclinic and short data are listed in Table I, $z$ being the number of inequivalent copper ions in unit cell.

Table I. Short results of X-ray analysis[5].

| | $z$ | $\beta$ | $a$ | $b$ | $c$ |
|---|---|---|---|---|---|
| $Cu(HCOO)_2 \cdot 4H_2O$ | 2 | 101°5′ | 8.18Å | 8.15Å | 6.35Å |
| $Cu(HCOO)_2 \cdot 2H_2O$ | 4 | 96°38′ | 9.54Å | 7.16Å | 8.59Å |

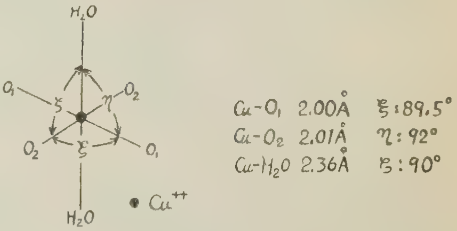

Fig. 1. Atomic configuration surrounding a $Cu^{++}$ ion in $Cu(HCOO)_2 \cdot 4H_2O$.

## § 2. Results from Resonance Absorption

### i) *Copper Formate Tetrahydrate* *$Cu(HCOO)_2 \cdot 4H_2O$*

The configuration of atoms surrounding a $Cu^{++}$ ion in this crystal is shown in Fig. 1. Since we have no exact information about the crystalline field at $Cu^{++}$ ion, we assume that

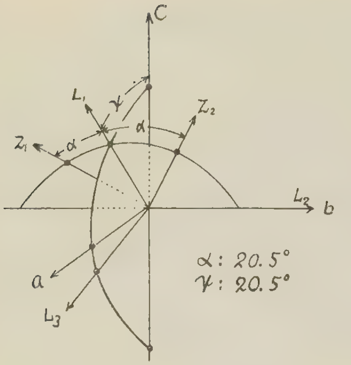

Fig. 2. Direction of $Z$-axes in $Cu(HCOO)_2\cdot 4H_2O$.

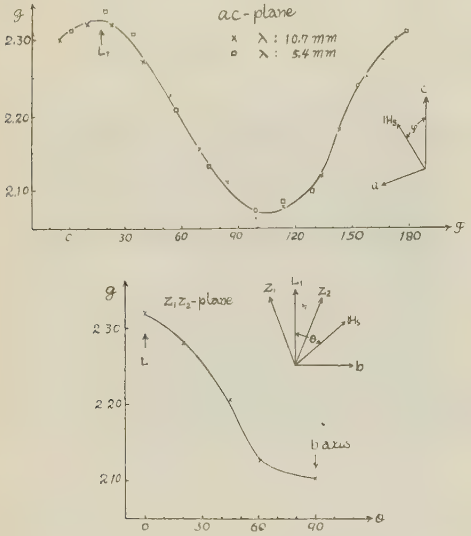

Fig. 3. Variation of $g$-value with orientation for static magnetic field in $Cu(HCOO)_2\cdot 4H_2O$.

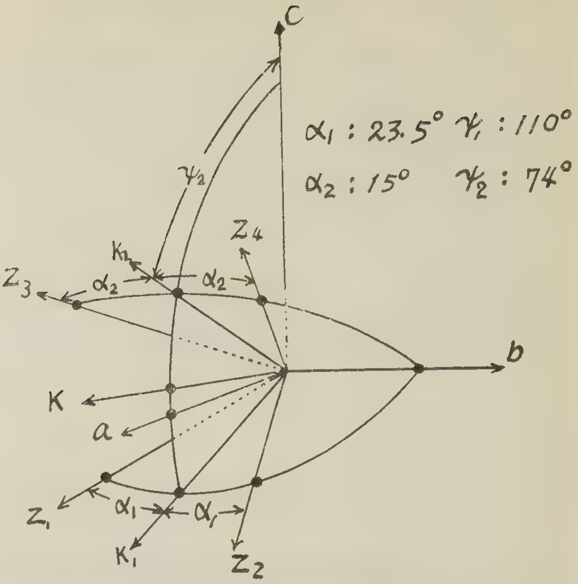

Fig. 4. Directions of $Z$-axes in $Cu(HCOO)_2\cdot 2H_2O$.

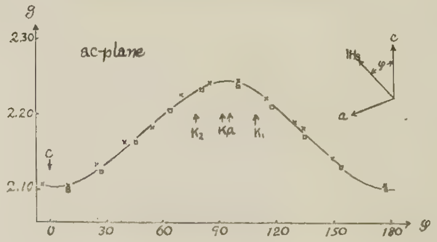

Fig. 5. Variation of $g$-value with orientation for $H_s$ in $Cu(HCOO)_2\cdot 2H_2O$.

Table II. Line width of $Cu(HCOO)_2\cdot 4H_2O$ at $\lambda=11$ mm in oer.

| | $H//a$ axis | $H//b$ axis | $H//c$ axis |
|---|---|---|---|
| Observed line width $\Delta H$ | 360 | 420 | 460 |
| Calculated dipolar width | 310 | 390 | 570 |

Table III. Line width of $Cu(HCOO)_2\cdot 2H_2O$ at $\lambda=11$ mm in oer.

| | $H//a$ axis | $H//b$ axis | $H//c$ axis |
|---|---|---|---|
| Observed line width | 230 | 240 | 140 |
| Calculated dipolar width | 590 | 400 | 480 |

the $H_2O$–$H_2O$ direction is the symmetry axis of crystalline field and we call this the $Z$-axis. There are two inequivalent $Cu^{++}$ ions in unit cell, so axes $Z_1$ and $Z_2$ which means the $Z$ axes of these ions orientate themselves differently as shown in Fig. 2. $L_1$ and $L_2$ in Fig. 2 are the bisector of the acute and obtuse angle between $Z_1$ and $Z_2$, and $L_3$ is the normal to the plane of $Z_1$ and $Z_2$. In $Z_1Z_2$ plane, only one peak is observed in every direction which may be ascribed to the exchange interaction, so we assume the observed peak shows the mean of $g$ values of two $Cu^{++}$ ions in unit cell. The observed $g$ values are shown in Fig. 3 as a function of direction. Assuming that the crystalline field arround each $Cu^{++}$ ion has tetragonal symmetry, the $g$ value may be estimated from these data as $g_{//}=2.35$ and $g_{\perp}=2.06$. The full line widths $\Delta H$ of absorption at $\lambda=11$ mm are listed in Table II, and the experimental error of $\Delta H$ is less than 20 oer. The calculated dipolar width is also listed in this table[6,7]. Though the exchange narrowing for these directions with the identical $g$ values may be expected[8,9], the observed widths are approximately the same as the calculated dipolar ones. All the line shapes are of Lorentzian type.

ii) *Copper Formate Dihydrate*
*$Cu(HCOO)_2 \cdot 2H_2O$*

This crystal has four $Cu^{++}$ ions in an unit cell, which make a face centered lattice of coppers. Directions of four $Z$-axes in this crystal are shown in Fig. 4. Each $Cu^{++}$ ion is surrounded by four oxygens and two water molecules as in its tetrahydrate. Only one peak is observed in any direction as the case of its tetrahydrate. When the sample is rotated in the $ac$-plane, the observed $g$-value reaches to its maximum value in $K$-direction as shown in Fig. 5. The observed half value widths at $\lambda = 11$ mm and calculated dipolar widths are shown in Table III. Now a considerable narrowing of width occurs.

Our thanks are due to Prof. Hiroo Kumagai for his continuous guidance and encouragement and to Miss H. Ibamoto at Ôsaka University for her preparation of the single crystals used in our measurements.

# Apparent Molecular Weight of Polytrifluorochloroethylene

By Atsuo NISHIOKA and Ryuzo KOYAMA
*Electrical Communication Laboratory, Musashino, Tokyo*

(Read June 3rd, 1955 and received September 20, 1955)

To clarify the accuracy and physical basis of the two methods, NST and ZST, giving the apparent molecular weight of Polytrifluorochloroethylene, some experiments were made by statistical means and their variances were analysed. We have derived theoretical relations between these apparent molecular weights and true average molecular weight by a simple model. The observed tendency of our experimental results between NST and ZST are qualitatively in accordance with our theoretical relations.

## § 1. Introduction

Fluorocarbon polymers are known by their excellent heat resistant, moisture proof and chemically resistant properties, but on the other hand, their insolubility at ordinary temperatures makes the measurement of their molecular weight difficult. Polytrifluorochloroethylene, $(-CF_2CFCl-)_n$, one of the fluorocarbon polymers, dissolves in certain chlorofluorocarbons at elevated temperature, but the operation of the measurement of molecular weight in dilute solution at high temperature is not easy, and these solvents are not easily available, and so the solution viscosity method is not suitable for the control of polymer and fabricating process. Therefore, several methods of determining apparent molecular weight related with melt viscosity were developed. Among these methods, there are parallel plate melt viscosity method, flow index method, no-strength-temperature test, and zero-strength-time test. Owing to the simple

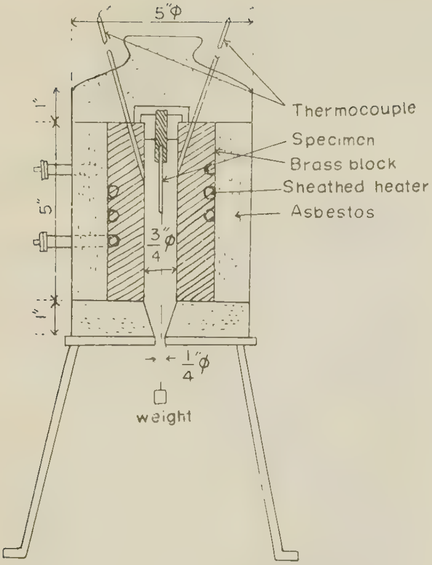

Fig. 1. NST testing apparatus.

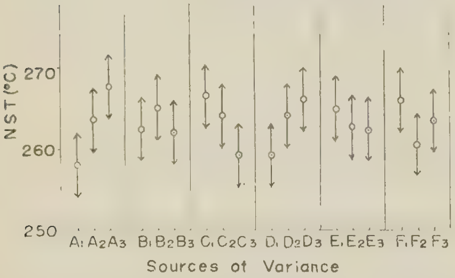

Fig. 2. Changes of sources of variances with each level at the confidence level of 95%.

operation, the last two methods are more practical than the others. No Strength Temperature test (NST) determines the temperature at which a standard notched and loaded sample breaks at constant heating rate, and Zero Strength Time test (ZST) determines the time at which the similar specimen breaks at constant temperature. Both the NST and the logarithm of ZST were already observed in a linear relation approximately with molecular weight. ZST test was developed recently as an improved method of NST test, but the accuracy of NST test and the physical basis of their dependence upon molecular weight has not been studied in detail.

We have performed some experiments on these two tests by a statistical method. In the following we discuss their accuracies and derive the relation between the apparent molecular weights and true average molecular weight by a simple model.

Table I. Design of Experiment.

| source of variation \ level | | 1 | 2 | 3 |

## § 2. No Strength Temperature Test

No Strength Temperature is the point at which a standard notched and loaded sample breaks under a standard rate of temperature rising¹⁾. To perform the test, a sample of the polymer is pressed into a 1/16 in. thick disc. A strip $1\frac{5}{8}$ in. long by 1/8 in. wide, which was cut from this disc, has a double notch end 3/64 in. wide, 1 in. from the end. A weight is then attached to the one end to give a total weight, 0.5 gram, of the sample and added weight from the notch down. This sample is then suspended in a heated oven held at 210°C, and the temperature is raised 1.5°C per min. until the sample breaks at the notch. The temperature of the oven is then read as the No Strength Temperature.

a) *Design of Experiment*

The sources of variation of NST are mainly composed of six factors, that is, the width of the notch, the thickness of the sample, the weight, the heating rate, starting temperature, and the waiting time from the insertion of the specimen to the beginning of heating. We designed our experiment by the statistical procedure with Latin Square of 18 specimens shown in Table I. The tested sample was Daiflon-resin of NST 270 manufactured by Osaka Kinzoku Kogyo K. K.

### b) *Experimental Results*

The testing apparatus used for this test was similar to that originally designed by Giannotta[2], but the NST was read by chromel-almel thermocouple (Fig. 1). Since the accuracy of the width of the notch seems to give predominant influence on NST value, we cut the double notch by means of special cutter and zig, not by a punch. The heating rate was adjusted by a geared temperature controller. The NST of the samples specified by the Table I were measured in randomized order. The numerical analysis of variance of the observed NST values is listed in the following Table II, and the tendencies of each factor were shown in Fig. 2.

As seen from Table II, NST is significantly affected by the notch width, weight and heating rate, but negligibly by the thickness, starting temperature and waiting time. The fact that the effect of thickness is very small, seems to be curious, but could be explained as follows. The weight of the specimen under the notch is comparable to the added weight, so the change of tensile stress due to the change of thickness is almost cancelled with the change of total weight due to that of the weight of the specimen. The mean value of NST under the specified condition is 267±6°C at the confidence level of 95%. The relative error of this value is small, but the variance of ±6°C seems to be large compared with the temperature range usually observed from 240°C to 310°C.

Another factor seemed to affect the NST value. It is the anisotropy effect which means the difference of tensile strength between the parallel and perpendicular to the radial direction, but this effect is not significant at the confidence level of 95%. So we have neglected this anisotropy effect.

### c) *Theory*

As seen from the above description, the result of this test seemed to be mainly determined by the notch width of the specimen, and NST increased proportionally with notch width and heating rate, and decreased with the added weight. Also the molecular weights of polytrifluorochloroethylene by high temperature osmometry[3] shows the approximately linear relationship to NST. However, the physical interpretation of this dependence of NST has not been ever studied. Difficulties of this study seem to lie in the special form of double notch, but we considered that the essential point of this test is the section of the notch and so we simplified this part in the following model.

We assume a rod-like specimen with the sectional area $A$ and the length $l$, attached a weight $W$ at the end. When the temperature of the specimen is raised at a constant rate, the elongation rate will be proportional to the tensile stress and the length, and reciprocally to melt viscosity at the temperature, So we have the next equation,

$$\frac{dl}{dt}=C\frac{Wl}{A\eta} \tag{1}$$

where $t$ is time, $C$ is the proportionality constant and $\eta$ is melt viscosity. And in relatively short range of temperature, the melt viscosity is related with absolute temperature $T$ by the formula,

$$\eta=\eta_0\exp(E/RT)\ , \tag{2}$$

where $\eta_0$ is a constant dependent upon molecular weight, $E$ is the activation energy for melt viscosity, and $R$ is the gas constant. Also the heating rate $k$ is constant, so we have

$$T=T_0+kt\ , \tag{3}$$

where $T_0$ is the starting temperature. Combining these equations, we have

$$\frac{dl}{dt}=\frac{CWl}{A\eta_0}\exp[-E/RT]. \tag{4}$$

Assuming that the volume of the specimen is constant, and NST is defined when $l$ becomes infinite at a temperature $T_c$, we have

$$\int_{T_0}^{T_c}\exp(-E/RT)dT=A_0k\eta_0/CW, \tag{5}$$

where $A_0$ is the initial area of cross section and $T_c$ is the No Strength Temperature. The exponential term of the left hand side of Eq. (5) can be expanded in series form around the starting temperature $T_0$. Then we have

$$\exp(-E/RT)=\exp\left\{(-E/RT_0\left[1-\left(\frac{T-T_0}{T_0}\right)+\left(\frac{T-T_0}{T_0}\right)^2-\left(\frac{T-T_0}{T_0}\right)^3+\cdots\right]\right\}. \tag{6}$$

Since $T_0$ is 210°C, and No Strength Temperature is usually found between 240°C and 310°C, $(T-T_0)/T_0$ is smaller than unity (1/16∼1/5). So, if we neglect the higher order term of $(T-T_0)/T_0$ in Eq. (6), then we have

$$\int_{T_0}^{T_c}\exp(-E/RT)dT=\int_{T_0}^{T_c}\exp\left\{(-E/RT_0)\left(1-\frac{T-T_0}{T_0}\right)\right\}dT$$
$$=\exp\left(-\frac{E}{RT_0}\right)\left(\frac{RT_0^2}{E}\right)\left\{\exp\left(\frac{E}{RT_0^2}(T_c-T_0)\right)-1\right\}. \tag{7}$$

From Eq. (5), we have

$$\exp\left(\frac{E}{RT_0^2}(T_c-T_0)\right)\left\{1-\exp\left(-\frac{E}{RT_0^2}(T_c-T_0)\right)\right\}=\frac{A_0k\eta_0}{CWT_0}\frac{E}{RT_0}\exp\left(\frac{E}{RT_0}\right) \tag{8}$$

$$\therefore\quad \frac{E}{RT_0^2}(T_c-T_0)+\log\left\{1-\exp\left(-\frac{E}{R^2T_0}(T_c-T_0)\right)\right\}=\log\eta_0+\log\frac{A_0kE}{CWRT_0^2}+\frac{E}{RT_0}. \tag{9}$$

If we assume that the molecular weight $M$ is approximately proportional to logarithm of melt viscosity in our temperature range, we can write

$$\log\eta_0=\alpha+\beta M. \tag{10}$$

So, Eq. (9) becomes

$$\frac{E}{RT_0^2}(T_c-T_0)+\log\left\{1-\exp\left(-\frac{E}{RT_0^2}(T_c-T_0)\right)\right\}=\beta M+\log\frac{A_0kE}{CWRT_0^2}+\alpha+\frac{E}{RT_0}. \tag{11}$$

Here the activation energy $E$ had already been found to be 15 Kcal/mol by Dexter[4], but recently Furuya[5] has obtained some higher values. So, if we assume it to be 20 Kcal/mol and take the range of $T_c$ between 240°C and 310°C, the first term of the left hand side of Eq. (11) varies from 1.207 to 4.025, whereas the second term varies from −0.357 to −0.018 and its contribution may be negligible above 250°C within the error of 5°C as seen from Fig. 3. In this figure $f_1$ and $f_2$ show the first and second terms of the left hand side of Eq. (11) respectively. The correction term $f_2$ cannot be neglected in the lower temperature range near 240°C, so the left hand side of Eq. (11) is not rigorously proportional to $T_c$ from 240°C to 310°C, but may be approximately considered to be linear above 250°C within the error of 5°C, and this error is decreased rapidly in higher temperature. Therefore this equation would be considered to show the approximate linear relation between NST and molecular weight in usually available temperature range of NST. Further, the second term of the right hand side of Eq. (11) show the dependence of NST upon cross section of the specimen $A_0$, heating rate $k$, added weight $W$, which is qualitatively in well accordance with the observed tendencies[6] (Fig. 2).

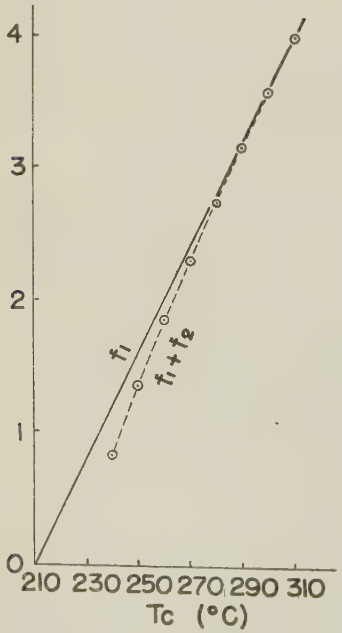

Fig. 3. Linearity of the left hand side of Eq. (12) with NST.

## § 3. Zero Strength Time Test

This test, developed recently by Kaufman et al[7], determines the time at which the standard sample like the NST test, breaks under the standard weight of 7.5 gram at constant temperature of 250°C. The specimen is almost the same as that of NST except the width of the notch (3/16 in.). We have performed this test using the same specimen of NST test. The weight was about 8.3 gram. The merit of this test is in its simple linear relation between the logarithm of ZST and solution viscosity.

a) *Experimental Results*

The tested specimens were three grades of Daiflon-resin, which have the NST of 242, 268 and 306, and another three grades of Fluorothene, namely FYTD, FYTH and FYTS, which have the NST of 281, 287 and 296 respectively. These values of NST were the average values measured on five specimens of each grade. The experiment was performed on two groups of 3×3 Latin Square specified by NST, furnace temperature and thickness of the sample. The observed ZST values were plotted against to NST as shown in Fig. 4. This result shows the linear relation between the NST and the logarithm of ZST in the temperature range from 240°C to 310°C. Although Kaufman[7] has reported the non-linear relation between the two values above 300°C and attributed this to the thermal degradation of this polymer, we observed fairly good linearity between NST and log ZST in this range and the effect of thermal degradation seems to be relatively small and practically negligible.

b) *Theory*

The feature of this test is in the linearity between log ZST and molecular weight. We shall now try to derive this relation by the similar model to that of NST test previously described. The fundamental equation is also the same in this case. Now in ZST test, as the temperature is constant, the melt viscosity is also constant. Assuming the constant volume of the notched part, we can obtain the following equation from Eq. (1).

$$t_c = A_0\eta/CW\,, \tag{12}$$

where $t_c$ is the Zero Strength Time and another symbols are the same as in NST case. This relation means that the Zero Strength Time is proportional to the melt viscosity. Then, from (12), we have

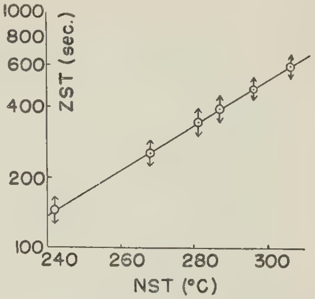

Fig. 4. Zero Strength Time versus No Strength Temperature.

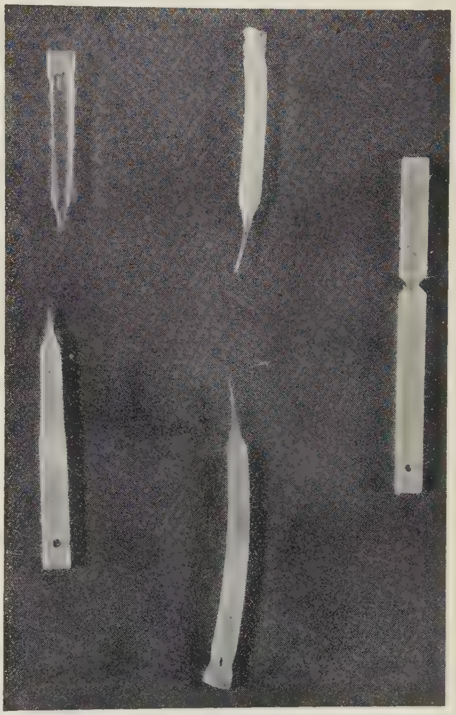

Fig. 5. Broken specimens of ZST (left) and NST (central). Original specimen is at the right.

$$\log t_c = \text{const.} + \log\eta + \log A_0/W\,, \tag{13}$$

Since $\log\eta$ is proportional to molecular weight $M$ as in the previous section, logarithm of the Zero Strength Time is proportional to molecular weight. Therefore we have

$$\log t_c = \beta M + \log A_0/W + \text{const.} \tag{14}$$

Comparing the equation (11) with (14), we can easily derive the linear relationship between NST and log ZST, which was observed experimentally. Since the variation term, $A_0/W$, is included in the same logarithmic form in Eqs. (11) and (14), the variance of NST and log ZST are comparable about these terms. This means that the accuracy of NST is higher than ZST, but comparable to log ZST.

In our simplified theory, the mechanism of the breaking of the specimen is assumed to be same in both cases, but the observation of the broken sample shown in Fig. 5 suggests different mechanisms for these two tests. The fact that the broken part of the notch is considerably elongated in NST test would be probably in favour of our model based on the melt viscosity, but the broken specimen of the ZST test is less elongated and has a finite sectional area at the tip, different from the negligible area of NST sample. Further, the surface of the tip is not uniform, suggesting the mechanism of breaking at weak points, pointed out by Yamada[8]. Therefore the mechanism of the breaking in both cases may be slightly different.

Another point to be mentioned is the assumption of constant volume. In our model, the narrow part of the notch is replaced by a rod-like specimen, but the possibility of the polymer flowing into the notched part from the other part cannot be neglected and so the above assumption may not be applied rigorously in our case.

Therefore, we must study in further detail about these points to interprete the mechanism of the breaking of the specimen more elaborately.

## § 4. Conclusion

From the observed results in our experiments and the theoretical discussion, we have the following conclusions.

(1) NST depends largely upon the notch width, but not upon the thickness of the specimen in its small variance.

(2) NST increases with the heating rate and the reciprocal of the added weight.

(3) NST does not depends significantly upon the small variance of starting temperature, the waiting time and anisotropy.

(4) NST is approximately proportional to molecular weight and logarithm of ZST from 240°C to 310°C.

(5) The accuracy of NST is higher than ZST, but comparable to log ZST.

(6) The thermal degradation effects in NST test is not significant up to 310°C.

These conclusions would not suggest the superiority of ZST test to NST test, differing from the suggestion of Kaufman[7].

### Acknowledgement

The authors express their sincere thanks to Mr. Ichimiya and Mr. Miyazaki for their encouragement on this work, and to Mr. Furuya for the use of his unpublished data, and Mr. Yamada for his helpful discussions. We are indebted to the courtesy of Osaka Kinzoku Kogyo K. K. for the performance of this experiment.

# A Study of the Compressilbe Flow past a Cherry Profile

By Hideo TAKAMI

*Department of Physics, Faculty of Science, University of Tokyo*

(Received September 14, 1955)

In this paper the compressible gas flow past a Cherry profile is studied by means of Kármán-Tsien's method, the $M^2$-expansion method and Meksyn-Imai's method. The velocity distributions over the surface of the profile are calculated for various free stream Mach numbers and compared with Cherry's exact one as well as with one another. Imai's $\Phi\Psi$-procedure in the $M^2$-expansion method is shown to be the most efficient for the study of the flow up to comparatively high (subsonic) Mach number. It is found that there exists a qualitative difference between the velocity distribution of Cherry's exact solution and those calculated by means of the approximate methods, and some discussions are given about Cherry's solution.

## § 1. Introduction

A number of methods of approach have been devised by many investigators to deal with the two-dimensional compressible flow of the inviscid gas past an obstacle; namely, the hodograph method, the thin-wing-expansion method and the $M^2$-expansion method. Among these the hodograph method alone enables us to treat the problem exactly even in the case of the transonic flow, because only in the hodograph variables we can have linear equations governing the compressible flow. Thus exact solutions of continuous transonic flow past a cylindrical obstacle were obtained by Lighthill [12] and Cherry [2] (for the adiabatic gas), and by Tomotika and Tamada [16] (for a certain hypothetical gas) by using the hodograph method.

In its exact form, however, the hodograph method has a disadvantage that it can hardly be applied to the study of the flow past an obstacle of *given* shape. For this purpose we must have recourse to some simple approximations in the hodograph plane itself or to successive approximations in the physical plane.

As for the former we may mention Kármán-Tsien's method [17] and Imai's WKB method [9], both of which essentially reduce the compressible flow problem to that of the incompressible one and have been applied to many cases on account of the simplicity of calculation.

On the other hand, the $M^2$-expansion method has been developed and applied by many investigators to the treatment of the flow past bodies of arbitrary shapes at moderate (subsonic) Mach number, while the thin-wing-expansion method has also been successfully applied to the study of the flows past thin obstacles under the condition that the disturbance velocities from the uniform flow are small.

Recently Meksyn [13] proposed an approximate method for the treatment of the flow at comparatively high Mach number, of which Imai [11] soon after pointed out the intimate relationship with the usual $M^2$-expansion method.

In this paper we shall apply the Kármán-Tsien method, the $M^2$-expansion method and the Meksyn-Imai method to the study of the compressible flow past a Cherry profile, and calculate the velocity distributions over its surface for various free stream Mach numbers. The calculated velocity distributions will be compared with Cherry's exact one as well as with one another to investigate the limitations of the validity of these approximate methods, and some conjectural discussions on Cherry's solution will be given.

## § 2. Cherry's Exact Solution

As is well known, Cherry [2] constructed a family of exact solutions for two-dimensional potential flow of a compressible fluid past a cylindrical obstacle by means of the hodograph method, and performed numerical calculations for particular values of parameters [3] [4]. One of his numerical solutions gives a continuous

transonic flow with free stream Mach number 0.5098 past a cylinder whose section is a doubly symmetrical oval with thickness ratio 0.931, the incident stream being parallel to the major axis of symmetry (Fig. 1). The flow field contains two supersonic regions adjacent to the body and the velocity distribution over the quadrant of its surface is shown in Fig. 2.

## § 3. The Mapping Function for the Cherry Profile and the Incompressible Velocity Distribution

For the present study of the flow past a Cherry profile, it is necessary to obtain the analytic function which maps the profile into the unit circle. This is conveniently done by means of the successive procedure developed by Imai [5] [10], of which the outline will be given in the following.

It is well known that the region outside an arbitrary profile $P$ in the $z(=x+iy)$-plane can be mapped conformally onto the region outside the unit circle $Z=e^{i\theta}$ in the $Z$-plane by an analytic function of the form:

$$z=c_{-1}Z+c_0+\frac{c_1}{Z}+\frac{c_2}{Z^2}+\cdots . \tag{3·1}$$

If the profile itself is expressed as $z_P=x_P(\theta)+iy_P(\theta)$ (cf. Fig. 3), the following relation holds between $x_P$ and $y_P$:

$$x_P(\theta)=\left\{1-\frac{1}{2}\,y_P{}^*(0)+\frac{1}{2}y_P{}^*(\pi)\right\}\cos\theta+y_P{}^*(\theta)$$
$$-\frac{1}{2}y_P{}^*(0)-\frac{1}{2}y_P{}^*(\pi)\ , \tag{3.2}$$

where $y^*(\theta)$ denotes the conjugate Fourier series associated with $y(\theta)$, i.e., if

$$y(\theta)=a_0+\sum_{n=1}^{\infty}(a_n\cos n\theta+b_n\sin n\theta)\ ,$$

then

$$y^*(\theta)=\sum_{n=1}^{\infty}(a_n\sin n\theta-b_n\cos n\theta)$$
$$=-\frac{1}{2\pi}\int_0^{2\pi}\{y(\varphi+\theta)-y(\theta)\}\cot\frac{\varphi}{2}d\varphi\ , \tag{3.3}$$

and it is assumed that the profile is symmetric with respect to the $x$-axis and cuts it at the points (1, 0) and (−1, 0).

Eq. (3.2) is the basic relation for the successive procedure. Let us calculate the values of $x_P$ and $y_P$ for $\theta=\theta_k=2\pi k/40$ $(k=0, 1, 2, \cdots, 39)$[*] as follows:

(1) Take $x^{(0)}(\theta_k)=\cos\theta_k$ as the 0th approximation and read the ordinates $y^{(1)}(\theta_k)$ on the profile corresponding to the abscissae $x^{(0)}(\theta_k)$.

(2) Calculate $y^{(1)\prime}(\theta_k)$ by the use of the Stirling interpolation formula.

(3) Replacing the integration in Eq. (3.3) by the summation, calculate

$$y^{(1)*}(\theta_k)=-\frac{1}{20}y^{(1)\prime}(\theta_k)+\sum_{s=1}^{19}\{y^{(1)}(\theta_{k+s})-y^{(1)}(\theta_{k-s})\}\frac{1}{40}\cot\frac{s\pi}{40}\,.$$

(4) By the use of Eq. (3.2) calculate

$$x^{(1)}(\theta_k)\equiv\left\{1-\frac{1}{2}y^{(1)*}(0)+\frac{1}{2}y^{(1)*}(\pi)\right\}\cos\theta_k+y^{(1)*}(\theta_k)-\frac{1}{2}y^{(1)*}(0)-\frac{1}{2}y^{(1)*}(\pi)\,,$$

thus completing the first approximation.

But, in general, the points $(x^{(1)}(\theta_k), y^{(1)}(\theta_k))$ do not lie on the original profile, so the above process must be repeated with $x^{(1)}(\theta_k)$ instead of $x^{(0)}(\theta_k)$, etc., until the process converges.

For the Cherry profile 7 steps are necessary in order to obtain the final values of $x_P$ and $y_P$.

Once we get $x_P$ and $y_P$, the velocity $q_{\text{inc}}$ on the surface for the incompressible flow with its undisturbed stream direction parallel to the $x$-axis is easily calculated as

$$\frac{q_{\text{inc}}}{U_{\text{inc}}}=\frac{1-\frac{1}{2}y_P{}^*(0)+\frac{1}{2}y_P{}^*(\pi)}{\sqrt{\left(\frac{dx_P}{d\theta}\right)^2+\left(\frac{dy_P}{d\theta}\right)^2}}\sin\theta\,, \qquad (3.4)$$

where $U_{\text{inc}}$ is the velocity of the undisturbed flow.

In Fig. 2 the values of $q_{\text{inc}}/U_{\text{inc}}$ are plotted against the arc length measured from the stagnation point. It may be noted that there exists a qualitative difference from the velocity distribution of Cherry's solution for the compressible flow.

## § 4. The Kármán-Tsien Method

Now we shall study the flow past the Cherry profile by means of Kármán-Tsien's method [17].

According to this, the velocity $q$ for the compressible flow with free stream Mach number $M$ is approximately given in terms of $q_{\text{inc}}$ and $M$ simply as follows:

$$\frac{q}{U}=\frac{q_{\text{inc}}}{U_{\text{inc}}}\,\frac{1-\lambda}{1-\lambda(q_{\text{inc}}/U_{\text{inc}})^2} \qquad (4.1)$$

where $U$ is the free stream velocity and

$$\lambda=\frac{1-\sqrt{1-M^2}}{1+\sqrt{1-M^2}}\,.$$

In Fig. 2, the values of $q/U$ calculated by Eq. (4.1) are shown for $M=0.350$ and 0.5098. (For comparison with the results obtained by the other methods, the values of $q/c_*$ are also shown for $M=0.420$ and 0.5098 in Figs. 5(b) and (d), $c_*$ being the critical sound velocity.)

As is well known, however, the velocity distribution thus obtained does not correspond to the original profile $P$, but to a different one, say $P'$, which is given as

$$\zeta_{P'}=z_P-\lambda\int_0^\theta(q_{\text{inc}}/U_{\text{inc}})^2(dz_P/d\theta)d\theta\,,$$

or

$$\left\{\begin{aligned}\xi_{P'}&=\int_0^\theta\{1-\lambda(q_{\text{inc}}/U_{\text{inc}})^2\}(dx_P/d\theta)d\theta\,,\\ \eta_{P'}&=\int_0^\theta\{1-\lambda(q_{\text{inc}}/U_{\text{inc}})^2\}(dy_P/d\theta)d\theta\,.\end{aligned}\right. \qquad (4.2)$$

The deformed contour for $M=0.5098$ is shown in Fig. 1 in comparison with the original Cherry profile.

So we must start with the incompressible flow past certain other profile which is to be deformed into the original one after the above-mentioned transformation. For this purpose, the following iterative procedure may be employed for the Mach number in question (cf. Fig. 4):

(1) For given $P$, calculate $q_{\text{inc}}/U_{\text{inc}}$ and the deformed profile $(\xi_0, \eta_0)$ according to (3.4) and (4.2).

(2) The profile $(\xi_0, \eta_0)$ is similarly enlarged into $(\xi_{0N}, \eta_{0N})$ so that $\xi_{0N}(0)=-\xi_{0N}(\pi)=1$.

(3) For $\xi_{0N}(\theta_k)$ read the ordinates $\bar{\eta}_{0N}(\theta_k)$ on $P$.

(4) Calculate $\bar{\eta}_0(\theta_k)\equiv\bar{\eta}_{0N}(\theta_k)\cdot\xi_0(0)$ and $\bar{\eta}_0{}'(\theta_k)$.

---

[*] Later we shall calculate the velocity only for these points, and this may be sufficient for the purpose of this paper.

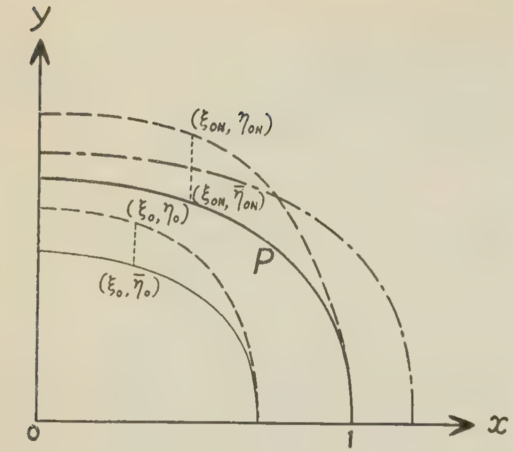

Fig. 4. The shapes of the profiles (one quadrant).
━━━ The original profile $P$,
——— the original profile (reduced),
– – – the deformed profile,
━ ━ ━ the deformed profile (enlarged),
━ - ━ - $(x_1, y_1)$.

(5) Calculate $y_1'(\theta_k) \equiv \bar{\eta}_0'(\theta_k)/\{1-\lambda(q_{\text{inc}}/U_{\text{inc}})^2\}$ (cf. (4.2)), $y_1''(\theta_k)$ and $y_1'^*(\theta_k)$.

(6) Calculate.

$$x_1'(\theta_k) \equiv -\left\{1-\frac{1}{2}y_1^*(0)+\frac{1}{2}y_1^*(\pi)\right\}\sin\theta_k + y_1'^*(\theta_k)\,, \qquad \text{(cf. (3.2))}$$

and

$$Q_1(\theta_k) \equiv \frac{1-\frac{1}{2}y_1^*(0)+\frac{1}{2}y_1^*(\pi)}{\sqrt{\left(\frac{dx_1}{d\theta}\right)^2+\left(\frac{dy_1}{d\theta}\right)^2}}\sin\theta_k\,. \qquad \text{(cf. (3.4))}$$

(7) Calculate

$$\begin{cases} \xi_1(\theta_k) \equiv \int_0^{\theta_k}(1-\lambda Q_1^2)x_1'\,d\theta\,, \\ \eta_1(\theta_k) \equiv \int_0^{\theta_k}(1-\lambda Q_1^2)y_1'\,d\theta\,. \end{cases}$$

If the shape of this profile $(\xi_1, \eta_1)$ is not similar to that of $P$, the above procedure is repeated for $(\xi_1, \eta_1)$ instead of $(\xi_0, \eta_0)$, etc., until the iteration converges and a profile, say $(\xi_n, \eta_n)$, similar to $P$ is finally obtained.

For the points $(\xi_n(\theta_k), \eta_n(\theta_k))$ on $P$ the velocities are calculated from (3.4) and (4.1) with $x_n$ and $y_n$ instead of $x_P$ and $y_P$.

In our case for $M=0.5098$, 11 steps of iteration are necessary to find the profile which is deformed into the Cherry profile. The profile is shown in Fig. 1 and the velocity distribution $q/U$ in Fig. 2. (Also $q/c_*$ is shown in Fig. 5(d).)

## § 5. The $M^2$-Expansion Method

We now apply the $M^2$-expansion method in the form developed by Imai [6], of which also a brief account will be given.

Suppose that a symmetrical obstacle* is placed in a uniform flow of Mach number $M$ whose direction is parallel to the axis of symmetry which we shall take as the $x$-axis (Fig. 3).

Now let us assume that the velocity potential $\Phi$ can be expanded in a power series in $M^2$:

$$\Phi(z)=\Phi_0(z)+M^2\Phi_1(z)+M^4\Phi_2(z)+\cdots, \qquad (5.1)$$

then the values of $\Phi_0, \Phi_1, \Phi_2, \cdots$ on the profile are calculated as

$$\begin{cases} \Phi_0(\theta)=2A\cos\theta\,, \\ \Phi_1(\theta)=P_1(\theta)-Q_1^*(\theta)\,, \\ \Phi_2(\theta)=\Phi_{20}(\theta)+(\gamma+1)\Phi_{21}(\theta) \\ \qquad =\{P_{20}(\theta)-Q_{20}^*(\theta)\}+(\gamma+1)\left\{P_{22}(\theta)-Q_{22}^*(\theta)-\frac{1}{2}\Phi_1(\theta)\right\}\,, \\ \cdots\cdots\cdots\cdots\cdots\cdots \end{cases}$$

Here $\theta$ has the same meaning as in Eq. (3.2), and

$$A=1-\frac{1}{2}y_P^*(0)+\frac{1}{2}y_P^*(\pi)\,,$$

$$\begin{cases} P_1(\theta)=-\frac{1}{2}q_0\sin\omega\int_0^s q_0^2\sin\omega\,ds\,, \\ Q_1(\theta)=-\frac{1}{2}q_0\cos\omega\int_0^s q_0^2\sin\omega\,ds\,. \end{cases}$$

---

* To avoid unnecessary complication the formulae will be given for a profile which is symmetrical with respect to the direction of the uniform flow.

$\omega$ is the angle between the $x$-axis and the tangent to the profile, so that

$$\sin\omega=\frac{y_P'}{\sqrt{x_P'^2+y_P'^2}}\,,\qquad \cos\omega=\frac{x_P'}{\sqrt{x_P'^2+y_P'^2}}\,,$$

$s$ is the arc length measured from the downstream stagnation point; and $q_0=-d\Phi_0/ds$ is equal to $q_{\rm inc}/U_{\rm inc}$ in Eq. (3.4). Further

$$\left\{\begin{aligned}
P_{20}(\theta)&=-\frac{1}{16}(q_0^2+1)A-\frac{1}{8}\,CF+\frac{1}{8}\left(\frac{dB}{d\theta}\cos\omega-\frac{dB^*}{d\theta}\sin\omega\right)E\\
&\qquad+\frac{1}{4}\,q_0\sin\omega\cdot G-\frac{A}{4}\cos\theta\,,\\
Q_{20}(\theta)&=-\frac{1}{16}(q_0^2-1)A-\frac{1}{8}\,DF-\frac{1}{8}\left(\frac{dB}{d\theta}\sin\omega+\frac{dB^*}{d\theta}\cos\omega\right)E\\
&\qquad+\frac{1}{4}\,q_0\cos\omega\cdot G\,,
\end{aligned}\right.$$

where

$$\left\{\begin{aligned}
A&=q_0\cos\omega\int_0^s q_0^2\cos\omega\,ds+q_0\sin\omega\int_0^s q_0^2\sin\omega\,ds\,,\\
B&=q_0\sin\omega\int_0^s q_0^2\cos\omega\,ds-q_0\cos\omega\int_0^s q_0^2\sin\omega\,ds\,,\\
C&=\sin\omega\,\frac{d}{d\theta}(q_0\cos\omega)+\cos\omega\,\frac{d}{d\theta}(q_0\sin\omega)\,,\\
D&=\cos\omega\,\frac{d}{d\theta}(q_0\cos\omega)-\sin\omega\,\frac{d}{d\theta}(q_0\sin\omega)\,,\\
E&=\left\{\left(\frac{dx_P}{d\theta}\right)^2+\left(\frac{dy_P}{d\theta}\right)^2\right\}^{-1/2}\int_0^s q_0^2\sin\omega\,ds\,,\\
F&=E\int_0^s q_0^2\cos\omega\,ds\,,\\
G&=\int_0^\theta\left(\frac{dB}{d\theta}\cos\omega-\frac{dB^*}{d\theta}\sin\omega\right)q_0\,d\theta\,,
\end{aligned}\right.$$

and

$$\left\{\begin{aligned}
P_{22}(\theta)&=-\frac{1}{8}\,q_0^2\sin 2\omega\int_0^s q_0^3\sin 2\omega\,ds\,,\\
Q_{22}(\theta)&=-\frac{1}{8}\,q_0^2\cos 2\omega\int_0^s q_0^3\sin 2\omega\,ds\,.
\end{aligned}\right.$$

$\gamma$ is the ratio of the specific heats, which we shall take to be 1.40 in the calculation.

If we also expand the velocity $q(\theta)$ as

$$q(\theta)=q_0(\theta)+M^2q_1(\theta)+M^4q_2(\theta)+\cdots,\tag{5.2}$$

then

$$q_n(\theta)=-\frac{d\Phi_n}{ds}=-\frac{d\Phi_n}{d\theta}\frac{d\theta}{ds}=-\frac{d\Phi_n/d\theta}{\sqrt{x_P'^2+y_P'^2}}\qquad (n=0,1,2,\cdots)^*.$$

Imai [7] further developed the theory as follows:

(1) The $\Psi$-procedure. From the mathematical point of view, the velocity potential $\Phi$ and the stream function $\Psi$ are equivalent quantities since the flow field is completely determined by giving either of them; in fact, we could have obtained the velocity from the steam function $\Psi$ according to the equation

---

* Here and later we take the velocity of the undisturbed flow as the unit of velocity.

$$\frac{\partial\Psi}{\partial n}=\frac{\rho q}{\rho_\infty}=q\left\{1+\frac{\gamma-1}{2}M^2(1-q^2)\right\}^{1/(\gamma-1)},$$

where $dn$ is the line element normal to the streamline, $\rho$ is the density and suffix $\infty$ means the value in the uniform flow. This procedure for calculating the velocity may be called "$\Psi$-procedure" as the counterpart of the usual "$\Phi$-procedure".

In general, the velocities calculated according to the $\Psi$-procedure is not identical with those from the $\Phi$-procedure, but the difference between them is, of course, within the order of the approximation employed and may give a measure of the errors involved in this approximation.

Practically $\partial\Psi/\partial n$ can easily be calculated if we know $q_0, q_1, q_2, \cdots$ in the $\Phi$-procedure.

Let the stream function $\Psi$ and the density $\rho$ be expanded as

$$\begin{cases}\Psi=\Psi_0+M^2\Psi_1+M^4\Psi_2+\cdots,\\ 1-\dfrac{\rho}{\rho_\infty}=M^2\rho_1+M^4\rho_2+\cdots,\end{cases}$$

where

$$\rho_1=\frac{1}{2}(q_0^2-1),\quad \rho_2=q_0q_1-\frac{2-\gamma}{8}(q_0^2-1)^2,\ \cdots,$$

then inserting these expansions and (5.1) into the relation

$$\frac{\partial\Psi}{\partial n}=-\frac{\rho}{\rho_\infty}\frac{\partial\Phi}{\partial s},$$

and comparing the terms of the same powers of $M^2$, we get

$$\begin{cases}\dfrac{\partial\Psi_0}{\partial n}=-\dfrac{\partial\Phi_0}{\partial s}=q_0,\\ \dfrac{\partial\Psi_1}{\partial n}=-\dfrac{\partial\Phi_1}{\partial s}+\rho_1\dfrac{\partial\Phi_0}{\partial s}=q_1-\rho_1q_0,\\ \dfrac{\partial\Psi_2}{\partial n}=-\dfrac{\partial\Phi_2}{\partial s}+\rho_1\dfrac{\partial\Phi_1}{\partial s}+\rho_2\dfrac{\partial\Phi_0}{\partial s}\\ \qquad=q_2-\rho_1q_1-\rho_2q_0,\\ \cdots\cdots\cdots\cdots\cdots\cdots\,.\end{cases}$$

In order to obtain $q$ from $\rho q/\rho_\infty$, it is convenient to use the numerical table (e.g. [8]).

(2) The $\Phi\Psi$-procedure. Also by means of the relation

$$\frac{\rho}{\rho_\infty}=\left\{1+\frac{\gamma-1}{2}M^2(1-q^2)\right\}^{1/(\gamma-1)},$$

in which the value from the $\Phi$-procedure is substituted for $q$, the velocity can be obtained as

$$q=\frac{\rho_\infty}{\rho}\frac{\partial\Psi}{\partial n},$$

which is the "$\Phi\Psi$-procedure" For the evaluation of $\rho/\rho_\infty$ also the use of the numerical table is convenient in practice.

Applying these procedures to the cases of a circular cylinder and a circular-arc aerofoil, Imai found some properties about them which may be summarized as follows:

(1) In the $\Psi$-procedure, as the iteration proceeds the approximated velocity in the high (low) speed region decreases (increases) contrary to the familiar character observed in the $\Phi$-procedure. It is therefore expected that by their combination we may be able to estimate the error involved less ambiguously than by using the $\Phi$-procedure alone, and so the $\Phi\Psi$-procedure may give the most plausible result within the order of the approximation employed since the latter is considered to give a mean (in some sense) of the results obtained by the $\Phi$- and the $\Psi$-procedures.

(2) In the $\Phi\Psi$-procedure the convergency is remarkably good even for such a high (subsonic) velocity that the convergency in the $\Phi$-procedure is too poor to presume the final value from the first few steps.

Now for the Cherry profile, numerical calculations are performed up to the second approximation, i.e. to the order of $M^4$, for $M$=0.350, 0.420, 0.483 and 0.5098 in order to confirm the above-mentioned properties and to study the limitations of the validity of these methods. The velocity distributions are shown in Figs. 5(a), (b), (c) and (d).

## § 6. The Meksyn-Imai Method

Meksyn [13] derived an approximate formula for calculating the velocity in a high subsonic flow and applied it to a few cases with success. He assumed that the streamlines change their shapes very little if the Mach number of the incident stream is increased from zero. Under this assumption, which he justifies from the numerical results by Woods, he shows that the velocity at any point in the flow can be obtained by solving an algebraic equation; namely, if $\alpha$ and $\beta$ are the velocity potential and the stream function for the incompressible flow and $\Phi$ the velocity potential for the compressible flow with free stream Mach number $M$, then the approximate integration of the fundamental equation gives

$$\frac{\partial\Phi}{\partial\alpha}=1+\frac{M^2}{8}\left(\frac{\partial\Phi}{\partial\alpha}\right)^3\left(1-\frac{\gamma-1}{2}M^2\right)P(\alpha,\beta)+\frac{M^4}{32}\left(\frac{\partial\Phi}{\partial\alpha}\right)^5S(\alpha,\beta)\,, \tag{6.1}$$

where $P(\alpha,\beta)$ and $S(\alpha,\beta)$ are certain functions of $\alpha$ and $\beta$ which are determined by the shape and the configuration of the obstacle in the flow*; and an appropriate root of this equation for $\partial\Phi/\partial\alpha$ gives us the desired velocity $q$ as

$$q=q_0\frac{\partial\Phi}{\partial\alpha}\,,$$

where $q_0$ is the velocity for the incompressible flow.

This formula enables us to calculate not only the velocity at each point in the flow, with $M$ as a parameter, but also a kind of critical Mach number above which no reasonable value for the velocity is obtained.**

Now Imai [11] points out that the functions $P$ and $S$ in Eq. (6.1) can easily be obtained if we know the results of the successive approximation by the $M^2$-expansion method; and that Meksyn's method is equivalent to the usual $M^2$-expansion method; namely, if we expand the velocity $q$ as in (5.2) and put $x=Mq/q_0$, then Eq. (6.1) leads to the following quintic equation for $x$:

$$x(1-ax^2-bx^4)=M\,, \tag{6.2}$$

where

$$\begin{cases} a=\left(1-\dfrac{\gamma-1}{2}M^2\right)\dfrac{q_1}{q_0}\,,\\[2ex] b=\dfrac{q_2}{q_0}+\dfrac{\gamma-1}{2}\dfrac{q_1}{q_0}-3\left(\dfrac{q_1}{q_0}\right)^2, \end{cases}$$

and an appropriate root of Eq. (6.2) again gives the velocity required.

By this procedure Imai has calculated the velocity on the surfaces of circular and elliptic cylinders, showing that this method gives quite satisfactory results even when the sonic velocity is approached on the surface.

The critical Mach number $M_c$, beyond which no physical solutions are possible in this method, is obtained as follows.

For $M=M_c$, Eq. (6.2) for $x$ must have double roots at the point of the greatest velocity; in other words, equations

$$bx^5+ax^3-x+M=0 \tag{6.2'}$$

and

$$5bx^4+3ax^2-1=0 \tag{6.3}$$

must have at least one root in common; so $M_c$ is determined as an appropriate root of the equation

$$\begin{vmatrix} b & 0 & a & 0 & -1 & M & 0 & 0 & 0\\ 0 & b & 0 & a & 0 & -1 & M & 0 & 0\\ 0 & 0 & b & 0 & a & 0 & -1 & M & 0\\ 0 & 0 & 0 & b & 0 & a & 0 & -1 & M\\ 5b & 0 & 3a & 0 & -1 & 0 & 0 & 0 & 0\\ 0 & 5b & 0 & 3a & 0 & -1 & 0 & 0 & 0\\ 0 & 0 & 5b & 0 & 3a & 0 & -1 & 0 & 0\\ 0 & 0 & 0 & 5b & 0 & 3a & 0 & -1 & 0\\ 0 & 0 & 0 & 0 & 5b & 0 & 3a & 0 & -1 \end{vmatrix}=0\,,$$

which is reduced to a sextic equation for $y=M^2$:

$$y^6+a_1y^5+a_2y^4+a_3y^3+a_4y^2+a_5y+a_6=0\,,$$

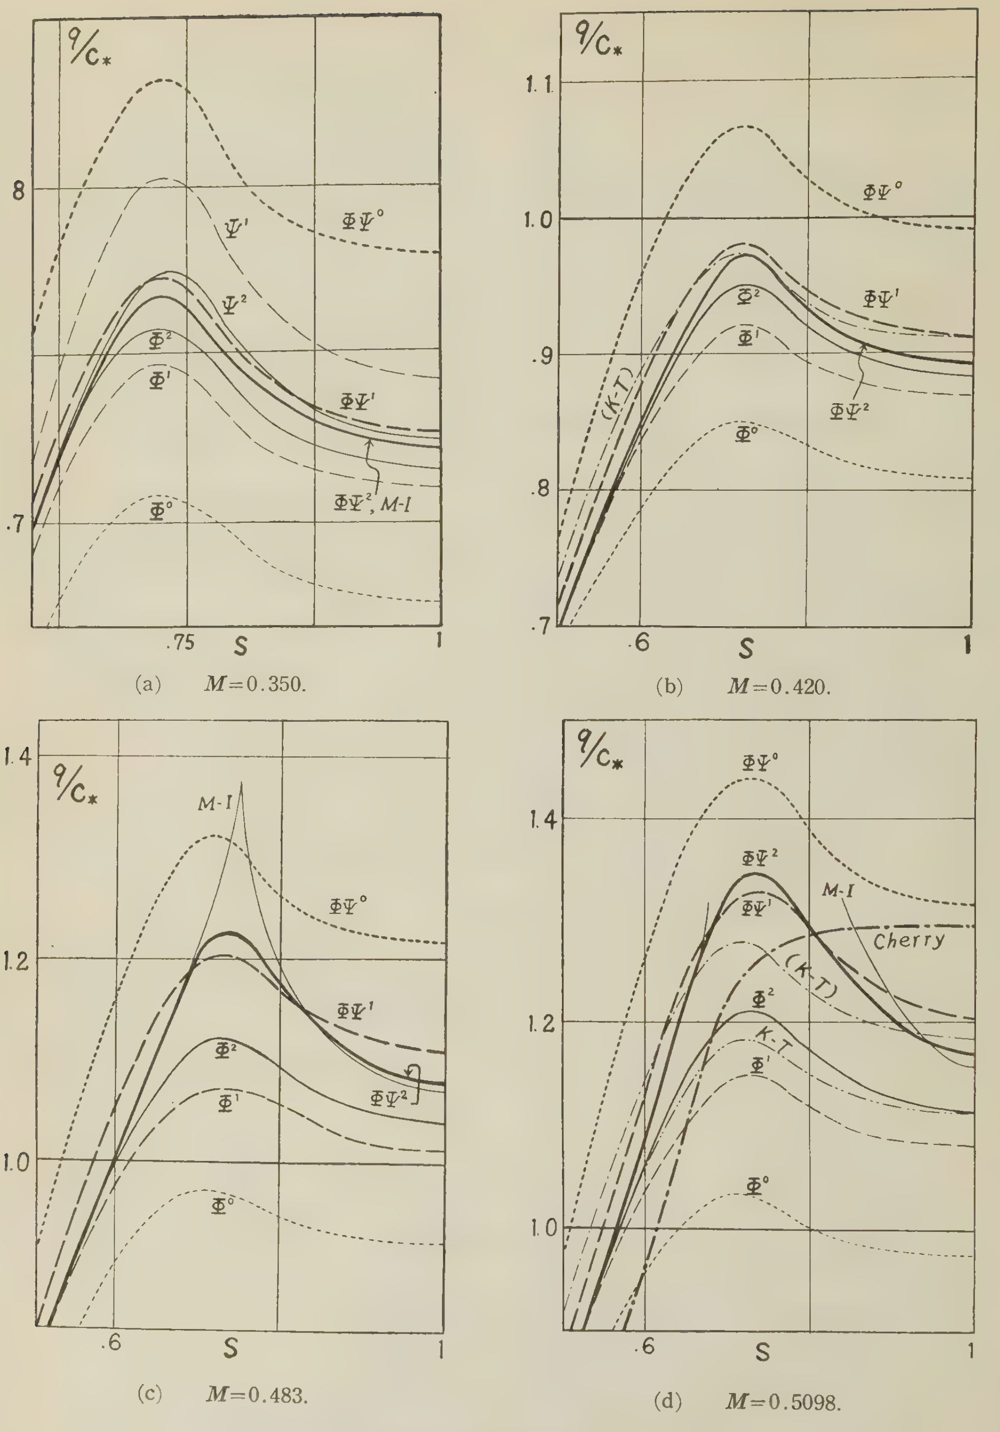
where

$$\begin{cases} a_1=-\dfrac{10}{\gamma-1}\,,\\[2ex] a_2=\dfrac{4}{27(\gamma-1)^2}\left\{270+2(\gamma-1)\dfrac{q_0}{q_1}+225b\left(\dfrac{q_0}{q_1}\right)^2\right\},\\[2ex] a_3=-\dfrac{8}{27(\gamma-1)^3}\left\{270+8(\gamma-1)\dfrac{q_0}{q_1}+675b\left(\dfrac{q_0}{q_1}\right)^2\right\},\\[2ex] a_4=\dfrac{8}{27(\gamma-1)^4}\left\{270+24(\gamma-1)\dfrac{q_0}{q_1}+1350b\left(\dfrac{q_0}{q_1}\right)^2\right.\\[2ex] \qquad\qquad\left.+32(\gamma-1)b\left(\dfrac{q_0}{q_1}\right)^3+1000b^2\left(\dfrac{q_0}{q_1}\right)^4-3125b^3\left(\dfrac{q_0}{q_1}\right)^5\right\},\\[2ex] a_5=-\dfrac{16}{27(\gamma-1)^5}\dfrac{q_0}{q_1}\left\{8(\gamma-1)+225b\dfrac{q_0}{q_1}+32(\gamma-1)b\left(\dfrac{q_0}{q_1}\right)^2+500b^2\left(\dfrac{q_0}{q_1}\right)^3\right\},\\[2ex] a_6=\dfrac{128}{27(\gamma-1)^5}\dfrac{q_0}{q_1}\left\{1+4b\left(\dfrac{q_0}{q_1}\right)^2\right\}^2. \end{cases}$$

---

* $S$ contains also $\gamma$ as a parameter.

** In this respect the $\Psi$-procedure also enables us to calculate another critical Mach number at which the method fails. It is clear that this Mach number corresponds to the first appearance of the sonic speed in the flow.



(a) $M=0.350$. (b) $M=0.420$.

(c) $M=0.483$. (d) $M=0.5098$.

Fig. 5 (a–d). The velocity distributions over the surface.

0th, 1st, 2nd: approximation of the $\Phi\Psi$-procedure,

Kármán-Tsien's method (simplified),

Kármán-Tsien's method,

Meksyn-Imai's method.

For the Cherry profile the value 0.483 for $M_c$ is obtained. The velocity distributions calculated by this method are shown in Figs. 5(a), (c) and (d).

## § 7. Numerical Discussions and Some Conjectures on Cherry's Hodograph Solution

(1) $M=0.350$ (Fig. 5(a)). It is almost certain that the $M^2$-expansion method will converge at this Mach number.

(2) $M=0.420$ (Fig. 5(b)). The sonic velocity begins to appear on the profile near this Mach number.

(3) $M=0.483$ (Fig. 5(c)). This is the critical Mach number according to Meksyn-Imai's method. Judging from the singular behaviour of the second approximation by the $\Phi\Psi$-procedure, the iteration will probably diverge in the high speed region.

(4) $M=0.5098$ (Fig. 5(d)). The velocity distributions calculated by all the methods are shown with that of Cherry's solution. The divergency of the $M^2$-expansion method in the high speed region is almost evident.

To sum up:

(1) The $\Phi\Psi$-procedure proves to have the following advantages over the $\Phi$- or the $\Psi$-procedure:

(i) The convergency is better as in the examples treated by Imai.

(ii) The singular behaviour of the velocity distribution calculated by this procedure suggests the divergency of the iteration (e. g. the second approximation for $M=0.483$), while it is more difficult to discriminate whether it converges or not by the $\Phi$-procedure.

(2) Meksyn-Imai's method gives almost the same velocity distribution as the $\Phi\Psi$-procedure though the latter excels the former a little in the labour for calculation. It is to be noted that the Meksyn-Imai method enables us to calculate a kind of critical Mach number and describes the probable flow pattern near this Mach number (Fig. 5(c)), but its numerical value seems to be somewhat larger than that at which the actual breakdown of the potential flow occurs, as was also the case with the examples treated by Meksyn.

(3) If the deformation of the profile is properly taken into account, Kármán-Tsien's method exactly solves the flow problem of a gas with $\gamma=-1$ and is expected to give a result lying between the first and the second approximations in the $\Phi$-procedure; in fact this is seen in the present calculation with $M=0.5098$ (Fig. 5(d)). Since the deformation takes place towards the increase of the thickness ratio, its disregard may result in an over-estimation of the effect of the compressibility so as to compensate the deficiency of the velocity which results from taking $\gamma$ to be $-1$. For example, this is seen from Tamada's result about a circular cylinder [14]. But in the case of the Cherry profile the disregard of the deformation gives the velocities somewhat larger than those calculated by the $M^2$-expansion method in the high speed region.

In the region where $q/c_* \lesssim 0.5$ the simplified procedure which neglects the deformation is also satisfactory as well as all other methods.

Now as our numerical results show, the velocity distributions calculated by various approximate methods are all different not only quantitatively but also qualitatively from that of Cherry's exact solution. The approximated velocity distribution has two maxima along each boundary streamline while in Cherry's solution it has only one maximum at the point of the maximum thickness. This discrepancy may be interpreted as follows.

Consider the compressible flow past the Cherry profile and suppose that we increase the Mach number $M$ of the main flow continuously from zero and that we investigate the flow by means of the $M^2$-expansion method.

In view of the fact that the Cherry profile has maxima of curvature in the neighbourhood of the points where the tangent to the profile makes the angle of 30° to the direction of the uniform flow, it is quite natural that the velocity distribution should have two maxima for $M=0$ and that these maxima should become more and more conspicuous with increasing $M$ as the calculation shows, until certain Mach number is reached at which a continuous potential flow breaks down.

Now, in general, the existence and uniqueness of the compressible potential flow past an obstacle of arbitrary shape have been mathematically proved [1] provided that the whole flow field is subsonic, so it is certain that the Mach number $M_{cr}$ at which the potential flow ceases to exist is not smaller than the Mach number $M_s$ which corresponds to the first appearance of the sonic speed in the flow.

As regards the convergency of the $M^2$-expansion method such a theorem does not seem to have been established, but it might be expected that the $M^2$-expansion method also does not fail till the appearance of the sonic speed if we examine the proof of the general existence theorem and remember the results of the famous electrical experiments by Taylor and Sharman [15], which also lead to the expectation that the $M^2$-expansion method may fail just at $M_s$.

For the Cherry profile the value of $M_s$ seems to be about 0.42 and the covergency of the $M^2$-expansion method is uncertain near this Mach number, but judging from the obvious divergency at $M=0.5098$ it is certain that Cherry's solution cannot be approximated by any of the methods employed in this paper.

On the other hand, it is also yet to be known whether the potential flow, in general, continues to exist or not beyond $M_s$, but it may be conjectured from the present calculation that the flow pattern represented by Cherry's hodograph solution does not belong to the family of potential flows which appear by increasing the Mach number of the main flow from zero, the shape of the profile being fixed.

## Acknowledgements

The writer would like to express his sincere and profound gratitude to Professor Isao Imai for his suggestion of this problem, and his continual guidance and encouragement and much valuable advice throughout this study.

The writer's thanks are also due to Professor Saburô Asaka, Dr. Mitutosi Kawaguti and Dr. Hidenori Hasimoto for their advice and discussions in the course of the calculation, and their kind inspection of the manuscript.

# Supersonic Jet with the Ambient Pressure corresponding to its Constant Pressure Point

By Hakuro OGUCHI

*Institute of Science and Technology, University of Tokyo, Tokyo, Japan*

(Received September 27, 1955)

In the present paper, a plane jet issuing from a parallel supersonic nozzle into the chamber where the pressure corresponds to the constant pressure point on the shock polar related to the uniform velocity at the exit of the nozzle is investigated by the hodograph method under the transonic approximation. The analytical expression for the stream function $\psi$ is obtained in the form containing appropriate constants which are determined from the condition on the shock polar. Actually, $\psi$ is calculated so that the shock condition is satisfied at three points on the shock polar. Using this value of $\psi$, the shock pattern and the velocity distribution along the axis of the jet are obtained. It is seen from these results that large variations of the flow variables occur in a comparatively narrow region downstream of the exit of the nozzle.

## §1. Introduction

Let us consider a jet issuing from a parallel supersonic nozzle. As is well known, a Mach shock configuration appears at the exit of the nozzle when the ambient pressure is moderately higher than the jet pressure. Guderley¹⁾ has given a clear physical interpretation to this phenomenon by applying a representation in the hodograph plane. If the ambient pressure is increased and the velocity on the free streamlines of the jet reaches just the local speed of sound, then Mach shock configuration is no more possible. The hodograph representation shows that, in case the ambient pressure lies between this critical one and the pressure corresponding to a normal shock, a single-shock pattern will appear at the exit in place of a Mach shock configuration. Flow patterns of this kind will be considered here (Fig. 1).

For simplicity, we make the assumption that the jet velocity inside the nozzle is so slightly greater than the local speed of sound that the transonic approximation is applicable without losing any essential features of the flow. It is, however, not easy to treat the problem analytically even under this approximation because of the existence of singularities at the ends of the nozzle walls similar to that appearing at the nose of a finite wedge in the case when a subsonic flow occurs behind the attached shock.

Especially, as will be seen in the subsequent section, if the ambient pressure takes the value corresponding to the constant pressure point on the shock polar, then the above singularities disappear. This particular value corresponds to the Crocco state for a finite wedge which has recently been analyzed by Tamada and Shibaoka²⁾. Since no singularities appear at the ends of the nozzle walls, the problem is considerably simplified in this particular case. In the following sections, this case will be analyzed by the hodograph method.

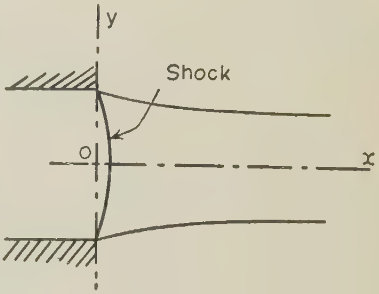

Fig. 1.

## §2. Mathematical Formulation

Let $V$ and $\tilde{\theta}$ be the magnitude of the velocity vector and its angle of inclination to the direction of the uniform flow ahead of the shock, respectively. A quantity $\tilde{u}$ is introduced according to the following relation:

$$\tilde{u}=(\gamma+1)^{1/3}\frac{V-a^*}{a^*}=(\gamma+1)^{-2/3}(M^2-1)\,, \qquad (1)$$

where $\gamma$ is the adiabatic exponent, $a^*$ the critical speed and $M$ the Mach number related to the velocity $V$. If $\tilde{u}$ and $\tilde{\theta}$ are assumed to be sufficiently small so that only their lowest power terms need be retained in the analysis, the equation for the upper half of the shock polar in the simplified hodograph has the form

$$\tilde{\theta}=(\tilde{u}_0-u)\sqrt{(\tilde{u}_0+\tilde{u})/2}\ ,$$

where $u_0$ is the value of $\tilde{u}$ corresponding to the jet velocity $V_0$ ahead of the shock. From the above relation, $-\tilde{u}_0$ corresponds to the velocity behind the normal shock. Let us consider the case when the modified velocity $\tilde{u}_A$ corresponding to the pressure on the free streamlines lies between 0 and $-\tilde{u}_0$. In Fig. 2 the states of flow immediately behind the shock emanuating at the end of the lower nozzle wall and on the lower free streamline of the jet map into the point A and the line AB, respectively. Then single-shock patterns are possible at the exit of the nozzle so that the image of its lower half in the hodograph is AC, the part of the upper half of the shock polar. Since, in this case, the axis of the jet maps into the line BC, the lower half of the jet hehind the shock at the exit of the nozzle corresponds to the imbedded domain ABC in the hodograph.

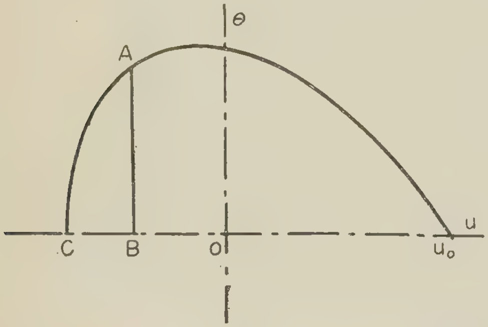

Fig. 2.

In the transonic approximation, as has been shown by Guderley[1)], the fundamental equation for the stream function $\psi$ reduces to the form

$$\psi_{\tilde{u}\tilde{u}}-\tilde{u}\psi_{\tilde{\theta}\tilde{\theta}}=0\ . \qquad (2)$$

On the upper half of the shock polar, the boundary condition requires that the lines of constant $\psi$ must have the slope

$$\frac{d\tilde{\theta}}{d\tilde{u}}=-\frac{\tilde{u}_0+7\tilde{u}}{3\tilde{u}_0+5\tilde{u}}\sqrt{\frac{\tilde{u}_0+\tilde{u}}{2}}\ .$$

On a line of constant $\psi$, $d\tilde{\theta}/d\tilde{u}$ can be replaced by $-\psi_{\tilde{u}}/\psi_{\tilde{\theta}}$ and therefore condition can also be written as

$$\psi_{\tilde{u}}-\frac{\tilde{u}_0+7u}{3\tilde{u}_0+5\tilde{u}}\sqrt{\frac{\tilde{u}_0+\tilde{u}}{2}}\psi_{\tilde{\theta}}=0\ . \qquad (3)$$

Since AB is the image of a free stream line, the condition $\psi$=const. is imposed on it and hence

$$\psi_{\tilde{\theta}}=0 \quad \text{on} \quad \text{AB}\ . \qquad (4)$$

At the point A, these two conditions cannot be, in general, simultaneously satisfied by regular functions, and as a due result, the flow is singular. In a particular case when $\tilde{u}_A=-3/5\ \tilde{u}_0$, however, the former condition reduces to the latter one at this point. Hence, no singularity appears at the point A. This point on the shock polar is called the constant pressure point[3)].

Let us investigate the behavior of the singularity from the local solution near the neighborhood of the point A. According to Guderley[1)], the following transformations are introduced as

$$\xi=\sqrt{|\tilde{u}_A|}(\tilde{u}+|\tilde{u}_A|)$$

and

$$\eta=\tilde{\theta}-\tilde{\theta}_A\ ,$$

where $\tilde{\theta}_A$ is the value of $\theta$ at the point A. Applying these transformations the differential equation (2) is rewritten in the form

$$\psi_{\xi\xi}+(1-\xi/\sqrt{|\tilde{u}_A|^3})\psi_{\eta\eta}=0\ .$$

For small values of $\xi$, this equation reduces to

$$\psi_{\xi\xi}+\psi_{\eta\eta}=0\ . \qquad (5)$$

Let us apply the boundary conditions (3) and (4) to the neighborhood of the point A, then these take the approximate forms as

$$\frac{d\eta}{d\xi}=-\frac{\psi_\xi}{\psi_\eta}=-\sqrt{\frac{\tilde{u}_0-|\tilde{u}_A|}{2|\tilde{u}_A|}}\frac{\tilde{u}_0+7|\tilde{u}_A|}{3\tilde{u}_0-5|\tilde{u}_A|}$$

$$=\tan\left(\frac{\pi}{2}-\gamma_2\right)$$

for $\quad \eta/\xi=\tan\left(\dfrac{\pi}{2}-\gamma_1\right)$

$$\psi=0 \qquad \text{for} \qquad \xi=0\ ,$$

when $\gamma_1$ is the angle of the tangent of the shock polar in the coordinates system with the $\eta$-axis and $\gamma_2$ the angle of the tangent of the streamline with the $\eta$-axis at the point A, and these signs are positive when measured clockwise (Fig. 3). From the definition, $\gamma_2$ is positive or negative according as the point A lies between the constant pressure point and the critical speed or the normal shock point, and $\gamma_1$ is always positive between the critical speed and the normal shock point. The solution of Eq. (5) satisfying the above two conditions is obtained in the form

$$\psi=\mathrm{Im}(i\zeta)^m\ ,$$

where

$$\zeta=\xi+i\eta$$

and

$$m=1-\gamma_2/\gamma_1\ .$$

At the constant pressure point, $\gamma_2=0$ or $m=1$. Since, according to Guderley[1], the curvature of the shock is proportional to $|\zeta|^{1-m}/m$, it tends to zero for the region between the critical speed and the constant pressure point as the point A is approached along the shock polar, while it tends to infinity in the region between the constant pressure point and the normal shock point. Hence it is seen that the constant pressure point in the case of a free jet plays the same role as the Crocco point in the case of a finite wedge. It is the subject of the present analysis to determine the full solution of this particular case.

Now it is convenient to introduce the following transformations[4]:

$$u=\tilde{u}/\tilde{u}_0\ ,\quad \theta=\sqrt{2}\,\tilde{\theta}/\tilde{u}_0{}^{3/2}\ . \tag{6}$$

Then, we obtain the normalized form of the boundary value problem. By substitution of Eq. (6), the fundamental equation (2) becomes

$$\psi_{uu}-2u\psi_{\theta\theta}=0\ . \tag{7}$$

The boundary conditions can now be summarized as follows:

1) On the image of the free stream line, AB,

$$\psi=-K \qquad \text{for} \qquad u=u_A=-3/5.$$

Here $K$ is a half of the total flow discharge and is given by

$$K=\rho^*a^*l\ ,$$

where $l$ is the semi-height of the nozzle and $\rho^*$ the density related to the critical velocity $a^*$.

2) On the image of the axis of the jet, CB,

$$\psi=0 \qquad \text{for} \qquad \theta=0\ .$$

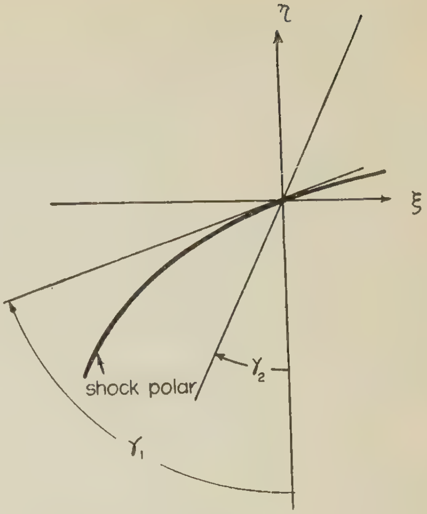

Fig. 3.

3) On the part of the shock polar, AC,

$$\psi_u-\frac{1+7u}{3+5u}\sqrt{1+u}\,\psi_\theta=0$$

for

$$\theta=(1-u)\sqrt{1+u}\ . \tag{8}$$

## § 3. Computation of $\psi$

As follows from the boundary conditions 1) and 2), there occurs a sink-type singularity at the point B corresponding to the flow infinitely downstream from the exit. Its behavior is the same as that in the subsonic free jet[5]. It can be shown that the singular solution, $\psi_s$, of the differential equation (4), subject to the boundary conditions 1) and 2), is written in the form

$$\psi_s=-\frac{2K}{\pi}\left(\frac{\theta}{2}\right.$$
$$\left.+\sum_{m=1}^{\infty}\left(\frac{u}{u_A}\right)^{1/2}\frac{K_{1/3}[m(-2u)^{3/2}/3]}{K_{1/3}[m(-2u_A)^{3/2}/3]}\sin m\theta\right)\ , \tag{9}$$

where $K_{1/3}$ is the modified Bessel function of the second kind of order 1/3. It follows by separation of variables that $\psi_s$ is a solution of Eq. (4). Also Eq. (6) becomes for $u=u_A$

$$\psi=-\frac{2K}{\pi}\left(\frac{\theta}{2}+\sum_{m=1}^{\infty}\frac{1}{m}\sin m\theta\right)$$
$$=\begin{cases}-K & \text{for} \quad 0<\theta<\pi \\ 0 & \text{for} \quad \theta=0\ .\end{cases}$$

Hence, $\psi_s$ of Eq. (6) satisfies the boundary conditions 1) and 2). If $m$ is sufficiently large, by the use of the asymptotic representation of $K_{1/3}$

$$\left(\frac{u}{u_A}\right)^{1/2}\frac{K_{1/3}[m(-2u)^{3/2}/3]}{K_{1/3}[m(-2u_A)^{3/2}/3]}$$
$$\simeq\left(\frac{u_A}{u}\right)^{1/4}\exp.\,[-m\{(-2u)^{3/2}-(-2u_A)^{3/2}\}/3]\ .$$

Since, in the region under consideration, $|u|\geq|u_A|$, then

$$\left(\frac{u}{u_A}\right)^{1/2}\frac{K_{1/3}[m(-2u)^{3/2}/3]}{K_{1/3}[m(-2u_A)^{3/2}/3]}\cdot 1\ .$$

Hence, in view of the convergence of the series $\sum\frac{1}{m}\sin m\theta$, the series in Eq. (9) is always convergent in the region ABC.

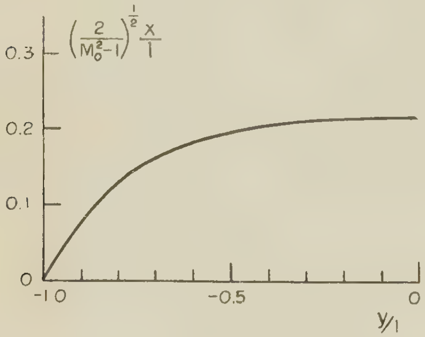

Fig. 4.

The regular solution satisfying the conditions $\psi=0$ on both AB and BC may be arbitrally added to $\psi_s$. In general, such regular solution, $\psi_r$, is written in the form

$$\psi_r=\sum_{m=1}^{\infty}KA_m\sqrt{-u}J_{1/3}[\lambda_m(-2u)^{3/2}/3]\sinh\lambda_m\theta\ , \tag{10}$$

where $A_m$s are appropriate constants and $\lambda_m$s are related to $j_m$s, the positive zeroes of Bessel function $J_{1/3}$, as

$$\lambda_m=3j_m(-2u_A)^{-3/2}\ .$$

Hence, the general solution of the differential equation (7) satisfying the condition 1) and 2) is given by

$$\begin{aligned}\psi&=\psi_s+\psi_r\\&=-\frac{2K}{\pi}\left(\frac{\theta}{2}+\sum_{m=1}^{\infty}\frac{1}{m}\left(\frac{u}{u_A}\right)^{1/2}\right.\\&\qquad\left.\times\frac{K_{1/3}[m(-2u)^{3/2}/3]}{K_{1/3}[m(-2u_A)^{3/2}/3]}\sin m\theta\right)\\&\quad+\sum_{m=1}^{\infty}KA_m\sqrt{-u}J_{1/3}[\lambda_m(-2u)^{3/2}/3]\sinh\lambda_m\theta\ .\end{aligned} \tag{11}$$

Finally the shock condition 3) determines the $A_m$s. In the actual calculation the aproximation has been adopted so that the shock condition 3) is satisfied at three points on the shock polar except the points A and C where it is apparent that this condition is fulfilled. Thus the first three terms in second series in Eq. (11) are used.

## § 4. Shock Patterns and Velocity Distributions along the Axis

The transformation from the hodograph to the physical one is, as is well known, governed by the following equation:

$$\left.\begin{aligned}&d(x/l)=(\gamma+1)^{1/3}(\tilde{u}_0/2)(2\tilde{u}\varphi_{\tilde{\theta}}d\tilde{u}+\varphi_{\tilde{u}}d\tilde{\theta}),\\&d(y/l)=d\varphi\ ,\end{aligned}\right\} \tag{12}$$

where

$$\varphi=\psi/K\ .$$

In the transonic approximation the slope of the shock is given by

$$dy/dx=(V_1-V_2)/a^*\tilde{\theta}\ , \tag{13}$$

where $V_1$ and $V_2$ are the velocities ahead of and behind the shock, respectively. By the use of Eqs. (1) and (6), Eq. (13) can be expressed in terms of $u$ and $\theta$ as

$$\frac{dy}{dx}=\sqrt{\frac{2}{\tilde{u}_0}}(\gamma+1)^{-1/3}\frac{1-u}{\theta}=\sqrt{\frac{2}{M_0{}^2-1}}\frac{1-u}{\theta}\ . \tag{14}$$

Substituting $\theta$ from Eq. (8) into the above equation, we get

$$\frac{dy}{dx}=\sqrt{\frac{2}{(M_0{}^2-)(1+u)}}\ .$$

Hence, if the origin of the Cartesian coordinates $(x, y)$ is chosen at the center of the nozzle exit, the shape of the shock is given by

$$\left.\begin{aligned}&\frac{x}{l}=\sqrt{\frac{M_0{}^2-1}{2}}\int_{-1}^{\varphi}\sqrt{1+u}\,d\varphi\ ,\\&\frac{y}{l}=\varphi\ .\end{aligned}\right\} \tag{15}$$

By the use of the above equations the shock pattern is calculated and its shape is shown in Fig. (4).

Let $x_N$ be the $x$ coordinate of the point of intersection of the shock with the exit of the jet. Then, it yields a maximum deviation of the shock from the exit and its value is obtaind as

$$x_N=\sqrt{\frac{M_0{}^2-1}{2}}\,l\int_{-1}^{0}\sqrt{1+u}\,d\varphi$$
$$\simeq 0.22[(M_0{}^2-1)/2]^{1/2}l\ .$$

Finally, the velocity distribution along the axis of the jet behind the shock is obtained by the integration of the first of Eqs. (12) and plotted in Fig. (5). The velocity on the axis is only slightly lower than that at the free streamline in the downstream part of the jet where

$$x > x_N + 2\sqrt{(M_0^2-1)/2}\cdot l$$
$$\cong 2.22\sqrt{(M_0^2-1)/2}\cdot l\ .$$

Hence, as the Mach number $M_0$ is close to unity in the present problem, it follows that large variations of the flow variables occur in a comparatively narrow region immediately behind the shock.

In the preceeding analysis only the particular case when the point A lies just at the constant pressure point has been treated. In general cases, however, the representation of the singularity at the point A should be added to the solution (11) so that the boundary conditions are fulfilled. In view of the local solution obtained before, it is suggested that, if the point A lies near the neighborhood of the constant pressure point, the existence of the singularity at the point A will have only little influence on the region except for its neighborhood. Hence, in these cases, the solution (11) may be considered to be the main part of the full solution.

The author wishes to express his sincere thanks to Professor Ryuma Kawamura for his helpful advice and kind inspection of the manuscript.

# On the Error of the Finite Difference Method in 1-dimensional Boundary Value Problems

By Hiroshi FUJITA

*Department of Physics, Faculty of Science, University of Tokyo*

(Received September 28, 1955)

The present paper is concerned with the error estimation of the finite difference method. Bounds of the error, which is committed in approximating the boundary value problem

$$-y''+qy=f,\quad y(0)=y(1)=0\,,\quad (q\geqq 0)\,.$$

by the corresponding difference equation, are given in some forms not involving the solution $y$ and, hence, calculable without solving the original problem. Our treatments are based on a theorem concerning an operator of the type $T^*T$ in a Hilbert space. The degree of convergence of the difference equation solution to the differential equation solution, as the difference interval approaches zero, is also studied.

## §1. Introduction and Survey of the Method

As for the numerical solution of boundary value problems associated with ordinary differential equations there are a number of methods[1)3)4)]. Among them the most familiar one in practice is the finite difference method, i.e., to approximate the differential equation by its *difference analogue* with a suitable difference interval (mesh length), though the use of the finite difference method seems more suitable for partial differential equations. Nevertheless, even if discussions are confined to cases of ordinary differential equations, little appears to be known about the accuracy of this method.

The object of the present paper is to estimate error bounds of this method, in the case of the boundary value problem associated with the ordinary differential equation $-y''+qy=f$ of the Schrödinger type and also to study the degree of convergence of the difference equation solution, as the difference interval approaches zero, under various continuity hypotheses on the coefficients $q(x), f(x)$ of the original equation. In this sort of error estimation it is a matter of question in what quantities the error bounds are expressed. Usual bounds explained in text-books do not seem satisfactory, at least, from the theoretical point of view, since they involve bounds of certain higher derivatives of the solution of the original problem, which may not exist and are, in general, very hard to estimate unless the original problem is solved. We intend to derive some error bounds expressible in terms of the "known" quantities in the sense that they are explicitly composed only of the values of $q(x)$, $f(x)$, and the quantities which are available once the difference equation is solved. We also give some error bounds involving neither the solution of the original problem nor the solution of the corresponding difference equation. The absence of the unknown quantities in error bounds permits us to study somewhat more easily the degree of convergence mentioned above.

Now we formulate our problem in precise terms and give a survey of the course we shall pursue.

By Problem (I) (abbr. P. (I)) we mean the following boundary value problem in the interval $I=(0,1)$:

$$\text{P. (I)}\begin{cases}-\dfrac{d^2y}{dx^2}+qy=f\,,\quad (0<x<1)\,, & (1.1)\\[4pt] y(0)=y(1)=0\,, & (1.2)\end{cases}$$

where $q(x)$ is a piecewise continuous* *non-negative* function and $f(x)$ is a piecewise continuous function.

Dividing the interval by equidistant $n+1$ "nodes" $\{x_k\}$, we denote the values of $q(x)$, $f(x)$ at $x_k$ by $q_k$, $f_k$ respectively, i.e.,

$$x_k=k/n,\qquad q_k=q(x_k),\qquad f_k=f(x_k),\qquad (k=0,1,\cdots,n). \tag*{(1.3)**}$$

---

* A function $u(x)$ is said to be piecewise continuous in $I$ if it is continuous everywhere in $I$ except a finite number of points $\xi_k$ and also $u(+0)$, $u(1-0)$, $u(\xi_k-0)$, $u(\xi_k+0)$ exist. Hence a piecewise continuous function is bounded in $I$.

** For example, if $q(x_k)$ does not exist, $(q(x_k-0)+q(x_k+0))/2$ is used for it.

Then the difference analogue of P. (I) corresponding to the difference interval $h=1/n$ turns out to be the following problem (P. (II)) for a $(n+1)$-component vector $u=\{u_k\}=\{u_0, u_1, \cdots, u_n\}$:

$$\text{P. (II)}\begin{cases} -\dfrac{1}{h^2}(u_{k+1}+u_{k-1}-2u_k)+q_k u_k=f_k\ , \\ \qquad\qquad (k=1, \cdots, n-1), & (1.4) \\ u_0=u_n=0\ . & (1.5) \end{cases}$$

Before going into the estimation of

$$R=\max_r |y(x_r)-u_r|\ ,$$

which is our main object, we note that even if $q(x)$ and $f(x)$ are modified in such a manner that their values at $\{x_k\}$ are not altered, the difference analogue of P. (I) still remains the same. In view of this fact, the estimation of $R$ is carried out in two steps as below. First, introducing $\bar{q}(x)$ and $\bar{f}(x)$ specified by the conditions that the graph of $\bar{q}(x)$ is the polygonal line composed of the segments connecting $(x_k, q_k)$ and $(x_{k+1}, q_{k+1})$ and $\bar{f}(x)$ is related with $\{f_k\}$ in the same manner, we set the following auxiliary problem, P. (I′),

$$\text{P. (I}'\text{)}\begin{cases} -\dfrac{d^2\bar{y}}{dx^2}+\bar{q}\bar{y}=\bar{f}\ , \quad (0<x<1)\ , & (1.6) \\ \bar{y}(0)=\bar{y}(1)=0\ . & (1.7) \end{cases}$$

In place of dealing with $R$ directly we appraise separately two quantities $R_1, R_2$ defined by

$$R_1=\max_{0\leqq\xi\leqq1} |y(\xi)-\bar{y}(\xi)|\ ,$$

$$R_2=\max_{0\leqq r\leqq n} |\bar{y}(x_r)-u_r|\ , \qquad (1.8)$$

the bounds of which can be combined to yield the desired estimate of $R$ by means of the obvious relation $R\leqq R_1+R_2$. The estimation of $R_1$ as well as that of $R_2$ is based on the following theorem[2)6)] given by Kato, which reads:

**Theorem 1.** *Let $T$ be a linear operator[5)] with its domain in a Hilbert space $\mathfrak{H}$ and its range in a second Hilbert space $\mathfrak{H}'$. Let $y$ be an element satisfying the equation*

$$T^*Ty=f\ , \qquad (1.9)$$

*where $T^*$ is the adjoint of $T$. For an element $d$ in the range of $T^*$ we set $\eta=(y, d)$. Let $u, v, \phi, \psi$ be any elements subjected to the conditions that $u, \phi$ belong to the domain of $T$ and $v, \psi$ belong to the domain of $T^*$ and, furthermore,*

$$T^*v=f\ , \qquad T^*\psi=d\ . \qquad (1.10)$$

*Then we have*

$$|\eta-A|\leqq\frac{1}{2}\varepsilon_1\varepsilon_2\ , \qquad (1.11)$$

*where*

$$\left.\begin{aligned} A&=\frac{1}{2}[(u, d)+(f, \phi)+(v, \psi)-(Tu, T\phi)]\ , \\ \varepsilon_1&=\|Tu-v\|\ , \qquad \varepsilon_2=\|T\phi-\psi\|\ . \end{aligned}\right\} \qquad (1.12)$$

To make this theorem applicable to our problem we reduce P. (I′) to the form of (1.9), choosing $T$ and $T^*$ as follows. As $\mathfrak{H}$ we take the real Hilbert space composed of functions in $L^2(0, 1)$ with the norm defined by

$$\|u\|^2=\int_0^1 u^2dx \qquad (1.13)$$

and as $\mathfrak{H}'$ we take the real Hilbert space composed of 2-component vector functions $v=\{v_1, v_2\}$ in $L^2(0, 1)\times L^2(0, 1)$ with the norm defined by

$$\|v\|^2=\|\{v_1, v_2\}\|^2=\int_0^1 v_1{}^2dx+\int_0^1 \bar{q}v_2{}^2dx\ . \qquad (1.14)$$

When we choose the operator $T$ so that any continuous and piecewise smooth*** function vanishing at $x=0, 1$ belongs to the domain of $T$ and

$$Tu=\left\{\frac{du}{dx}, u\right\}\ , \qquad (11.5)$$

then $T^*$ is determined so that

$$T^*v=T^*\{v_1, v_2\}=-\frac{dv_1}{dx}+\bar{q}v_2 \qquad (11.6)$$

and any $v=\{v_1, v_2\}$ with continuous and piecewise smooth $v_1$ belongs to the domain of $T^*$. It is easily verified that the equation

$$T^*T\bar{y}=\bar{f} \qquad (1.17)$$

implies P. (I′)****. In dealing with $R_1$, $d$ is taken to be Dirac's delta function $\delta(x-\xi)$ with its singularity at $\xi$ so that $\eta$ reduces to $\bar{y}(\xi)$, although this use of the delta function requires a later justification, which can be carried out by a customary procedure but is omitted here. The other elements $u, v, \phi, \psi$ are constructed in a certain connection with the solution $y(x)$ of P. (I) and the Green

---

*** A function $u(x)$ is said to be piecewise smooth if $u'(x)$ is piecewise continuous.

**** Strictly speaking, all operators appearing here must be closed. Hence, the differential operators in above should be interpreted as their closed extensions.

function of P. (I). Details and results of this procedure are shown in § 2.

For the estimation of $R_2$ worked out in § 3, $d$ is again Dirac's delta function $\delta(x-x_r)$ with its singularity at $x_r$ and $u, v$ are constructed in a certain manner making use of the solution $\{u_k\}$ of P. (II), while the constitution of $\phi, \psi$ is related with the following difference equation, P. (III), which may be regarded as the difference analogue of the formal equation $T^*TG=\delta(x-x_r)$ characterizing the Green function of P. (I′):

$$\text{P. (III)}\begin{cases} -\dfrac{1}{h^2}(g_{k+1}+g_{k-1}-2g_k)+q_k g_k=d_k\,, \\ \qquad\qquad (k=1,\cdots,n-1)\,, & (1.18) \\ g_0=g_n=0\,, & (1.19)\end{cases}$$

where $d_k=0$ or $1/h$, according as $k\neq r$ or $k=r$. We can derive from (1.11) a bound of $R_2$ in terms of $\{q_k\}$, $\{f_k\}$, $\{u_k\}$ and $h$, which are to be regarded as quantities given originally or known after solving P. (II). Furthermore, it is also possible to give another bound of $R_2$ in a form not containing $\{u_k\}$ but $\{q_k\}$, $\{f_k\}$ only, and hence, calculable without solving P. (II).

Having obtained the bounds of $R$ in the way stated above, we shall pass to the study of the order of $R$ as $h\to 0$ under various continuity hypotheses on $q(x)$ and $f(x)$ in § 4.

## § 2. Estimation of $R_1$

In this section we are concerned first with the deduction of some preliminary inequalities and thereafter with the estimation of $R_1$ referred to in the preceding section. While all notations which already appeared keep the same meanings, by $T_0$ and $T_0^*$ we denote those operators defined in the same way as $T$ and $T^*$ except that use is made of $q(x)$ in place of $\bar{q}(x)$. Then P. (I) can be written as

$$T_0^*T_0y=f\,. \tag{2.1}$$

In this section ′ is used only in order to represent the differentiation with respect to $x$. Now we establish the following lemma.

**Lemma 1.** *Let $y(x)$ be the solution of* P. (I). *Then we have*

$$\max_x|y(x)|\leqq\frac{\|f\|}{2a}\,, \tag{2.2}$$

*where $a=(\pi^2+Q_m)^{1/2}$ and $Q_m$ is the minimum (or g.l.b.) of $q(x)$.*

Proof. For any $\xi(0<\xi<1)$ let $K_\xi(x)$ be a function of $x$ equal to $(1-\xi)x$ or $\xi(1-x)$, according as $0\leqq x\leqq\xi$ or $\xi\leqq x\leqq 1$, i.e., the Green function associated with the differential operator $-d^2/dx^2$ and the boundary condition (1.2). It is known that for any continuous and piecewise smooth function $u(x)$ vanishing at $x=0$, 1, the relation

$$|u(\xi)|=|(u', K_\xi')|\leqq\|u'\|\cdot\|K_\xi'\|$$

holds, which can be combined with the relation

$$\|K_\xi'\|^2=\xi(1-\xi)\leqq 1/4 \quad \text{to yield}$$

$$\max_x|u(x)|\leqq\|u'\|/2\,. \tag{2.3}$$

On the other hand, the inequalities

$$\|T_0y\|\geqq\lambda_0\|y\|\geqq(\pi^2+Q_m)^{1/2}\|y\|=a\|y\|\,, \tag{2.4}$$

where $\lambda_0^2(\lambda_0>0)$ is the least eigenvalue of the operator $T_0^*T_0$, follow immediately from Rayleigh's principle and the fact that $\pi^2+Q_m$ is a positive lower bound of $\lambda_0^2$.

In view of (2.1) and (2.4), we have

$$\|T_0y\|^2=(f,y)\leqq\|f\|\cdot\|y\|\leqq\|f\|\cdot\|T_0y\|/a\,,$$

and consequently

$$\|y'\|\leqq\|T_0y\|\leqq\|f\|/a\,, \tag{2.5}$$

whence follows the desired inequality by virtue of (2.3).

**Lemma 2.** *Let $G_\xi=G_\xi(x)$ be the Green function of* P. (I), *with the discontinuity of its derivative at $x=\xi$, considered as a function of $x$. Then we have*

$$0\leqq G_\xi(x)\leqq 1/4\,,\quad (0\leqq x\leqq 1, 0<\xi<1)\,. \tag{2.6}$$

Proof. Since the left inequality is well-known, we need only to prove the right inequality. From the relation

$$\|G_\xi'\|^2+(qG_\xi, G_\xi)=G_\xi(\xi)$$

we obtain at once $\|G_\xi'\|^2\leqq G_\xi(\xi)$, which can be combined with (2.3) to yield

$$\|G_\xi'\|^2\leqq G_\xi(\xi)\leqq\|G_\xi'\|/2\,.$$

In consequence we have

$$\|G_\xi'\|\leqq 1/2\,. \tag{2.7}$$

Again taking account of (2.3) we observe that the desired inequality follows from (2.7).

Making use of these lemmas, from Theorem 1 we can deduce the following theorem which gives bounds of $R_1$.

**Theorem 2.** *Let $\hat{q}$ and $\hat{f}$ be any upper bounds of $\int_0^1|\Delta q|dx$ and $\int_0^1|\Delta f|dx$ respective-*

*ly, where* $\Delta q=q(x)-\bar{q}(x)$ *and* $\Delta f=f(x)-\bar{f}(x)$. *Then for* $R_1$ *in* (1.8) *we have the following estimate*:

$$R_1\leqq(1+\hat{q})\left(\frac{\hat{q}}{8a}\|f\|+\frac{\hat{f}}{4}\right), \tag{2.8}$$

*where* $a$ *is the same as in Lemma 1.*

Proof. Let $T$ and $T^*$ be those defined in §1. $\delta(x-\xi)$ is taken as the element $d$ in Theorem 1 as stated there. On the other hand, we choose $u$, $v$, $\phi$, $\psi$ such that

$u=y(x)$, the solution of P. (I),

$\phi=G_\xi(x)$, the Green function of P. (I) with its singularity at $\xi$,

$v=\{v_1, v_2\}$, where $v_2$ is $y(x)$ and $v_1$ is defined as

$$v_1=y'(0)+\int_0^x(\bar{q}y-\bar{f})dx ,$$

$\psi=\{\psi_1, \psi_2\}$, where $\psi_2$ is $G_\xi(x)$ and $\psi_1$ is defined as

$$\psi_1=G_\xi'(0)+\int_0^x(\bar{q}G_\xi-\delta(x-\xi))dx .$$

It can be easily verified that these elements satisfy the conditions required in Theorem 1.

$v_1$ can be reduced to another form more convenient for calculations:

$$\begin{aligned}v_1&=y'(0)+\int_0^x(qy-f)dx+\int_0^x(\Delta f-\Delta qy)dx\\&=y'(0)+\int_0^x y''dx+\int_0^x(\Delta f-\Delta qy)dx\\&=y'(x)+\int_0^x(\Delta f-\Delta qy)dx ,\end{aligned}$$

that is, putting

$$r_1(x)=\int_0^x(\Delta f-\Delta qy)dx ,$$

we can write as

$$v_1=y'(x)+r_1(x) .$$

Similarly, we can derive

$$\psi_1=G_\xi'(x)+r_2(x) ,$$

where $$r_2(x)=-\int_0^x\Delta qG_\xi dx .$$

With these elements we calculate $A$, $\varepsilon_1$ and $\varepsilon_2$ in (1.12). First, we have

$$\begin{aligned}&(u, d)=y(\xi) ,\\&(\bar{f}, \phi)=(f-\Delta f, G_\xi)=(f, G_\xi)-(\Delta f, G_\xi)\\&\qquad=y(\xi)-(\Delta f, G_\xi)\end{aligned}$$

and, moreover,

$$\begin{aligned}(v, \psi)-(Tu, T\phi)&=(v_1, \psi_1)-(y', G_\xi')\\&=(y'+r_1, G_\xi'+r_2)-(y', G_\xi')\\&=(r_1, G_\xi')+(y', r_2)+(r_1, r_2) .\end{aligned}$$

On the other hand, noting

$$r_1'=\Delta f-\Delta qy , \quad r_2'=-\Delta qG_\xi ,$$

we obtain

$$\begin{aligned}(r_1, G_\xi')&=-(r_1', G_\xi)=-(\Delta f-\Delta qy, G_\xi)\\&=-(\Delta f, G_\xi)+(\Delta qy, G_\xi) ,\\(y', r_2)&=-(y, r_2')=(y, \Delta qG_\xi)=(\Delta qy, G_\xi) .\end{aligned}$$

Thus we find

$$A=y(\xi)+(\Delta qy, G_\xi)-(\Delta f, G_\xi)+\frac{1}{2}(r_1, r_2) ,$$

while it is obvious that

$$\begin{aligned}\varepsilon_1&=\|Tu-v\|=\|y'-v_1\|=\|r_1\| ,\\\varepsilon_2&=\|T\phi-\psi\|=\|G_\xi'-\psi_1\|=\|r_2\| .\end{aligned}$$

From these results, in view of (1.11), we arrive at

$$\begin{aligned}|y(\xi)-\bar{y}(\xi)|\leqq&|(\Delta qy, G_\xi)|\\&+|(\Delta f, G_\xi)|+\|r_1\|\cdot\|r_2\| .\end{aligned} \tag{2.9}$$

By referring to Lemma 1 and Lemma 2 we can appraise the terms on the right side of (2.9) as

$$\begin{aligned}|(\Delta qy, G_\xi)|&\leqq\frac{1}{4}(\max|y(x)|)\int_0^1|\Delta q|dx\\&\leqq\frac{1}{8a}\|f\|\cdot\hat{q} ,\\|(\Delta f, G_\xi)|&\leqq\frac{1}{4}\int_0^1|\Delta f|dx\leqq\frac{1}{4}\hat{f} ,\\\|r_1(x)\|\leqq\max|r_1(x)|&\leqq\int_0^1|\Delta f|dx\\&+\int_0^1|\Delta qy|dx\leqq\hat{f}+\frac{1}{2a}\|f\|\cdot\hat{q} ,\\\|r_2(x)\|\leqq\max|r_2(x)|&\leqq\int_0^1|\Delta q|G_\xi dx\leqq\frac{1}{4}\hat{q} ,\end{aligned}$$

which lead (2.9) to the form

$$|y(\xi)-\bar{y}(\xi)|\leqq(1+\hat{q})\left(\frac{\hat{q}}{8a}\|f\|+\frac{\hat{f}}{4}\right). \tag{2.10}$$

Since the right side of (2.10) is independent of $\xi$, we have established the validity of (2.8).

**Corollary.** *As* $h$ *tends to zero, we have*

$$R_1=O\left(\int_0^1|\Delta q|dx\right)+O\left(\int_0^1|\Delta f|dx\right).$$

*Remark* 1. Occasionally in practice

$$\int_0^1|\Delta q|dx , \quad \int_0^1|\Delta f|dx$$

may be appraised graphically. Moreover, $\max|\Delta q|$ and $\max|\Delta f|$ are admissible as $\hat{q}$ and

$\hat{f}$ respectively.

*Remark* 2. Without applying Theorem 1 we can derive another bound of $R_1$ as follows. Putting $r(x)=y(x)-\bar{y}(x)$, we note that $-r''+\bar{q}r=-\Delta qy+\Delta f$, i.e., $T^*Tr=-\Delta qy+\Delta f$, which yields

$$\|Tr\|^2\leq(\|\Delta qy\|+\|\Delta f\|)\cdot\|r\| .$$

Hence, we have, in view of (2.3) and the relation $\|Tr\|\geq a\|r\|$,

$$|r(x)|\leq\frac{1}{2}\|r'\|\leq\frac{1}{2}\|Tr\|\leq\frac{1}{2a}(\|\Delta qy\|+\|\Delta f\|)$$

which can be led by means of Lemma 1 to the following inequality:

$$R_1\leq\frac{1}{4a^2}\|\Delta q\|\cdot\|f\|+\frac{1}{2a}\|\Delta f\| . \qquad (2.11)$$

In some cases (2.11) is possibly sharper than (2.8). However, (2.8) is seen more convenient for our subsequent study of the degree of convergence.

## § 3. Estimation of $R_2$

This section is devoted to the deduction of bounds of $R_2$ along the line indicated in § 1. It seems convenient to introduce some notions and formulae concerning finite differences beforehand. All notations already defined hold their meanings here, unless otherwise stated. We denote the interval $(x_k, x_{k-1})$ by $I_k$ $(k=0, 1, \cdots, n-1)$.

**1.** First of all, we introduce three real unitary spaces $E_{n+1}, E_n$ and $E_{n-1}$ such that

$E_{n+1}$ is $(n+1)$-dimensional and provided with the norm

$$\|u\|^2=\|\{u_k\}\|^2=h\sum_{k=0}^{n}u_k^2$$

$E_n$ is $n$-dimensional and provided with the norm

$$\|u\|^2=\|\{u_k\}\|^2=h\sum_{k=0}^{n-1}u_k^2 ,$$

$E_{n-1}$ is $(n-1)$-dimensional and provided with the norm

$$\|u\|^2=\|\{u_k\}\|^2=h\sum_{k=1}^{n-1}u_k^2 .$$

Besides usual inequalities valid for the norm in a unitary space, e.g., Schwarz' inequality, it holds in $E_n$ that

$$h\sum_{k=0}^{n-1}|u_k|\leq\|u\|\leq\max_k|u_k| . \qquad (3.1)$$

The vectors $\{q_i, q_{i+1}, \cdots, q_j\}$ and $\{f_i, f_{i+1}, \cdots, f_j\}$, where $q_k$ and $f_k$ are those in (1.3), may be regarded as elements of $E_{n+1}$, $E_n$ or $E_{n-1}$, according as $(i=0,\ j=n)$, $(i=0,\ j=n-1)$ or $(i=1, j=n-1)$. Whichever space may $\{q_k\}$ belong to, we shall use always the same letter $q$ to denote it, since any confusions in the sequel possibly caused by this convention seem avoidable with a little care. This is the same for $\{f_k\}$. For any vector $u=\{u_k\}$ in one of these spaces $qu$ means the vector $\{q_k u_k\}$. Evidently we have

$$\|qu\|=\|\{q_k u_k\}\|\leq\max_k|u_k|\cdot\|q\| . \qquad (3.2)$$

We turn to the definition of some finite difference operators. To any vector $u=\{u_k\}$ in $E_{n+1}$ we make correspond a vector $Du$ in $E_n$ specified by

$$(Du)_k\equiv Du_k=(u_{k+1}-u_k)/h ,$$
$$(k=0, 1, \cdots, n-1) ,$$

where $h$ is $1/n$ as before.

It is worthwhile to remark that if $y_k$ is the value of a function $y(x)$ at $x=x_k$ $(k=0, 1, \cdots, n)$, $Dy_k$ turns out to be the divided finite difference (the finite difference quotient) of $y(x)$ at $x_k$ in accordance with the customary definition. Moreover, if $y(x)$ is a function such that its graph is the polygonal line joining $(x_k, y_k)$ in order, which is the case for $\bar{q}(x)$ and $\bar{f}(x)$, $y(x)$ can be expressed as

$$y(x)=y_k+(x-x_k)Dy_k \quad \text{in} \quad I_k ,$$
$$(k=0, 1, \cdots, n-1) ,$$

and also we find

$$\|dy/dx\|=\|Dy\| ,$$

where the left side represents the norm of $dy/dx$ in the sense of (1.13) and the right side the norm of the vector $Dy$ in $E_n$. The following formulae concerning the operator $D$ are almost evident by definition:

$$h\sum_{k=i}^{j}Du_k=u_{j+1}-u_i , \qquad (3.3)$$

$$h\|Du\|\leq2\|u\| , \qquad (3.4)$$

$$D(qu)_k\equiv Dq_k u_k=u_k Dq_k$$
$$+q_k Du_k+hDu_k Dq_k , \qquad (3.5)$$

$$\|D(qu)\|\leq\max_k|q_k|\cdot\|Du\|$$
$$+\max_k|u_k|\cdot\|Dq\| . \qquad (3.6)$$

Furthermore, we introduce the operator $D^{(2)}$ from $E_{n+1}$ to $E_{n-1}$ defined by the conditions

$$(D^{(2)}u)_k\equiv D^{(2)}u_k=(u_{k+1}+u_{k-1}-2u_k)/h^2 ,$$
$$(k=1, \cdots, n-1) .$$

By definition it is evident that

$$D^{(2)}u_k=(Du_k-Du_{k-1})/h , \qquad (3.7)$$

$$h\sum_{k=i}^{j}D^{(2)}u_k=Du_j-Du_{i-1} . \qquad (3.8)$$

If we identify any $u, v$ in $E_{n+1}$, such that

$u_0=u_n=v_0=v_n=0$, with $\{u_1, u_2, \cdots, u_{n-1}\}$ and $\{v_1, v_2, \cdots, v_{n-1}\}$ in $E_{n-1}$ respectively, we have

$$(Du, Dv)=-(D^{(2)}u, v)=-(u, D^{(2)}v)\,, \qquad (3.9)$$

and we note that P. (II) and P. (III) can be written respectively as

$$-D^{(2)}u+qu=f\,, \quad u_0=u_n=0\,, \qquad (3.10)$$

$$-D^{(2)}g+qg=d\,, \quad g_0=g_n=0\,, \qquad (3.11)$$

and also that the relation

$$(f, g)=(-D^{(2)}u+qu, g)=(u, -D^{(2)}g+qg)$$
$$=(u, d)=u_r \qquad (3.12)$$

holds, which shows that $g=\{g_k\}$ displays a role similar to that of the Green function.

Some inequalities, which is useful later, concerning the solution $u=\{u_k\}$ of P. (II) are written out in the following lemma.

**Lemma 3.** *Let* $u=\{u_k\}$ *be the solution of* P. (II) *and let* $\bar{Q}_m$ *be* $\min_k q_k$. *Then we have*

$$\max_k |u_k| \leq \frac{\|f\|}{2a}\,, \qquad (3.13)$$

$$\|Du\| \leq \frac{\|f\|}{a}\,, \qquad (3.14)$$

$$\|D^{(2)}u\| \leq \|f\|+\frac{\|f\|\cdot\|q\|}{2a}\,, \qquad (3.15)$$

*where* $a$ *is the positive square root of* $(2(1-\cos \pi h)/h^2)+\bar{Q}_m$ *and* $\|q\|$, $\|f\|$ *are those in* $E_{n-1}$.

Proof. First we note that for any vector $u$ in $E_{n+1}$ such that $u_0=u_n=0$, the inequality

$$\max_k |u_k| \leq \|Du\|/2 \qquad (3.16)$$

can be established in a manner similar to that used for (2.3). Then noting that the least eigenvalue of the eigenvalue problem

$$-D^{(2)}v=\lambda v\,, \qquad v_0=v_n=0\,,$$

is known to be $2(1-\cos \pi h)/h^2$, we can deduce (3.13) and (3.14) similarly to (2.2) and (2.5). Finally (3.15) follows immediately from (3.10) by virtue of (3.2) and (3.13).

*Remark* 1. In our later treatments it is convenient to put

$$D^{(2)}u_0=-f_0 \quad \text{and} \quad D^{(2)}u_n=-f_n$$

for the solution of P. (II) so that we can write

$$-D^{(2)}u_k+q_k u_k=f_k\,, \quad (k=0, 1, \cdots, n)$$

and $DD^{(2)}u$ is well-defined. Even if we interpret $\|D^{(2)}u\|^2$ as $h\sum_{k=0}^{n}(D^{(2)}u_k)^2$ in accordance with this convention, (3.15) still remains valid, provided that $\|f\|$, the first term of the right side of it, is interpreted as that in $E_{n+1}$.

Concerning the solution $g=\{g_k\}$ of P. (III) we can deduce the following lemma analogous to Lemma 2.

**Lemma 4.** *Let* $g=\{g_k\}$ *be the solution of* P. (III). *Then we have*

$$0 \leq g_k \leq 1/4\,, \quad (k=0, 1, \cdots, n) \qquad (3.17)$$

$$\|Dg\| \leq 1/2\,. \qquad (3.18)$$

2. We have now reached a point to derive the bounds of $R_2$ by use of Theorem 1. We agree with the convention that any functions or constants not exceeding 1 in their absolute values may be denoted always by the same letter $\theta$. Here in applying Theorem 1 we let $d$ be $\delta(x-x_r)$ and $T$, $T^*$ be those defined in § 1. The elements $u, v, \phi, \psi$ in Theorem 1 are constructed from $u=\{u_k\}$, $g=\{g_k\}$, the solutions of P. (II) and P. (III) as below.

$u$ and $\phi$ are defined respectively by the conditions that

$$u=\bar{u}(x)=u_k+(x-x_k)Du_k\,,$$
$$\phi=\bar{g}(x)=g_k+(x-x_k)Dg_k$$

in $I_k$, $(k=0, 1, \cdots, n-1)$.

In other words, the graph of $\bar{u}(x)$, $\bar{g}(x)$ are the polygonal line joining $(x_k, u_k)$ in order and the polygonal line joining $(x_k, g_k)$ in order respectively. Hereby we remark that $\bar{q}(x)$, $\bar{f}(x)$ in P. (I′) can be expressed as

$$\bar{q}(x)=q_k+(x-x_k)Dq_k\,,$$
$$\bar{f}(x)=f_k+(x-x_k)Df_k$$

in $I_k$, $(k=0, 1, \cdots, n-1)$.

In accordance with the conditions $T^*v=\bar{f}$, $T^*\psi=\delta(x-x_r)$, we take $v=\{v_1, v_2\}$ and $\psi=\{\psi_1, \psi_2\}$ such that

$$v_1=\int_0^x (\bar{q}\bar{u}-\bar{f})dx+Du_0+\frac{h}{2}f_0\,, \qquad (3.19)$$

$v_2$ is identical with $\bar{u}(x)$,

$$\psi_1=\int_0^x (\bar{q}\bar{g}-\delta(x-x_r))dx+Dg_0\,, \qquad (3.20)$$

$\psi_2$ is identical with $\bar{g}(x)$.

We note that $v_1$ can be reduced to a form more convenient for our calculations. In fact, the contribution of $I_l$ to the integral in (3.19) is calculated as

$$h(q_l u_l-f_l)+\frac{h^2}{2}(u_l Dq_l+q_l Du_l-Df_l)$$
$$+\frac{h^3}{3}Du_l Dq_l$$

$$=hD^{(2)}u_i+\frac{h^2}{2}DD^{(2)}u_i-\frac{h^3}{6}Du_iDq_i$$

by means of (3.5) and (3.10).

By referring to (3.3), (3.7), (3.8) and Remark 1 we note that

$$h\sum_{i=0}^{k-1}D^{(2)}u_i=hD^{(2)}u_0+(Du_{k-1}-Du_0)$$
$$=Du_k-hD^{(2)}u_k-Du_0-hf_0\ ,$$
$$h\sum_{i=0}^{k-1}DD^{(2)}u_i=D^{(2)}u_k-D^{(2)}u_0=D^{(2)}u_k+f_0\ ,$$

and hence,

$$\int_0^{x_k}(\bar{q}\bar{u}-\bar{f})dx+Du_0+\frac{h}{2}f_0$$
$$=Du_k-\frac{h}{2}D^{(2)}u_k-\frac{h^3}{6}\sum_{i=0}^{k-1}Du_iDq_i\ .$$

On the other hand, putting $t=x-x_k$, we find

$$\int_{x_k}^{x}(\bar{q}\bar{u}-\bar{f})dx=tD^{(2)}u_\kappa+\frac{t^2}{2}DD^{(2)}u_k$$
$$-\left(\frac{ht^2}{2}-\frac{t^3}{3}\right)Dq_\kappa Du_k\ .$$

From these results and the inequality

$$\left|\frac{ht^2}{2}-\frac{t^3}{3}\right|\leqq\frac{h^3}{6}\ ,\quad(0\leqq t\leqq h)\ ,$$

we obtain

$$v_1=Du_k+r_1(x)\quad\text{in}\quad I_k\ ,$$

where

$$r_1(x)=\left(t-\frac{h}{2}\right)D^{(2)}u_k+\frac{t^2}{2}DD^{(2)}u_k$$
$$+\theta\frac{h^2}{6}\|Dq\|\cdot\|Du\|\quad\text{in}\quad I_k\ .$$

In a similar manner, noting that for $x$ contained in $I_k$, the relation

$$\int_0^x\delta(x-x_r)dx=h\sum_{i=0}^{k}d_i$$

holds, $\{d_i\}$ being those defined in P. (III), we can take $\psi_1$ into the form

$$\psi_1=Dg_k+r_2(x)\quad\text{in}\quad I_k\ ,$$

where

$$r_2(x)=\left(t-\frac{h}{2}\right)(qg)_k+\frac{t^2}{2}D(qg)_k$$
$$+\frac{h^2}{6}\theta\|Dq\|\cdot\|Dg\|\quad\text{in}\quad I_k\ .$$

Making use of these elements, we calculate $A$, $\mathcal{E}_1$ and $\mathcal{E}_2$ in (1.12). First, it is easily seen that

$$\mathcal{E}_1=\|Tu-v\|=\|r_1\|\ ,$$
$$\mathcal{E}_2=\|T\phi-\psi\|=\|r_2\|\ . \qquad (3.21)$$

By definition we have

$$\eta=\bar{y}(x_r)\ ,\quad(u,d)=(\bar{u}(x),\delta(x-x_r))=u_r\ ,$$

and moreover, be means of (3.12) we can verify

$$(\bar{f},\phi)=(\bar{f}(x),\bar{g}(x))=(f,g)-\frac{h^2}{6}(Df,Dg)$$
$$=u_r-\frac{h^2}{6}(Df,Dg)\ .$$

Also we note that

$$(v,\psi)-(Tu,T\phi)$$
$$=\sum_{k=0}^{n-1}\left(Du_k\int_{I_k}r_2dx+Dg_k\int_{I_k}r_1dx\right)+(r_1,r_2)\ ,$$

while by a little calculation we obtain

$$\sum_{k=0}^{n-1}Du_k\int_{I_k}r_2dx=\frac{h^2}{6}(Du,Dqg)$$
$$+\theta\frac{h^2}{6}\|Dq\|\cdot\|Du\|\cdot\|Dg\|\ ,$$
$$\sum_{k=0}^{n-1}Dg_k\int_{I_k}r_1dx=\frac{h^2}{6}(Dg,DD^{(2)}u)$$
$$+\theta\frac{h^2}{6}\|Dq\|\cdot\|Du\|\cdot\|Dg\|\ .$$

Consequently, $A$ can be written by use of (3.10) and (3.18) as

$$A=u_r-\frac{h^2}{12}[(Df,Dg)-(DD^{(2)}u,Dg)-(Du,Dqg)]$$
$$+\theta\frac{h^2}{6}\|Dq\|\cdot\|Du\|\cdot\|Dg\|+\frac{1}{2}(r_1,r_2)$$
$$=u_r-\frac{h^2}{12}[2(Df,Dg)-(Dqu,Dg)-(Du,Dqg)]$$
$$+\theta\frac{h^2}{12}\|Dq\|\cdot\|Du\|+\theta\frac{1}{2}\|r_1\|\cdot\|r_2\|\ .$$

Thus by virtue of (3.21) and the above results, (1.11) implies

$$|\bar{y}(x_r)-u_r|\leqq\frac{h^2}{12}|2(Df,Dg)-(Dqu,Dg)$$
$$-(Du,Dqg)|+\frac{h^2}{12}\|Dq\|\cdot\|Du\|+\|r_1\|\cdot\|r_2\|\ .$$

Since by referring to (3.1) and Lemma 4 we have

$$|(Df,Dg)|\leqq\|Df\|/2\ ,$$
$$|(Dqu,Dg)|\leqq\|D(qu)\|/2,$$
$$|(Du,Dqg)|=|(D^{(2)}u,qg)|\leqq\|(D^{(2)}u\|\cdot\|qg\|$$
$$\leqq\|D^{(2)}u\|\cdot\|q\|/4\ ,$$

only $\|r_1\|$ and $\|r_2\|$ still remain to be calculated. By elementary calculations we find

$$\|r_1\|^2\leqq\frac{h^2}{12}\|D^{(2)}u\|^2+\frac{h^3}{12}\|D^{(2)}u\|\cdot\|DD^{(2)}u\|$$

$$+\frac{h^3}{12}\|D^{(2)}u\|\cdot\|Dq\|\cdot\|Du\|+\frac{h^4}{20}\|DD^{(2)}u\|^2$$
$$+\frac{h^4}{18}\|DD^{(2)}u\|\cdot\|Dq\|\cdot\|Du\|+\frac{h^4}{36}\|Dq\|^2\cdot\|Du\|^2, \tag{3.22}$$

and, consequently, by use of (3.4) we deduce

$$\|r_1\|^2\leq\frac{h^2}{12}\|D^{(2)}u\|^2+\frac{h^2}{6}\|D^{(2)}u\|^2$$
$$+\frac{h^2}{6}\|Du\|\cdot\|D^{(2)}u\|\cdot\|Dq\|$$
$$+\frac{h^2}{5}\|D^{(2)}u\|^2+\frac{2h^2}{9}\|D^{(2)}u\|\cdot\|q\|\cdot\|Du\|$$
$$+\frac{h^2}{9}\|q\|^2\cdot\|Du\|^2$$
$$=h^2\Big[\frac{9}{20}\|D^{(2)}u\|^2+\frac{7}{18}\|D^{(2)}u\|\cdot\|Du\|\cdot\|q\|$$
$$+\frac{1}{9}\|q\|^2\cdot\|Du\|^2\Big]. \tag{3.23}$$

The estimate of $\|r_1\|$ given by (3.23) can be reduced to the following one less sharp but more concise than (3.23), i.e.,

$$\|r_1\|\leq h\Big[\frac{3}{\sqrt{20}}\|D^{(2)}u\|+\frac{1}{3}\|q\|\cdot\|Du\|\Big].$$

Similarly, we obtain

$$\|r_1\|^2\leq\frac{h^2}{12}\|qg\|^2+\frac{h^3}{12}\|qg\|\cdot\|Dqg\|$$
$$+\frac{h^3}{12}\|qg\|\cdot\|Dq\|\cdot\|Dg\|+\frac{h^4}{20}\|Dqg\|^2$$
$$+\frac{h^4}{18}\|Dqg\|\cdot\|Dq\|\cdot\|Dg\|+\frac{h^4}{36}\|Dq\|^2\cdot\|Dg\|^2, \tag{3.24}$$

whence in consideration of (3.1), (3.4), (3.17) and (3.18) we arrive, after modifying the numerical coefficient without breaking the validity, at

$$\|r_2\|\leq\frac{h}{3}\|q\|.$$

Summing up all results so far obtained and again modifying the numerical coefficient of $\|D^{(2)}u\|\cdot\|q\|$ appropriately, we observe that the inequality

$$|y(x_r)-u_r|\leq h^2\Big[\frac{1}{12}\|Df\|+\frac{1}{24}\|Dqu\|$$
$$+\frac{1}{12}\|Dq\|\cdot\|Du\|+\frac{1}{4}\|D^{(2)}u\|\cdot\|q\|$$
$$+\frac{1}{9}\|q\|^2\cdot\|Du\|\Big]$$

holds. Furthermore, since the right side of this inequality is independent of $r$, we have established the following theorem concerning $R_2$.

**Theorem 3.** *Let notations be above. We have the following estimate of $R_2$.*

$$R_2\leq h^2\Big[\frac{1}{12}\|Df\|+\frac{1}{24}\|Dqu\|+\frac{1}{12}\|Dq\|\cdot\|Du\|$$
$$+\frac{1}{4}\|D^{(2)}u\|\cdot\|q\|+\frac{1}{9}\|q\|^2\cdot\|Du\|\Big]. \tag{3.25}$$

*Remark* 2. As for the norms appearing in (3.25), it is remarked that $\|D^{(2)}u\|$ should be interpreted as that in $E_{n+1}$ in the sense of Remark 1 of this section, while on the other hand $\|q\|$ may be taken as that in $E_{n-1}$.

*Remark* 3. When we are interested particularly in the asymptotic bounds of $R_2$ ($h\to0$) under more stringent conditions of regularity for $q(x)$ and $f(x)$, we can derive one different from (3.25) in its form, although (3.25) gives a bound of $R_2$ for any $h$ and for any $q(x)$, $f(x)$ provided with the properties stated in P. (I). That is, we assume that each of $q(x)$ and $f(x)$ satisfies the Lipschitz condition of order 1, which implies that $Dq_k$ and $Df_k$ as well as $\|Dq\|$ and $\|Df\|$ are bounded as $h$ tends to zero. Under this assumption, noting (3.6), Lemma 3 and the inequality

$$\|DD^{(2)}u\|\leq\|Df\|+\|D(qu)\|,$$

we observe that all norms appearing in (3.22) are bounded, and hence,

$$\|r\|^2{}_1\leq\frac{h^2}{12}\|D^{(2)}u\|^2+o(h^2), \quad (h\to0).$$

Similarly from (3.24) follows the inequality

$$\|r_2\|^2\leq\frac{h^2}{12}\|qg\|^2+o(h^2), \qquad (h\to0).$$

Thus we find, taking account of (3.17),

$$\|r_1\|\cdot\|r_2\|\leq\frac{h^2}{48}\|D^{(2)}u\|\cdot\|q\|+o(h^2), \quad (h\to0) \tag{3.26}$$

Making use of (3.26) we can deduce

$$R_2\leq h^2\Big[\frac{1}{12}\|Df\|+\frac{1}{12}\|Dq\|\cdot\|Du\|+\frac{1}{24}\|Dqu\|$$
$$+\frac{1}{24}\|D^{(2)}u\|\cdot\|q\|\Big]+o(h^2), \quad (h\to0), \tag{3.27}$$

by a reasoning similar to that used for (3.25).

Furthermore, from Theorem 3 we can derive a bound of $R_2$ not involving $u=\{u_k\}$, i.e., by referring to (3.6) and Lemma 3 we immediately obtain the following theorem.

**Theorem 4.** *Let $a$ be the same as in Lemma 3 and let $Q_M$ be $\max\limits_k q_k$. Then we have*

$$R_2 \leq h^2 \left[ \frac{1}{12} \|Df\| + \frac{5}{48} \frac{\|f\| \cdot \|Dq\|}{a} + \frac{1}{24} \frac{Q_M \|f\|}{a} + \frac{1}{4} \|q\| \cdot \|f\| + \frac{1}{4} \frac{\|q\|^2 \cdot \|f\|}{a} \right]. \tag{3.28}$$

**Corollary.** *As $h$ tends to zero, we have*

$$R_2 = O(h^2) + O(h^2 \|Dq\|) + O(h^2 \|Df\|) .$$

*Remark* 4. In (3.28) $\|f\|$ should be interpreted as that in $E_{n+1}$ and $\|q\|$, on the contrary, may be taken as that in $E_{n-1}$.

*Remark* 5. Under the same conditions as for (3.27), we have the following asymptotic bound of $R_2$:

$$R_2 \leq h^2 \left[ \frac{1}{12} \| Df \| + \frac{5}{48} \frac{\|f\| \cdot \|Dq\|}{a} + \frac{1}{24} \frac{Q_M \cdot \|f\|}{a} + \frac{1}{24} \|q\| \cdot \|f\| + \frac{1}{48} \frac{\|q\|^2 \cdot \|f\|}{a} \right] + o(h^2) , \quad (h \to 0) . \tag{3.29}$$

## § 4. Degree of Convergence

In this section we study the degree of convergence of $u = \{u_k\}$, the solution of P. (II), to $y(x)$, the solution of P. (I), under various continuity hypotheses on $q(x)$ and $f(x)$, which are originally assumed to be picewise continuous (See the foot note in § 1.), as the difference interval $h$ approaches zero. Rewriting $u = \{u_k\}$ by $u(h) = \{u_k(h)\}$, we define $u(x, h)$ for any $x$ contained in $I$ by the condition

$$u(x, h) = u_r(h), \quad \text{where} \quad r = x/h .$$

It is intended to ascertain the degree of convergence of

$$E(x, h) = y(x) - u(x, h)$$

uniform with respect to $x$, provided that $h$ tends to zero in such a manner that the sequence $\{E(x, h)\}$ is infinite. For this purpose, noting that the bounds of $R = R(h)$, which we have succeeded in obtaining, can be regarded as uniform bounds of $E(x, h)$, we need, by virtue of Corollaries in § 2 and § 3, only to investigate the orders with respect to $h$ of the following quantities:

$$Q_1 = \int_0^1 |\Delta q| dx , \qquad F_1 = \int_0^1 |\Delta f| dx ,$$

$$Q_2 = h^2 \|Dq\| , \qquad F_2 = h^2 \|Df\| .$$

In estimating these quantities, it may be worthwhile to note that the relations

$$Q_1 \leq \max_x |\Delta q(x)| , \qquad Q_2 \leq h^2 \max_k |Dq_k| ,$$

$$Q_2 \leq 2h \|\{q_k\}\| ,$$

$$F_1 \leq \max_x |\Delta f(x)| , \qquad F_2 \leq h^2 \max_k |Df_k| ,$$

$$F_2 < 2h \|\{f_k\}\| ,$$

hold and, moreover, for example, if $\Delta q = O(h^\alpha)$ in $I_k$, the contribution of $I_k$ to $Q_1$ turns out to be $O(h^{\alpha+1})$. Although in view of these facts we can rather easily study the degree of convergence under various situations, we do not give the results in full but only illustrate some of them in the following propositions. Concerning these propositions we remark that the relation $R = O(h^\alpha)$ implies that $E(x, h)$ converges to zero, as $h$ tends to zero, uniformly with the degree of convergence equal to or higher than that of $h^\alpha$. Furthermore, we assume without loss of generality that $f(x)$ is provided with its regularity same as or better than that of $q(x)$, since $F_1$ and $F_2$ depend on $f(x)$ respectively in the same manner as $Q_1$ and $Q_2$ depend on $q(x)$ and also the order of $R$ is specified as the lowest one among the orders of $Q_1, Q_2, F_1, F_2$.

($a$) Let $q''(x)$ exist and be bounded in $I$. Then

$$R = O(h^2) , \qquad (h \to 0) .$$

($b$) Let $q(x)$ satisfy the *Lipschitz condition* of order 1, i.e., let a constant $M$ exist such that the inequality

$$|q(x_1) - q(x_2)| \leq M |x_1 - x_2|$$

holds for any $x_1$ and $x_2$ contained in $I$. Then

$$R = O(h) , \qquad (h \to 0) .$$

This is the case, in particular, if $q'(x)$ exists and is bounded in $I$.

($c$) Let $q(x)$ satisfy the Lipschitz condition of order 1 and let $q''(x)$ be piecewise continuous. Then

$$R = O(h^2) , \qquad (h \to 0) .$$

This is the case, in particular, if the graph of $q(x)$ is a polygonal line.

($d$) Let $q'(x)$ be piecewise continuous. Then

$$R = O(h) , \qquad (h \to 0) .$$

This is the case, in particular, if $q(x)$ is a step function which has jumps at a finite number of points.

In conclusion the author wishes to express his sincere thanks to Prof. T. Kato for his valuable suggestions and kind advices.

# The Time Lag and other Undesirable Phenomena observed in Vacuum Photo-tubes at Weak Illumination I

By Masao SUGAWARA

*Hitachi Central Research Lab. Kokubunji-machi, Kitatamagun, Tokyo*

(Received August 29, 1955)

It has been known that in the case of accurate photoelectric photometry of weak light intensity, even the vacuum photo-tube shows the abnormal and undesirable effects such as non-linearity of photoelectric current to the flux of illumination, the variation of photoelectric current with the lapse of time, etc. But, it has not yet been clarified on what factors they depend.

The present writer has experimentally studied these abnormal effects by varying the applied voltage, the wave length, and the flux of illuminating light.

The results show that photoelectric materials, such as caesium, adhering to the undesired portion of the tube wall in poor contact with the photocathode are presumed to be the main cause of these abnormalities.

## §1. Introduction

The photo-tube is often used for measuring the flux of weak illumination, but some abnormal effects are observed in some tubes and the effects introduce the error in measurements.

The classical papers by Ives, Dushman and Karrer$^{1)}$, Preston and McDermott$^{2)}$ described these abnormal effects. For the photo-tubes and photo-multipliers, generally used now, researches have been made by Kortum and Maier$^{3)}$. They have pointed out that in many cases the photoelectric current or the secondary emission current is not accurately proportional to the flux of illumination, and this is due to residual gasses in the tube, the fatigue of the photo-cathode, space charges, photoelectric materials adhering to the undesired portion of the tube wall and temperature variation of the tube. Kuwabara$^{4)}$ has investigated the fatigue of silver-caesium oxide photo-tube from the view of photometry. Discontinuous change in current-voltage characteristics of the photo-tubes which affects the validity of the measurement was reported by Taylor$^{5)}$ and Mori$^{6)}$. They attributed this phenomenon to the electric charges on the inner wall of the tube and photo-electrons as well as secondary electrons from the photoelectric materials on the undesired portion of the tube wall. As described above, various abnormalities have been observed and various factors to be considered as their causes were suggested. But unfortunately, the relations between these factors and abnormalities have not yet been fully clarified. It was found experimentally that there were a few tubes which did not show abnormalities at all. In what follows, the results obtained in the experi-

ments and some considerations regarding to the abnormalities will be described.

## § 2. Experimental Arrangement of Apparatus used and Procedures

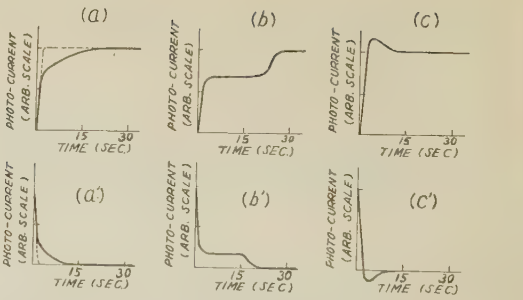

Fig. 4. Typical Time-Photocurrent Curves for Time Lag.
(a), (b), (c) : Light on
(a′), (b′), (c′) : Light off
Dotted line : Normal Case

In fig. 1, the optical system used in this experiment is shown schematically. A light source *L* is a 2800°K tungsten incandescent lamp, and the monochromatic beam enters into the photo-tube *T* through a slit *S* and a shutter *Q*. Between *S* and *Q*, a filter *C* can be inserted. The measurement was carried out under a sufficiently dry condition to avoid the leakage through the outside of the tube. The photoelectric current is amplified and measured with an ammeter *M*.

The amplifier used in this experiment was shown in Fig. 2. Its linearity was previously examined by applying various voltages to the input side and was proved to be quite reliable over a wide range of the voltage. The time constant of the amplifier, including the ammeter responsibility 1.4∼1.8 seconds, was less than 1 second. Resistance *Rg* was 800 megohms. One scale reading on the ammeter corresponded to $1.8\times10^{-12}$ amp. of the phototube current. The time interval was measured with a stopwatch of the scale division one second reading.

At first, after the shutter was opened, the time elapsed till the photo-electric current attained an ultimate value was measured. At the same time, the variation of the current during this interval was also observed. Similar measurements were also carried out immediately after closing the shutter.

Secondly, the spectral transmittance of a filter was measured and compared with the standard value which was determined by using a standard photo-tube*. The standard spectral transmittance of the filter used is shown in Fig. 3.

---

* Recently, the spectral transmittance of the standard filter has been measured accurately with photo tubes at Electrotechnical Laboratory, Japan. Some silver-caesiumoxide phototubes made in this laboratory were checked with the transmittance of the same filter. From these were selected the ones which revealed an error within 0∼+0.3% in the range from 380 mμ to 800 mμ compared with that measured at E. T. L., and these were used as standard photo-tubes.

## § 3. Experimental Results

### (1) *Abnormal Effects*

### (a) *Time lag*

The time lag of the photo-tube current can be classified into three types as "A", "B" and "C".

In "A" type time lag (Fig. 4 a, a′), the photo-tube current immediately reaches a certain value lower than the ultimate value and gradually approaches the ultimate one. In "B" type (Fig. 4 b, b′), the tube current immediately reaches a certain value, and after remaining there for a time, increases to an ultimate value. And in "C" type (Fig. 4 c, c′), the tube current, after overpassing an ultimate value, comes to the ultimate one.

In many cases, one of the above mentioned types appears individually, but sometimes more complex phenomena, such as successive appearance of "A" and "C" type are observed. In the cases of "A" and "C" types, the duration before coming to the ultimate value is comparatively short (within 30 secs.), while in the case of "B" type it often requires a few minutes.

Time lag phenomenon must be distinguished from the so-called fatigue of the photo-tube and it will be considered as one of the abnormal effects of the photo-tube. Photo-tubes whose time lag is greater than 1.4∼1.8 seconds, which correspond to the responsibility of the microammeter used, are regarded as abnormal.

### (b) *Fluctuations in the measured transmittance of a filter.*

In the cases of using different photo-tubes, the results of transmittance measurements of a filter are generally different from the standard value of that filter, and this difference will be designated by a term "discordance". This discordance may be mainly due to the lack of flux-current proportionality. Photo-tubes which show a discordance of more than 0.5% are regarded as those with an abnormality.

### (2) *Relation between abnormalities and Wave Length*

Abnormal effects are affected by the illuminating wave length, but it seems that there are no fixed relations between abnormal effects and wave lengths. Somewhat common facts are as follows;

(i) Abnormal effects are generally conspicuous at a shorter wave length

(ii) "A" type and "C" type time lags occur in a rather wide range of wave length, while "B"-type is limited to a narrow range.

(iii) In many cases, photo-tubes with "B" type time lag at the beginning of illumination show "A" type time lag at the interception of light and reveal a large discordance.

Table I represents the results on the abnormal effects of the caesiumoxide vacuum photo-tube whose shape is shown in Fig. 5.

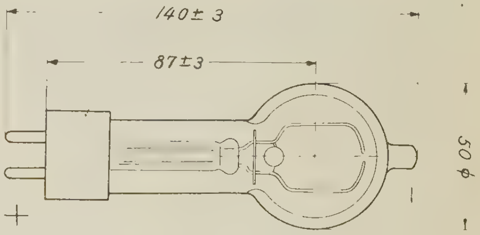

Fig. 5. Front View of the Photo-tube used for Measurement.

Table I. Abnormal Effects of Phototube.
(for Silver-Caesiumoxide Phototube)

| Wave length in mμ | Discordance in % | Time lag | | | |
|---|---|---|---|---|---|

Remarks: Photocurrent: $1.8 \times 10^{-10}$A
Anode voltage: 30 volts
Discordance: (measured)
-(standard)

### (3) *Effects of Applied Voltage and Illuminating Flux*

The abnormal effects varies according to the applied voltage as well as the flux of illumination. The oscillograms of the time-current characteristics at various illuminating fluxes are reproduced in Fig. 6. From (a) in

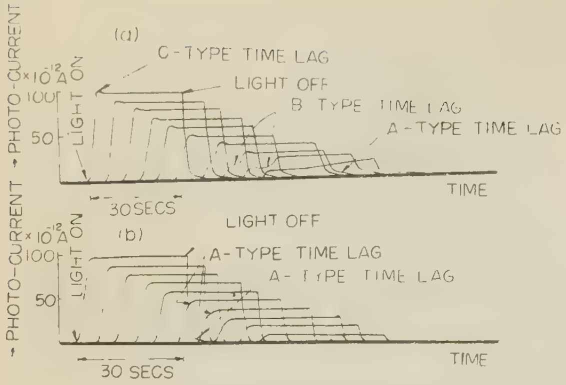

Fig. 6. Variations of Time Lag by the Flux of incident Light.
(a) Antimony-Caesium Photo-tube, Anode Voltage: 70 Volts, Wave length: 480 m$\mu$.
(b) Silver-Caesiumpxide Photo-tubes, Anode Voltage: 90 Volts, Wave length: 780 m$\mu$.

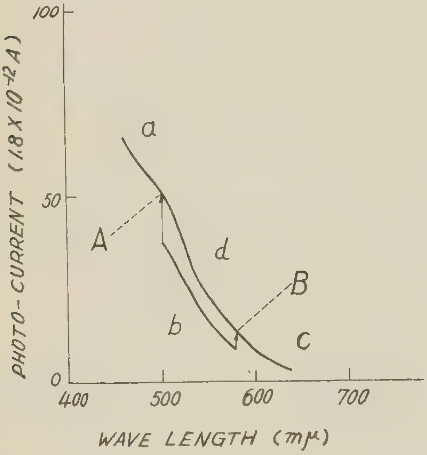

Fig. 7. Typical Example of Dual Characteristics observed in Spectral Response (for Antimony-Caesium Photo-tubes).

the figure for antimony-caesium tubes, it can be seen that the time lag at the beginning of illumination changes from "C" to "B" type and finaly to "A" type as the illuminating intensity is decreased. While, from (b) for silver-caesiumoxide tubes, only "A" type can be seen in a certain range of illuminating flux. Similar phenomena can be observed when the applied voltage is changed.

The discordance does not show any fixed relation with the applied voltage and the flux of illuminating light. Examples of the discordance measured are shown in Table II. The discordance is not always large even at the point where the current-voltage characteristic is not saturated, at such a voltage as 5V and 10V.

(4) *"B" type time lag*

Among the abnormal effects, the most noticeable is "B" type time lag. Furthermore, it is interesting to note that photo-tubes with "B" type time lag often show duality in spectral sensitivity which will be described in detail hereafter.

In Fig. 7, the most typical example is shown. A discontinuous response curve a-b-c is obtained when the illuminating flux is cut off in the intervals of the current measurements at different wave lengths, while in the case of continuous illumination a continuous curve a-d-c is obtained. "B" type time lag is often observed at points near *A* and *B* in Fig. 7. Namely, the duality of the response occurs generally accompanying the "B" type time lag. The current-voltage curves of the photo-tubes, in the case of the wave length at which "B" type time lag appears, generally show discontinuous changes at certain voltages, the duality being observed as well. Similar abnormality is observed in the current-flux characteristics. According to these facts three abnormalities are seemed to be brought about by the same cause.

As previously mentioned, in the case that, "B" type, time lag occurs at the beginning of illumination, "A" type time lag often appears when light is cut off. No abnormal effects, however, are observed if the illumination is resumed before the photo-current fully returns to zero. In the cases of other types of time lags, similar phenomena are also observed. The time lag decreases as the interval of interruption of light is shortened.

(5) *Effects of Heating*

Heating the whole tube above the room temperature affects the appearance of the abnormal effects and often changes normal photo-tubes to abnormal ones. "C" type time lag is usually observed after heating is repeated. (refer to Table III)

Local heatings of a portion of the neck or the window at 100°∼200°C for 20∼30 minutes also cause considerable changes in the abnormal effects. Contrary to the case of whole tube heating, a portional heating often changes abnormal tubes into normal ones. But after a few days, these phototubes show again, similar abnormal effects as before. (Fig. 8)

Table II. Discordance of Phototubes at Various Voltages.
(for Silver-Caesiumoxide Phototubes)

| | Wave length used | Voltage (V) / Relative light intensities | 150 | 110 | 50 | 20 | 10 | 5 |
|---|---|---|---|---|---|---|---|---|
| Ordinary Photo-tube | (mμ) 500 | 200 | 0.3 | 0.1 | 0.1 | -0.5 | -0.1 | -0.2 |
| | | 100 | 0.2 | 0.1 | 0 | -0.8 | -0.2 | -0.2 |
| Photo-tube Containing film | (mμ) 500 | 200 | 0 | 0 | 0 | 0 | -0.1 | 0.2 |
| | | 100 | 0 | 0 | 0 | 0 | -0.2 | 0 |

Photo-tubes kept in a dark place at room temperature often show a variation of abnormal effects with the lapse of time. This is also believed to be due to a similar cause.

## § 4. Effects of Transparent Conducting Film at the Window

Solution of $SnCl_2$ in conc. HCl, for example, sprayed onto the inner surface of glass bulb heating at 400°C forms a transparent conducting film. Silver-caesiumoxide photo-tubes with the bulb treated in this manner were trially made to remove the surface charge on the inner wall, which often had been described by many experimenters. It was found that time lags of these tubes were always within 1.8 sec. in the wave length range of 380~800 mμ. Discordance was also measured. They were quite satisfactory compared with the results obtained with the ordinary phototubes (Table II). The current-voltage characteristics showed no stepwise changes.

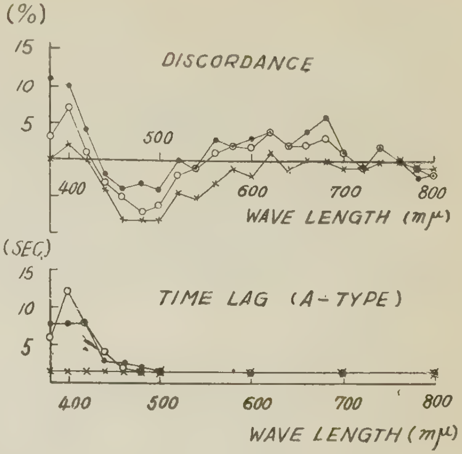

Fig. 8. Example of the Changes of Abnormal Effects caused by Heating the Photo-tube Neck and Window.
— — before heating
—×— after heating (30 min. 200°C)
—○— left at room temp. for 24 hours after heating.

Furthermore, even after a continuous heating

| | 800 | -0.1 | | -0.3 | | 1.6 | | 1.6 |

of the tube at 50°C for 1,000 hours, the time lag was within 1.6 sec. for the monochromatic light in the wave length range from 380 m$\mu$ to 800 m$\mu$. Discordance was also within 0.5% at the anode voltage 30 V and photoelectric current $1.8 \cdot 10^{-10}$ amp.

In Table III, examples of the results for these tubes measured before and after heating in comparison with ordinary tubes, are shown.

## § 5. Discussion

As shown Figs. 4 and 6, there are three types of time lag and the type of time lag of photo-tube varies from one to another when the applied voltages, the flux of illuminating beam and the wave length are changed. Therefore, it is presumed that the main cause of time lag is irrespective of type.

Furthermore, from the fact that the appearances of time lag as well as discordance are changed by heating only a limited portion of the neck or the window of the tube at 100°∼200°C for 20∼30 minutes as shown in Fig. 8, it is considered that above two kinds of abnormalities are due to common causes.

It has been known that the photoelectric current decreases with the lapse of time and this phenomenon has been called the fatigue of the photo-cathode. According to de Boer's hypothesis[7], which is still generally accepted though it is not perfect, caesium ions produced by photo-ionization on the photoelectric surface are not all neutralized because of the poor supply of the electron through the layer of photo-cathode and consequently the fatigue phenomenon takes place. But neither the occurrence of various types of time lag, nor their dependence on the flux of illumination, the anode voltage and the wave length used, can be explained by Boer's hypothesis.

Asmus[8] carried out the experiment on the alkali-halide photo-tubes with similar effects and some interpretations have been attempted[9]. But unfortunately, these seem to be still insufficient to explain such complex abnormal effects as observed in our experiments.

Residual gas and the temperature change of the tube surface cannot be considered as the main factor and the slight discordance, as shown in Table II, even in the unsaturated region of the current-voltage curve suggests that the space charge effect is not important.

The interpretation of the abnormalities might be conceived as follows: Small quantities of caesium or the like adhere on the inner surface of the photo-tube in poor contact with the main cathode. By incident of light their potential will change with the photo-emission, and these cause the abnormalities. The change of abnormalities by local heating of the tube would be due to the fact that caesium on the portion heated would evaporate and remove to other portions and consequently the distribution of caesium be changed. As this is an enforced state, naturally a thin film of caesium would be gradually built up again on the former position, and the more or less similar state as before be formed with the lapse of time.

The fact that the photo-tubes provided with a conducting film on the wall as stated in the section 4 hardly show any abnormality, endorses the above reasoning.

The observed results in detail relating to the process of how the photoelectric materials adhering to the tube wall will produce these abnormalities will be described in the next paper.

## § 5. Conclusion

The writer has carried out the experiments about the abnormal effects and found out that photo-tubes without abnormalities are scarce. The abnormal effects differ according to the tubes and are affected by the applied anode voltage, the flux of illuminating light, the wave length and lapse of time. Results are summarized as follows:

(a) Fatigue phenomenon should be separated from the abnormal effect.

(b) Space charge and residual gas cannot be considered as the main cause of abnormalities.

(c) Photoelectric materials, such as caesium, adhering to the undesired portion of the tube wall in poor contact with the main photocathode are regarded as the governing factor.

## Acknowledgment

The writer wishes to express his gratitude to Dr. Hamada, Dr. Tadano, Mr. Kiuchi and Mr. Makino for their kind guidance throughout this work and he also wishes to thank

Messrs. Takei and Morito for their helpful discussions.

# Short Notes

J. Phys. Soc. Japan **11** (1956) 175～176

## Energy Band Structure of the Carborundum SiC Crystal

By Syôiti Kobayasi

*Department of Physics, Faculty of Science Hiroshima University, Hiroshima, Japan*

(Received October 29, 1955)

Here we report a preliminary result (namely, the result computed by Bloch's tight-binding approximation) of the energy band structure of SiC crystal.

There exist some modifications in the crystal structure of SiC, the typical one of which is of zinc blende (diamond) type. The band structures of the zinc blende type of monatomic crystals such as diamond, silicon, and germanium have been already studied by many workers[1] by various methods.

The assumptions in our computation by Bloch's tight-binding method are as follows: the electronic configurations of C and Si atoms in their free state are assumed to be

$$[(1s)^2](2s)^1(2p)^3 \text{ and } [(1s)^2(2s)^2(2p)^6](3s)^1(3p)^3,$$

respectively. As for AO's of core electrons of both atoms, we have used the SCF solutions of each atom.[2,3] As for AO's of valence electrons of both atoms, the Hartree solution[2] is adopted for $2s$ orbital of C atom, the Hartree solution[3] of $\mathrm{Si}^{+2}$ for $3s$ orbital of Si atom, and Slater's function with atomic shielding constants[4] for both $2p$ orbitals of C atom and $3p$ of Si atom. Concerning the atomic energy levels, the computed values[2] based on the Hartree approximation are used for the levels of $2s$ and $2p$ electrons of C atom, while the empirical ones derived from the analysis of atomic spectra[5] are used for $3s$ $(-0.52008e^2/a_0)$ and $3p$ $(-0.29955e^2/a_0$; $a_0$ is the Bohr radius) of Si atom. In practical computation, we have only taken into account the overlapping of a chosen Si–AO with the nearest neighboring AO's of four C atoms ($\sqrt{3}a/4$ apart from it) and the next nearest AO's of twelve Si atoms ($a/\sqrt{2}$ apart from it; $a$ is the edge length of the cube which contains four unit cells). Similar approximation is taken for a chosen C–AO. Further, the three center integrals are neglected approximately throughout our calculation.

In accordance with the mentioned approximations, we calculated the band structure by essentially the same method as what Morita[1] applied to diamond. The results obtained are shown in Fig. 1.

In Fig. 1 the minimum separation between valence and conduction bands seems to occur at $\vec{k}=(0,0,0)$, being about 6 ev in comparison with the experimental value[6] of about 3 ev by ultraviolet absorption. According to our computation, the valence bands at $\vec{k}=(1/a, 0, 0)$ are separated, by 10 ev, into branches; this result may be taken to show the characteristic difference between monatomic and diatomic crystals, since two $X_1$-points in Fig. 1 have been found[1] to coincide with each other in the monatomic crystals. Further, it should be

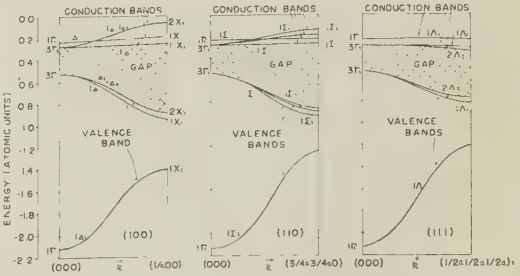

Fig. 1. Behavior of energy bands of the carborundum SiC crystal along 100, 110, and 111 directions, respectively. $a$ is the edge length of the cube which contains four unit cells.

noted that the result shown in Fig. 1 is a little modified, by allowing for Parmenter's consideration[7] on the symmetry properties of the energy bands of the zinc blende structure.

Our next program is to perform a quantitative computation by using the OPW method,[8] which is now in progress.

The author wishes to express his sincere gratitude to Professor T. Muto of Tokyo University for suggesting this work as well as for constant guidance. He is grateful to Dr. J. Yamashita of Tokyo University for his kind advices. Thanks are also due to Mr. E. Yamaka, Dr. A. Morita, Professors T. Matsubara, E. Hirahara, and H. Tazaki for their valuable suggestions.

# Photo-induced Hall Effect of V-center in KI

By E. YAMAKA and K. SAWAMOTO
*The Electrical Communication Laboratory*
T. ISHIDA
*Tokyo College of Science*

(Received November 24, 1955)

Although some investigations for optical absorption of V-centers in alkali-halide crystals have been done in the past[1], measurements of photoconductivity and Hall effect have not yet been carried out, the mechanisms of electronic transitions associated with optical absorptions being left unclarified. Especially determination of signs of charge carriers released by lights from composite V centers, such as $V_2$ of $V_3$, will be interested in interpretation of bleaching. This article describes a preliminary report of photo-induced Hall effect in KI.

Large single crystals of KI were made from melt and additive colorations were performed with iodine at about 530°C. Absorption curves without and with coloration are shown in Fig. 1. Light sources for various absorption bands were obtained by combinations of a high pressure mercury dicharge tube with various filters, their transparent curves being shown in Fig. 2. The apparatus used has the high input impedance preamplifier developed by MacDonald[2].

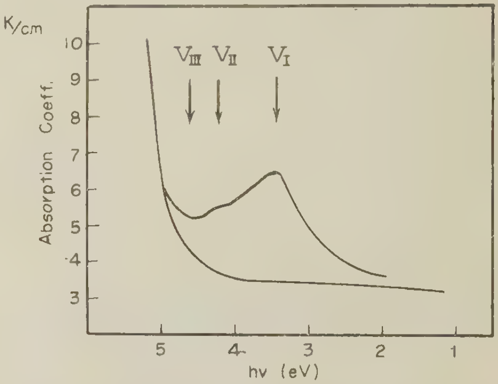

Fig. 1. Absorption curves of KI without and with iodine-coloration. The notation of bands is followed to that of reference 3.

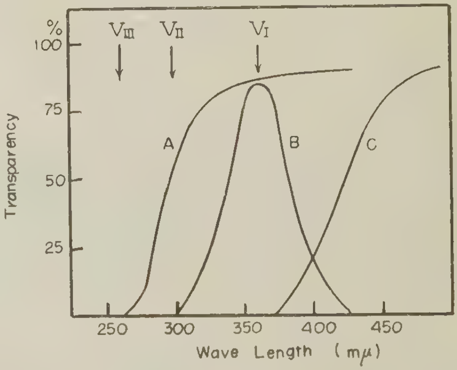

Fig. 2. Transparent curves of various filters used to obtain light of $V_I$, $V_{II}$, $V_{III}$ bands.

Samples were sealed in vacuum in order to avoid humidity.

Photoresponce was observed only with filter A, which in turn indicates that only $V_{II}$ band is responsible for photocurrent and Hall effects showed that associated charge carriers are holes. On the other hand Uchida and Nakai[3] concluded from their optical measurements that $V_I$ and $V_{II}$ bands correspond transitions from the ground state of $V_2$ center (composed from two positive ion vacancies and two holes) to two excited states. From this model our results lead to the conclusions that a electron tranfers from the valence band or excited state, which lies near the top of that band, to the ground state of V-center, leaving a mobile positive hole in the valence band.

Hall mobility of holes lies in the range of 2 to 6 cm²/volt sec at 30 CPS (the lowest frequency available in our apparatus). The measurements at higher frequencies were impossible due to a parastic capacity, so that we could not decide the true mobility free from space charge. Distribution of observed values may be due to various states of space charge in each specimen.

# Disturbance by Probe in Plasma

By Takayoshi OKUDA and Kenzo YAMAMOTO

*Faculty of Engineering, Nagoya University, Nagoya*

(Received November 18, 1955)

The recently published articles[1,2,3] on the probe study concern with the situation of the probe with negative potential with respect to the space potential and the mechanism of positive ion collection through the transition (or extra-sheath) region between plasma and positive ion sheath, particularly at the low pressure.

Now we deal with some problems which concerns with the disturbance by probe, including both cases of negative and positive probes. To see how the disturbance is responsible for the deformation of the probe characteristic in plasma at higher pressure, we carry out following experiments.

A thin probe (diameter 0.1~0.2 mm) is movably inserted into a disturbed region formed around a thick probe (diameter 0.5~1.5 mm) fixed in a plasma. As the disturbance made by the thin probe is negligibly small compard with that made by the thick probe, we can observe the disturbance made by the thick probe by using the thin probe to measure the ion current and the potential distribution in the disturbed region. The discharge tube used has a diameter of 3.5 cm, and is filled with argon of the pressure 10~$10^{-4}$ mm Hg, mounted by an oxide cathode, a nickel anode, and molybdenum probes.

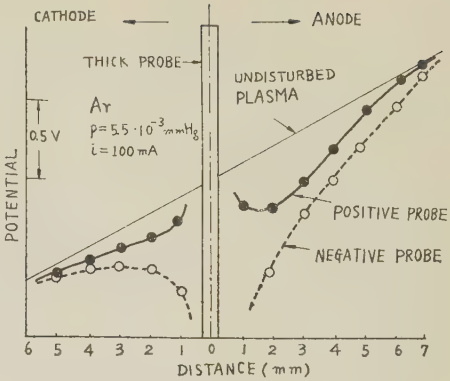

Fig. 1. Potential distribution near a cylindrical thick probe. The solid line: the thick probe is at 5 V positive against plasma potential, electron current is 4 mA. The dotted line: the thick probe is at 77 V negative against plasma potential, positive ion current is 150 μA. Argon, pressure $1\times10^{-2}$ mm Hg, discharge current 100 mA. The thick probe: diameter 0.5 mm, length 4 mm. The thin probe: diameter 0.1 mm, length 4 mm.

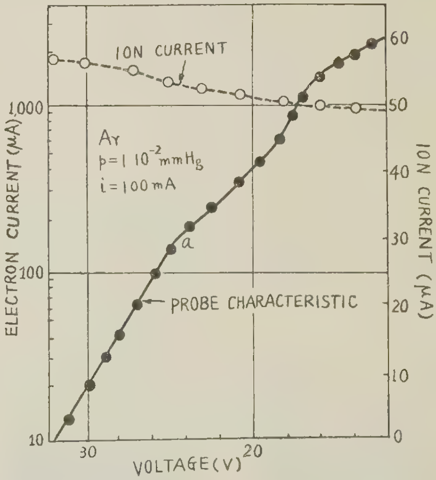

Fig. 2. Probe characteristic of a cylindrical thick probe and saturated ion current of a cylindrical thin probe. The solid line: probe characteristic of the thick probe, voltage is measured with reference to the anode. The dotted line: saturated ion current of the thin probe 1 mm away from thick probe. Argon, pressure $5.5\times10^{-3}$ mm Hg, discharge current 100 mA. The thick probe: diameter 1.5 mm, length 4 mm. The thin probe: diameter 0.1 mm, length 4 mm.

The solid line in Fig. 1 represents the measured potential distribution when the pressure is $1.10^{-2}$ mm Hg, the discharge current 100 mA and the thick probe has a positive potential with reference to its space potential; the dotted line shows the potential distribution of a negative probe. In all pressure we can observe such a potential distribution accompanying a potential sinking formed near the probe even in a case of positive probe. In this case the potential sinking occurs in the same place as the transition region which exists for the negative probe. Here, it must be expected that the potential sinking has a considerable effect on the electron current collected by the probe. The saturated positive ion current of the thin probe in the region of the potential sinking is weaker than that in the undisturbed plasma which is several mm away from the thick probe. That extent to which the probe disturbs the plasma increases with increasing pressure.

The solid line in Fig. 2 indicates a Langmuir's probe characteristic[4] of the thick probe when the argon pressure is $5.5\times10^{-3}$ mm Hg and the discharge current 100 mA, the dotted line indicates the saturated ion current of the thin probe put in the anodic side 1 mm away from the thick probe, showing that when the potential of the thick probe approaches the space potetial, the plasma density near the probe decreases. Therefore, the departure from the linearity at point $a$ on the characteristic curve is not due to the deviation from the Maxwellian distribution of electron energy but the decrease of the plasma density near the probe. This is new interpretation for the nonlinearity of the semi-log plot of the probe characteristic. Further, we find that the linearity in the semi-log plot of the probe characteristic at higher retarding voltage is fairly well held (see Fig. 2), but the reciprocal of the slope of the semi-log plot or the value of the electron temperature evaluated directly from the slope appreciablly decreases as the probe diameter increases and this effect is more appreciable as the pressure increases. The electron temperatures evaluated from the slope of the semi-log plot are tabulated in Table I, for several probes with different diameters. At lower pressure less than $10^{-4}$ mm Hg, no appreciable variation of electron temperature with probe diameter is observed.

Table I. Electron temperature evaluated from the slope of the semi-log plot of probe characteristic for several cylindrical probes with different diameters. Low voltage arc of argon, discharge current 100 mA, probe length 5 mm.

| pressure (mm Hg) | diameter (mm) | | | |
|---|---|---|---|---|
| | 0.2 | 0.5 | 0.8 | 1.5 |
| 1 | 24,600 | 22,000 | 19,300 | 13,900 |
| 0.1 | 31,300 | 23,000 | 22,000 | 20,300 |
| 0.005 | 34,800 | 34,800 | 34,000 | 33,500 |

(unit: °K)

Accordingly, from the experimental results above mentioned, it is cofirmed that the disturbance occuring in a plasma near a probe results in a non-linearity of semi-log plot of the probe characteristic or erratic evaluation of the variables of the plasma such as the electron temperature and the plasma density.

The probe measurement in plasma at higher pressure is valid only if this disturbance is taken into consideration.

# Experimental Studies of the Interaction of a Plane Shock Wave with a Circular Cylinder

By Kim, Chul-Soo
*Department of Physics, Faculty of Science,*
*University of Tokyo*
and Kôichi Ôshima
*Institute of Industrial Science,*
*University of Tokyo*

(Received November 18, 1955)

When a plane shock wave of arbitrary strength advances into a still air and encounters a body of arbitrary shape, an unsteady flow takes place within the region bounded by the reflected shock and the surface of the body. Although considerable attention has been paid to "pseudo-stationary interaction" (1), (2), no work on "pure unsteady problem" seems to have been undertaken, so far as the authors are aware.

Here, an attempt is made to give a brief survey of unsteady shock interaction with a circular cylinder as a typical body which has an intrinsic length. Numerous observations at different times are necessary even for the case of given shock strength and given dimension of the cylinder, since the flow patterns in the reflected region are not similar to each other. Experiments were carried out at the Institute of Industrial Science using the shock tube

Fig. 3. Isopicnics in reflected regions and their corresponding interferograms.
(a) regular reflection, (b) Mach reflection.

(3) with a uniform cross section of $6\times15$ cm$^2$. As the first series of our studies, circular cylinders with diameters of $d=2$ and 4 cm, and shock intensities of $\xi=P_1/P_2=0.24$, 0.33 and 0.54 were used, where $P$ is the pressure and the subscripts 1, 2 refer to the states just in front of and behind the incident shock respectively. Reflection and diffraction of the plane shock were observed by schlieren photographs using the delay circuit (3) with which $1\sim2\,\mu$ sec time control was possible. The locations of reflected shocks for $\xi=0.33$ and $d=4$ cm are shown in Fig. 1, where $I$, $R$ and $M$ represent the incident, the reflected and the Mach shocks respectively, and $S$ the slip stream. The angles of transition from regular to Mach reflection for fixed $\xi$ are given in Fig. 2. Here it is interesting that the regular reflection continues to exist slightly above the theoretical extreme value for the range of $\xi$ in our experiments, and this phenomenon has the same tendency as in the pseudo-stationary case of a wedge (4), (5). The isopycnics $\rho/\rho_2=$const in

the region behind the reflected front are shown in Fig. 3 as well as their corresponding interferograms. In every case of our experiments, the density in the vicinity of the cylinder nose was at most 7~12% smaller than the theoretical value for the shock reflection at rigid plane wall. This fairly large discrepancy may be due to the convexity of the surface of the circular cylinder.

Further experiments with widely varying cylinder diameters and shock strengths seem to be necessary for the full understanding of these phenomena.

We wish to express our gratitude to Professor F. Tamaki for suggesting this study as well as for continual encouragement. We also wish to thank Dr. M. Kawaguti for his helpful discussions during this work.

## Effect of $Fe_2O_3$ on the Properties of Barium Titanate Single Crystals

By Atsuo NISHIOKA, Kyozo SEKIKAWA
and Masakazu OWAKI

*Electrical Communication Laboratory,*
*Musashino, Tokyo*

(Read at October 10, 1955,
Received November 13, 1955)

Recently Remeika[1] has reported a method of growing large single crystals of barium titanate from the melts of barium titanate powder and potassium fluoride with a small amount of added impurity of ferric oxide, and briefly described the change of Curie point and d.c. conductivity with the atomic percentage of iron. D.c. conductivity of barium titanate ceramics had already been measured by Swanson[2], Ogawa[3], Nomura[4], and Weise[5], but the data on single crystals have not yet been published in detail.

We have prepared the single crystals of barium titanate by the method of Remeika, varying the atomic percentage of iron, and have measured the optical and dielectric Curie point, lattice constants and d.c. conductivity. The content of iron included in the melts except the added ferric oxide was less than 0.057 atomic percentage, whereas the range of the content of added iron lay between 0.2 and 10 atomic percentage.

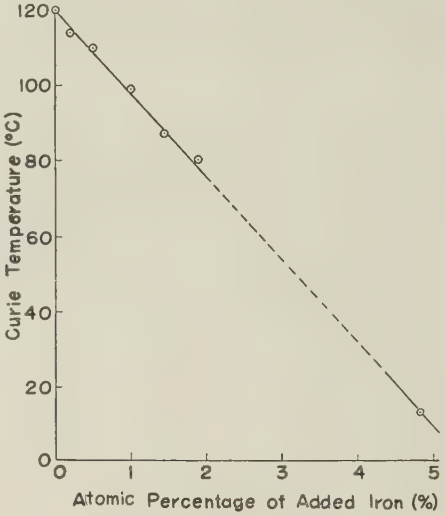

Fig. 1.

The change of Curie point with the content of iron is shown in Fig. 1, determined by the observation using polarizing microscope and the measurement of dielectric constant at 1 kc/s. From 0.2 to 5 atomic percentage the Curie point drops linearly and the value at 25°C was estimated about 4.5 atomic percentage. This value is different from the data of Remeika (2.5%). Above 2.0 atomic percentage the colours of the crystals become dark green to blackish. This would be considered to correspond the change of the gap of the energy band.

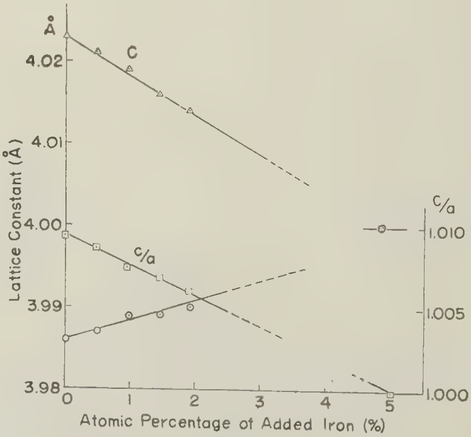

Fig. 2. Lattice Constants and Axial Ratio.

The X-ray analysis shows the gradual change of lattice constants a and c, and axial ratio of this tetragonal crystal as seen from Fig. 2. The crystal of 5.0 atomic percentage of iron has cubic symmetry at room temperature. The observed changes of the crystal structure was seemed to be in well accordance with the tendencies of optical and dielectric Curie points. The lattice volume does not change appreciablly in the range of added iron in our experiment.

Fig. 3 shows d.c. conductivity measured from room temperature to about 150°C. Single crystals did not show appreciable absorption current, which had been suggested by Nomura and Sawada[4]. So the contribution to the conductivity should be entirely due to electrons. The activation energy of d.c. conductivity $\Delta E$, defined by the following formula

$$\sigma=\sigma_0 \exp(-\Delta E/2kT),$$

is the energy between impurity level and conduction or full band. The values of $\Delta E$ estimated from Fig. 3 are shown in Table I. They have some fluctuations in small content of added iron, but would have a tendency of gradual decrease in larger content about 5.0 atomic percentage. Its value of no added iron would be corresponding to the energy gap between donour level of $Ti^{3+}$ ion and conduction band as in the case of titanium dioxide semiconductor[6], and in the larger content of added iron would be the gap between the acceptor level of $Fe^{3+}$ ion and full band as suggested by Remeika[1]. The maximum resistivity at room temperature was found near 0.2 atomic percentage, which is well accorded with the data of Remeika[1], but the tendency of the change in this case is very complicated, different from other cases. Therefore the definite value of $\Delta E$ cannot be estimated. These interesting character would be perhaps due to the coexistence of nearly equall numbers of electrons and holes. Further experimental results and detailed discussions will be published lately.

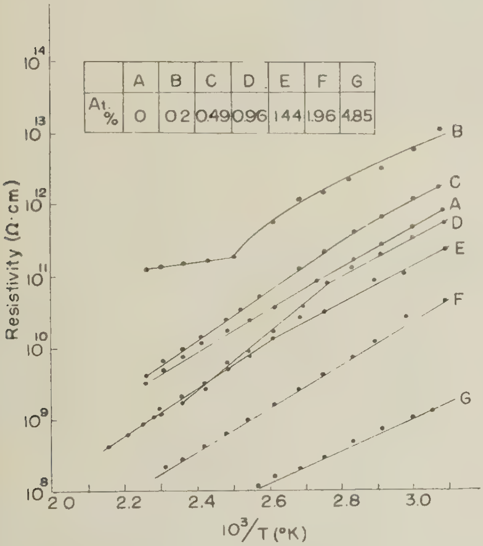

Fig. 3. Temperature Dependence of the Resistivity.

Table I. Activation energy of d.c. conductivity $\Delta E$.

| Atomic percentage of added iron (%) | 0 | 0.49 | 0.96 | 1.44 | 1.91 | 4.95 |
|---|---|---|---|---|---|---|
| $\Delta E$ (eV) | 0.68 | 0.76 | 0.86 | 0.78 | 0.70 | 0.50 |

# Focusing Properties of a large Mass Spectrograph newly constructed at Osaka University

By Hisashi MATSUDA

*Department of Physics, Faculty of Science, Osaka University*

(Received November 4, 1955)

A large double focusing type mass spectrograph was newly constructed at Osaka University in order to increase the accuracy of atomic mass measurement by about one order of magnitude. In this apparatus are adopted $\sqrt{2}\pi/3$ cylindrical electric field and $\pi/3$ uniform magnetic field. The focusing properties of this apparatus are discussed from both theoretical and experimental aspects. The direction and velocity focal planes are calculated, and their deviations due to various conditions such as the change of the position of source, the fringing field effect, the deviation of the geometry, etc. are discussed. These results are compared with the experimental procedure of the focal adjustment. A maximum resolving power of 500,000 was obtained experimentally at the present condition, and the mass dispersion is about 9 cm for 1% mass difference in this case.

## § 1. Introduction

The accuracy of the atomic mass determination in the field of mass spectroscopy has been increased greatly since several years ago. This increase of the accuracy was caused mainly by the improvement of the focusing conditions, that is, the improvement of the collimation of the ion beam, the adoption of the device to make the width and length of the main slit as small as possible, the fine adjustment of the geometry of the apparatus, etc.$\cdots$. A resolving power of several ten thousands was obtained with the apparatus of the same size as before, which was several times larger than before[1][2][3]. At Osaka University, the improvement of the Bainbridge-Jordan type mass spectrogaph, which had been constructed by Asada, Okuda, Ogata, et al. in 1939[4], was achieved during 1949~1950 and a maximum resolving power of about 60,000 was obtained, while the experimental resolving power of this apparatus had been estimated to be 7,000~8,000 before the improvement.

These results show that the focusing property of cylindrical electric field and uniform magnetic field is empirically very good when these fields are combined in tandem and that the ion optical analysis calculated by Herzog[5] is very useful for the construction of mass spectrograph.

After the successful improvement of the Bainbridge-Jordan type mass spectrograph, the construction of a new large mass spectrograph, was planned at Osaka University in order to raise the resolving power and increase the accuracy by about one order of magnitude. This plan was accomplished upon the foundation of the Herzog's analysis, and the double focusing mass spectrograph with a cylindrical electric field and a uniform magnetic field was adopted from the reason described above. In order to have large mass dispersion, which is necessary to measure the line distance on the photographic plate accurately, the distance from the exit of the magnetic field to the photographic plate must be made as long as possible, while the total length of the ion path must be made as small as possible to reduce the loss of ion intensity and to decrease the scattering effect. As the dimension of the apparatus was restricted by the floor space of the laboratory and by the economical reason, the resolving power of the apparatus was deviced to be as large as possible for a given size of the apparatus. In these considerations, the angle of the electric field was chosen to be $\sqrt{2}\pi/3$, and that of the magnetic field $\pi/3$. The schematic view of the apparatus is shown in Fig. 1.

The construction of the new large mass spectrograph was started in 1952 and a resolving power of 500,000 was experimentally obtained with this apparatus near the end of 1954. It proved that the accuracy of the

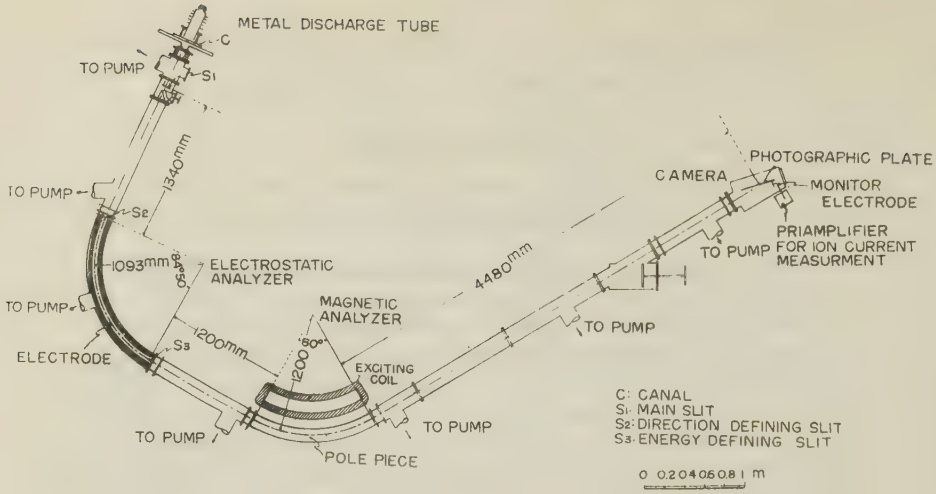

Fig. 1. Schematic diagram of the apparatus.

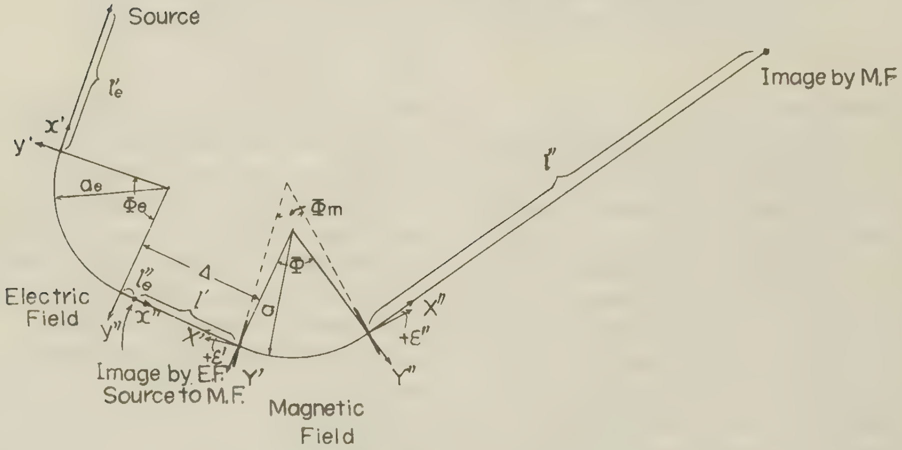

Fig. 2. Coordinate system.

measurement of doublet mass difference may be estimated to be several times larger than that by modified Bainbridge-Jordan type mass spectrograph.

The detail of the basic consideration and the general description of this apparatus have been published already[6]. In this paper, the focusing properties of this apparatus are described from both theoretical and experimental aspects.

## § 2. Focusing Properties in the Ideal Case

In the coordinate system shown in Fig. 2, the quantities which describe the focusing characteristics are given in the following way:

$\Phi_e$: angle of the cylindrical electric field,

$\Phi_m$: angle of the uniform magnetic field,

$\Phi$: deflection angle of the ion beam in the magnetic field,

$a_e$: radius of the central beam in the electric field,

$a_m$: distance from the entrance point of the ion beam to the apex of the pole boundary of the magnetic field,

$a$: radius of the ion beam in the magnetic field,

$\Delta$: distance from the exit of the electric field to the entrance of the magnetic field,

$l_e'$ and $l_e''$: distance respectively from the source and from the image to the edge of the electric field,

$l'$ and $l''$: distance respectively from the source and from the image to the edge of the magnetic field,

$\varepsilon'$ and $\varepsilon''$: angle respectively between the incident-, and deflected-, ion beam and the normal to the pole edge of the magnet.

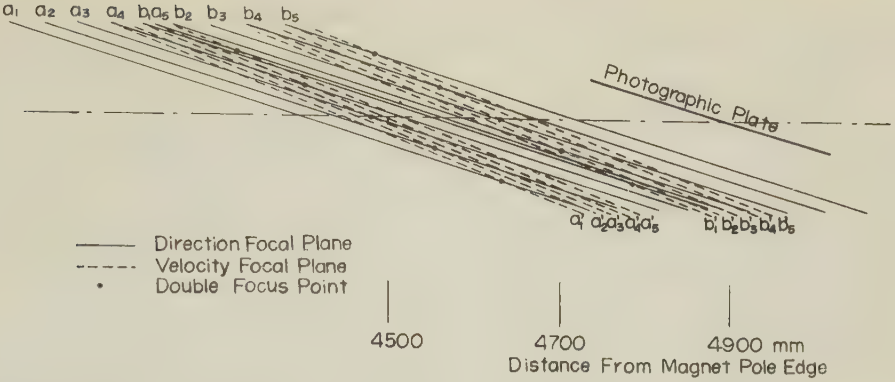

Fig. 3. Deviation of focal planes by the change of the position of source.

$a$ : direction-

$a'$: velocity- focal planes in ideal case.

$b$ : direction-

$b'$ : velocity- focal planes in consideration of the effect due to fringing field $d=5$ mm).

suffix $1{:}\eta=-0.008$, $2{:}\eta=-0.004$, $3{:}\eta=0$, $4{:}\eta=+0.004$, $5{:}\eta=+0.008$.

When designing a double focusing mass spectrograph, some of these quantities can be chosen arbitrarily. The following values were chosen from the standpoint to obtain high resolving power and large mass dispersion in comparison with the size of the apparatus:

$$\Phi_e=\frac{\sqrt{2}\,\pi}{3}\,,\qquad \Phi_m=\frac{\pi}{3}\,,$$

$$a_m=\Delta=1200\text{ mm}\,,$$

$$\varepsilon'=0\,,\qquad l_e''=0\,.$$

The quantities $a$, $\Phi$, $\Phi_m$, $\varepsilon''$ have the following relations to each other;

$$\Phi=\Phi_m+\varepsilon'+\varepsilon''=\frac{\pi}{3}+\varepsilon''$$

$$a=\frac{a_m\sin\Phi_m}{\sin\varepsilon''+\sin(\Phi_m+\varepsilon')}=\frac{a_m}{1+\frac{2}{\sqrt{3}}\sin\varepsilon''}\,.$$

The relation between the source and the image in the direction focusing is as follows: cylindrical electric field

$$(l_e'-g_e)(l_e''-g_e)=f_e^2 \qquad (1)$$

$$f_e=\frac{a_e}{\sqrt{2}\sin\sqrt{2}\,\Phi_e}=\frac{2}{\sqrt{6}}a_e \qquad (1\text{ a})$$

$$g_e=\frac{a_e\cot\sqrt{2}\,\Phi_e}{\sqrt{2}}=-\frac{a_e}{\sqrt{6}}\,, \qquad (1\text{ b})$$

uniform magnetic field

$$(l'-g')(l''-g'')=f^2 \qquad (2)$$

$$g'=a\frac{\cos\varepsilon'\cos(\Phi-\varepsilon'')}{\sin(\Phi-\varepsilon'-\varepsilon'')}=\frac{a}{\sqrt{3}} \qquad (2\text{ a})$$

$$g''=a\frac{\cos\varepsilon''\cos(\Phi-\varepsilon')}{\sin(\Phi-\varepsilon'-\varepsilon'')}$$

$$=\frac{2}{\sqrt{3}}a\cos\varepsilon''\cos\left(\frac{\pi}{3}+\varepsilon''\right) \qquad (2\text{ b})$$

$$f=a\frac{\cos\varepsilon'\cos\varepsilon''}{\sin(\Phi-\varepsilon'-\varepsilon'')}=\frac{2}{\sqrt{3}}a\cos\varepsilon''. \qquad (2\text{ c})$$

In the case when the arrangement of the both fields is in tandem as shown in Fig. 2, the image by the electric field is also the source of the magnetic field in itself, that is,

$$l'=\Delta-l_e''=\Delta=1200\text{ mm}\,.$$

The ion beam having a small velocity difference can be focused by the combination of the electric and magnetic fields, and the distance between the pole edge of the magnetic field and the velocity focusing point, $X''$, is given by the following relation:

$$X''=g''+\frac{f^2}{X'-g'} \qquad (3)$$

$$X'=\frac{-B+a(1-\cos\Phi)}{C-\sin\Phi-\tan\varepsilon'(1-\cos\Phi)}$$

$$=\frac{-B+a(1-\cos\Phi)}{C-\sin\Phi} \qquad (3\text{ a})$$

$$B=\Delta\sqrt{2}\sin\sqrt{2}\,\Phi_e+a_e(1-\cos\sqrt{2}\,\Phi_e)$$

$$=\frac{\sqrt{6}}{2}\Delta+\frac{3}{2}a_e \qquad (3\text{ b})$$

$$C=-\sqrt{2}\sin\sqrt{2}\,\Phi_e=-\frac{\sqrt{6}}{2} \qquad (3\text{ c})$$

The double focusing condition, which makes the velocity focus and the direction focus coincide at one point, is given by

$$a_e\left(1+\frac{l_e''-g_e}{f_e}\right)=a(1-\cos\Phi)$$
$$-l'[\sin\Phi+\tan\varepsilon'(1-\cos\Phi)]\,. \quad (4)$$

In order to hold the double focusing condition in the case of $a=a_m$, the radius of the electric field, $a_e$, must be 1093 mm, and $l_e'$ is determined to be $1.225\,a_e=1340$ mm from eq (1), and the distance between the magnet pole edge and the double focusing point is calculated to be 4480 mm.

In the case of mass spectrograph, mass spectra must be taken on the photographic plate and it is desirable to set the photographic plate along the focal plane. From the relations described above, both directional and velocity focal planes may be calculated by changing radius $a$ in the magnetic field and are shown in Fig. 3. The angle between the ion beam and the directional, and velocity, focal plane is proved to be $\theta_d=17°$ and $\theta_v=21°$ respectively. Each plane lies along almost straight line in the region of several ten centimeters at both sides the double focusing point and they intersect with an angle of about 4°.

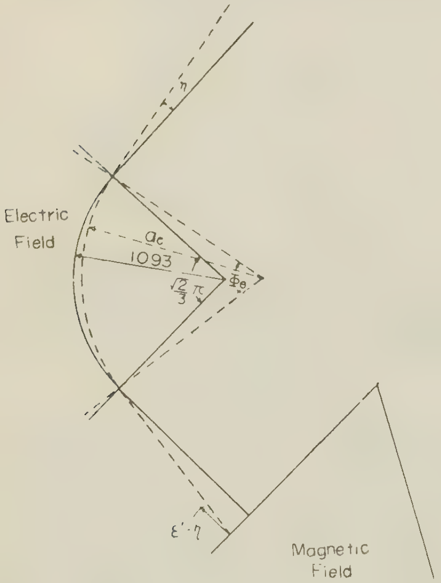

Fig. 4. Relation between $\eta$, $a_e$ and $\Phi_e$.

The resolving power $R$ is given by the relation:

$$R=\frac{a_e}{2s}\left(1+\frac{l_e'-g_e}{f_e}\right)=\frac{3}{2}\frac{a_e}{s}\,,$$

where $s$ is the width of the source slit. A resolving power of 550,000 is expected in the case of $s=0.003$ mm. The width of the final image, $2b''$, is calculated to be

$$2b''=\left|\frac{f}{g'-l'}\cdot\frac{f_e}{l_e'-g_e}\cdot s\right|=1.37\,s$$

and when the photographic plate is located along the directional focal plane, the image width on the plate is expected to be $1.37\,s$ cosec $17°=4.66\,s$, that is about 4.5 times as large as the initial slit width. The mass dispersion for 1% mass difference may prove to be 76 mm in this case.

The convergent angle $\alpha''$ after the beam leaves the magnet is calulated to be

$$\tan\alpha''=0.732\,\alpha+0.866\,\beta$$

where $\alpha$ is the divergent angle at the source and $\beta$ is defined by the relation $v=v_0(1+\beta)$ where $v$ is the velocity of the ion. In the case of $\alpha=1/2000$, which corresponds to the slit width of 1.37 mm at the entrance of the electric field, the increase of the image width on the photographic plate may be estimated to be 0.034 mm by 1 cm deviation from the direction focusing point, and in the case $\beta=1/2000$, corresponding to the slit width of 2.2 mm at the exit of the electric field, the increase is about 0.04 mm. In order to keep the breadth of the image not to exceed 0.01 mm in the region about 20 cm long on the photographic plate which is located through double focusing point, $\beta$ must be chosen to be smaller than 1/8000 if the plate is just on the directional focal plane, and the deviation of the plate from the direction focal plane has to be smaller than 3 mm along the beam direction if $\alpha=1/2000$. These conditions are rather rigorous in the actual adjustment but not impossible.

## § 3. The Shift of the Double Focusing Point due to the Change of the Position of Source

Let us consider the deviation of the focal plane when the position of the source is changed while the positions of the electric and magnetic fields are unchanged. Consider a beam entering into the electric field with the incident angle $\eta$ but at the same position and going out from the same point of the exit as shown in Fig. 2. These relations are shown in Fig. 4. Assume that this beam goes through the electric field along a circular orbit and that the electrostatic force acting on the ion is towards the center of the circle. These assumptions may be considered to be reliable if the angle $\eta$ is not so large. In this case the deflection angle in the electric field, $\Phi_e$, and the radius $a_e$ is given as follows:

$$\Phi_e=\frac{\sqrt{2}}{3}\pi-2\eta\ ,$$

$$a_e=\frac{1093\sin(\pi/3\sqrt{2})}{\sin((\pi/3\sqrt{2})-\eta)}\ \mathrm{mm}\ .$$

This beam enters into the magnetic field with the angle $\varepsilon'=\eta$ at the position $1200(1+\tan\eta)$ mm apart from the apex, so that the following values are given concerning the magnetic field:

$$a_m=1200(1+\tan\eta)\,\mathrm{mm}\ ,$$

$$\Delta=\frac{1200}{\cos\varepsilon'}\ \mathrm{mm}\ ,$$

$$\varepsilon'=\eta\ ,$$

$$l'=\frac{1200}{\cos\varepsilon'}\ \mathrm{mm}-l_e''\ .$$

$l_e''$ is no longer zero though $l_e'$ maintains the same value of 1340 mm as before. The values $l''$ and $X''$ can now be calculated by the eqs. (2), (3). Fig. 3 shows the focal planes with various values of $\eta$, keeping the distance $l_e'$ constant (1340 mm). It must be noted that the position of the double focusing point can be adjusted by changing $\eta$, that is, by adjusting the position of source along the direction perpendicular to the berm direction. The deviation of $l_e'$ causes a change in the direction focusing ponit, but no change in the velocity focal plane. The change of 5 mm in $l_e'$ causes about 10 mm change in $l''$. The adjustment of the double focusing point can also be achieved by changing $l_e'$.

## § 4. The Effect due to the Fringing Field and the Deviation of the Dimensions

In the discussions described above, the calculations are all based on the assumption that the field is sharply cut off at the boundary of the field region. On the other hand, in the actual case, there exists a fringing field near the boundary which changes gradually from the maximum constant value to zero. To discuss the focusing properties, this effect must be considered.

In the cylindrical electric field, the effect by the fringing field causes a change in the deflection angle $\Phi_e$ and other lens constants, the magnitude of which depends on the shape and size of the earth plate placed near the edge of the condenser electrodes⁷⁾, so that the effect can be adjusted by changing its shape. In our case, the structure of the electrodes near the edge of the cylindrical electric field is as shown in Fig. 5. According to Herzog's calculation, the effective boundary of the electric field may be changed from $\xi=0$ to $\xi=-3$ mm, $\xi$ being the distance from the edge of the condenser electrode to the effective boundary, by changing the slit-width $2b$ from $b=10$ mm to $b=3$ mm.

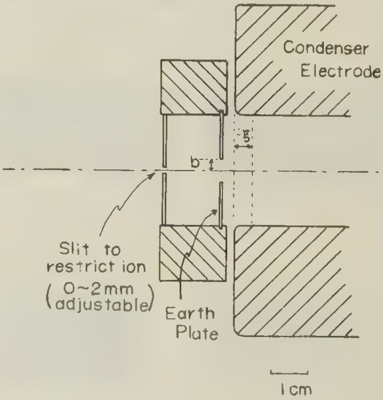

Fig. 5. Structure of the electrodes near the edge of the electric field.

In the uniform magnetic field, the effect due to the fringing field is considered as follows. Consider a beam entering into the uniform field region through the fringing field. The focusing action due to the magnetic field which has two parallel boundaries may be considered to be zero on the median plane independently of the field strength, because $\Phi-\varepsilon'-\varepsilon''=\Phi_m$ in eq (2) is zero. Therefore there is no focusing action in the fringing field so long as the strength of it is uniform along the direction parallel to the magnet edge. The fringing field causes only the deflection of ion beam and the displacement of the entrance point into the uniform field region. The deflection in the fringing field causes a change in the incident angle, $\varepsilon'$, to the uniform field region. This gives also a change in the lens constants $g'$, $g''$, $f$ in eq (2). The change in $\varepsilon'$, denoted by $\delta\varepsilon'$, is calculated to be⁸⁾⁹⁾¹⁰⁾

$$\tan\delta\varepsilon'=\frac{d}{(a^2-d^2)^{1/2}}\ ,$$

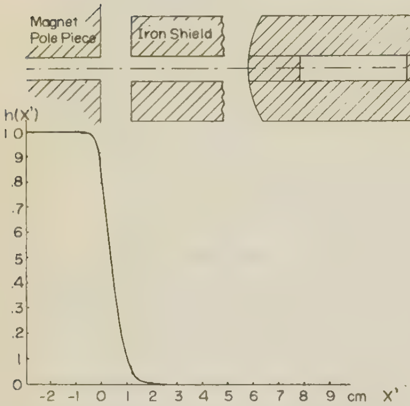

Fig. 6. Dimension of the magnetic shield and value of $h(X')$.

$$d=\int_{X'=l'}^{X'=-1} h(X')dX'-1\ ,$$

$$\int h(X')dX'=\int \frac{\mathrm{H}(X')}{\mathrm{H}_0}dX'\ .$$

where $\mathrm{H}_0$ is the field stregth of the uniform field region and $\mathrm{H}(X')$ the field strength of the fringing field at the position $X'$, and $X$ is measured by the gap width of the magnet in this formula. The distance from the apex of the magnetic field to the entrance point at $X'=0$ is given by $a_m'$ and is

$$a_m'=a_m\int_{l'}^{0}\frac{\int_{l'}^{X'} h(X')dX'}{\left[a^2-\left\{\int_{l'}^{X'} h(X')dX'\right\}^2\right]^{1/2}}dX'\ .$$

The same effect may exist at the exit from the magnetic field too. The value of $h(X')$ may be determined experimentally by measuring the fringing field distribution, and $\int h(X')dX'$ by using a planimeter from the curve of $h(X')$.

The fringing field effect can be decreased by a considerable amount if a suitable magnetic shield is placed near the edge of the megnetic field. The dimension of the magnetic shield placed near the both edges of the magnet of the large mass spectrograph is shown in Fig. 6 with the measured value of $h(X')$. In this case the shift in $a_m$ is almost negligible so that it may be allowable to put $a_m'=a_m$. The value of $d$ is estimated to be about 5 mm from the curve, and the gap width is 9 mm in this case. The focal plane can now be calculated in consideration of the effect due to the fringing field. For simplicity the deflection angle $\Phi_e$ in the electric field is considered to be unchanged by the adjustment of $b$ in Fig. 5. The focal planes thus obtained are shown in Fig. 3 with various positions of source as before.

In the actual case of the large mass spectrograph, the focal plane determined experimentally differs very much from this. The distance from the magnet pole edge to the focal point obtained experimentally is about

30 cm longer than that calculated. This fact may be considered to be due to the effect that the effective edge of the magnetic field due to the fringing field has a curvature. This causes a change in $\mathcal{E}'$ and $\mathcal{E}''$ so that the focal point is shifted by a considerable amount. The deviations of $l''$ and $X''$ from the ideal case, $a=1200$ mm, $\varPhi=\pi/3$, are shown in Table I referring to the various values of $\mathcal{E}'$ and $\mathcal{E}''$. From this, if the effective edge has a curvature of radius ~1 m and the direction of entering ion beam has a distance of ~1 cm from the center of curvature, the shift of focal point may be estimated to be about 30 cm. This effect is more serious to the velocity focus. The fact that the effective edge of the magnetic field has a curvature is likely to happen because of the finite size of the pole piece. The effect due to the change of the position of source described in § 3 becomes much larger in this case.

The effect due to the deviation of $\varDelta$ and $\varPhi_e$, keeping other values to be constant, are shown in Table II and Table III respectively. These results show that if $\varDelta$ or $\varPhi_e$ is made to be large, the focusing point has a tendency to approach to the magnet.

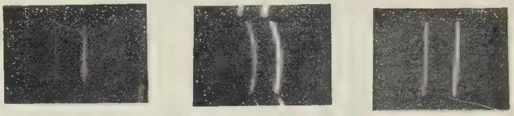
| $\varPhi_e$ | 1.47296 | 1.47696 | 1.48096 ($\sqrt{2}\pi/3$) | 1.48496 |
|---|---|---|---|---|
| $\xi$ | −4.3 | −2.2 | 0 | +2.2 mm |
| deviation of $X''$ | +20 | +10 | 0 | −10 mm |
| deviation of $l''$ | +26 | +12 | 0 | −12 mm |

## § 5. The Comparison with the Experiment

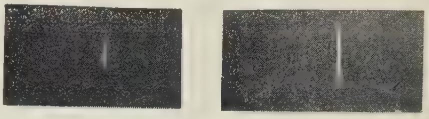
In the actual case, many quantities such as $a$, $\varPhi$, $\mathcal{E}'$, etc. are not able to be known precisely and can only be estimated. However, the tendency of the shift of focal plane by the change of various conditions is expected from the theoretical calculation and nearly coincide with the experiment.

The effect due to the fringing field is most important. This gives the influence not only to the change in the focusing point but also to the shape of the image. When the fringing field of the magnet has field components other than $z$-component perpendicular to the ion beam, the image on the photographic plate may be curved. In Fig. 7, some of these examples are shown: (a) is the image when ion beam is passed through near the center of the magnetic shield, (b) is the image when it is passed through near the side wall, and (c) is the image without the magnetic shield. The image is not curved in (a), but curved in (b) and (c). In the case of (c) the fringing field may be disturbed by the iron pipe placed near the magnet to obtain vacuum. The effect shown in Fig. 7 (b) is not appreciable if the ion beam passes through the region apart from the side wall by more than gap width of the magnetic shield.



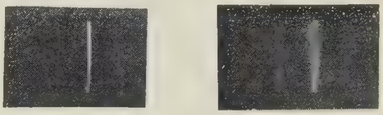
(a) (b) (c)

Fig. 7. Examples of the effect of the fringing field to the shape of the image.



(a) diameter: 0.7 mm (b) diameter: 1 mm

Fig. 8. Examples of the image distorted when the entrance slit of the electric field is a hole.



(a) slit position is good (b) not good

Fig. 9. Example of distorted image.

The local electric field near the slit placed at the entrance or the exit of the electric field gives a influence to the image. Fig. 8 shows the image in the case that the entrance slit of the electric field is a hole in a metal plate; the image is distorted in both up and down sides. Fig. 9 shows the distortion of image when a long slit (long along the direction perpendicular to the electric force line) is shifted to the radial direction. So the slit which restricts the breadth of ion beam is placed in the field free region and another wide slit is placed near the electrodes to cut off the electric field as shown in Fig. 5.

The effect due to the change of the position of source is rather larger than that the calculation described in § 3 predicts. This fact may be considered to be caused by the curved effective edge of the magnetic field. The radius of curvature is estimated to be 50~100 cm from the experimental procedure. For the beam passed near the side wall of the magnetic shield, the experimental focal plane was seriously curved and this suggest that the curvature is large near the side of the shield and this is plausible. This region can not be used too by the effect to the shape of image as described above. The adjustment of the position of source is also useful for the purpose to hold the ion beam in the desirable region of the magnetic shield.

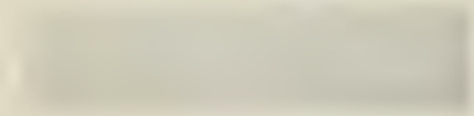


Fig. 10. $N_2^{14}-C^{12}O$ doublet.

Doublets were shifted by changing the potential between the energy selectrodes. The base potential (doublet 1) was 1350.40 volts and each shift (doublet 2-7) was made by successive addition of 2.03670 volts. During the whole exposure the magnetic and electric fields were kept constant within a change of less than $10^{-6}$. From this, a value of $112.441 \pm 0.019$ ($10^{-4}$ amu) was obtained as the doublet mass difference.

In our case, the length $l''$ and $X''$ obtained experimentally was much longer than that expected. This fact may be considered to be due to large $a$ and $\varepsilon'$. However, a large $l''$ (or $X''$) is desirable to have a large mass dispersion, so that the distance was made as long as possible. On the other hand, the distance from the exit of the magnetic field to the photographic plate is restricted by the floor space of the laboratory, that is, $X''$ can not be made too large. Therefore, the distance $\Delta$ was elongated in order to maintain $X''$ within a desirable length, and the adjustment to obtain double focusing point on the photographic plate was made by changing the position of source. In the final geometry by which the sharpest image was obtained, the values of $l_e'$, $\Delta$, and $l''(X'')$ were 132 cm, 124 cm, and 490 cm respectively. In this case other values of the focal quantities are estimated to be as follows:

$$a \sim 1220 \text{ mm} ,$$

$$\Phi \sim \frac{\pi}{3} ,$$

$$\varepsilon' \sim 0.02 ,$$

$$\eta \sim 0.01 .$$

The angle between the direction of ion beam and the photographic plate was about 16° and the plate was located nearly along the direction focal plane.

The image width of about 0.02 mm was obtained by photographing the $N_2^{14}-C^{12}O^{16}$ doublet, and this corresponds to a resolving power of about 500,000. In this case the width of the slit placed near the entrance and exit of the electric field was both 0.4 mm, and this corresponds to $\alpha = 1/6600$, and $\beta = 1/11000$ respectively. For this value of $\alpha$ and $\beta$, the second order aberration is almost negligible. The main slit width $s$ was about 0.002 mm and the image width on the photographic plate that is expected theoretically is calculated to be $5.6s = 0.011$ mm. The broadening of the image may be due to the instability of the magnetic field and the scattering effect of ions by the residual gas in the vacuum chamber. The mass dispersion was estimated to be about 9 cm for 1% mass difference and almost coincide to the value obtained graphically. The photograph of the $N_2^{14}-C^{12}O^{16}$ doublet is shown in Fig. 10.

## § 6. Conclusion

The final dimension of the large mass spectrograph differed from the initial design by a considerable amount but it was not too large, It proved that the large mass spectrograph has a experimental resolving power and mass dispersion nearly expected.

The calculation of the fundamental characteristics of the apparatus and of the focal planes based upon the Herzog's analysis is very useful for the initial design and for experimental procedure of the adjustment. The calculation gives the knowledge about the tendency of the shift of the focusing point due to the change of various focusing conditions.

At any rate, the focusing points exists if the fields and focusing conditions are good. In order to place the double focusing point to a desirable place, there may be many possibilities of methods by changing some of the focal quantities. Especially the adjustment by the change of the position of source is useful for this purpose. The calculation of the focal plane in the case of these variations gives a knowledge about focusing properties and suggest how to proceed the experiment. The fringing fields give serious effects to the focusing properties, so that the treatment must be prudent.

# On the Analysis of the Slow Particles Emitted from Cosmic-Ray Stars (I)

By Shigeo NAKAGAWA, Eiji TAMAI, Humiaki HUZITA
and Kiyoaki OKUDAIRA

*Department of Physics, Rikkyo (St. Paul's) University,*
*Ikebukuro, Tokyo, Japan*

An analysis of the nature of tracks of the stars ending in the G5 emulsion was made by measuring their width (diameter). Six groups of tracks having different width were observed. We identified two of these groups as that of $\alpha$ particles and Li nuclei by comparing their width with those of $\alpha$ particles emitted from radiothorium stars and with those of hammer tracks. As for the more thicker tracks, the charge determination on the tracks of each group was made by measuring their thin-down lengths. These measurements seem to indicate that the width of track was approximately proportional to $\sqrt{Z}$ ($Z$: atomic number).

The energy and the angular distribution of each group were also examined. The curves of the energy distribution of protons and $\alpha$ particles approximately agreed with those deduced from the evaporation model, assuming the appropriate nuclear temperature and Coulomb barrier height. The angular distributions of these were nearly isotropic. It was noted that the number of slower $\alpha$ particles measured seems to be considerably larger than that deduced from theory.

## § 1. Introduction

Charges of particles stopped in the nuclear emulsion usually have been identified by the following methods of measuring[1]:

(i) $\delta$ ray frequency
(ii) $\delta$ ray cut off length
(iii) gap density
(iv) thin-down length

As methods (i), (ii), and (iii) need comparatively long tracks, they do not seem to be suitable

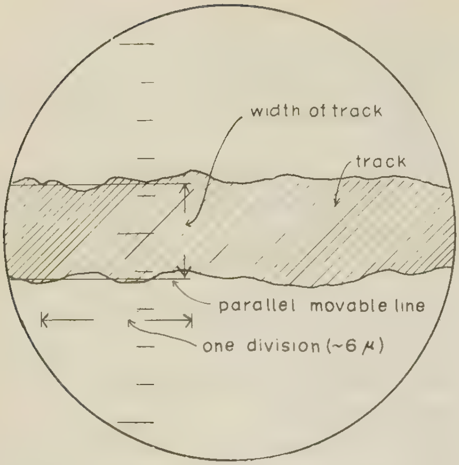

Fig. 1. Eyepiece with screw micrometer.

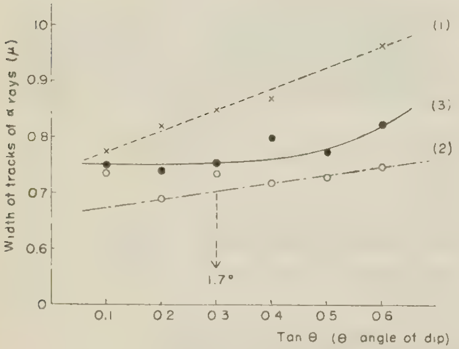

Fig. 2. Width of tracks of α rays from radiothorium stars (Number of curve indicates the region of location of the tracks;
(1) 0→20 μ from the surface
(2) 0→20 μ above the bottom
(3) between (1) and (2).)

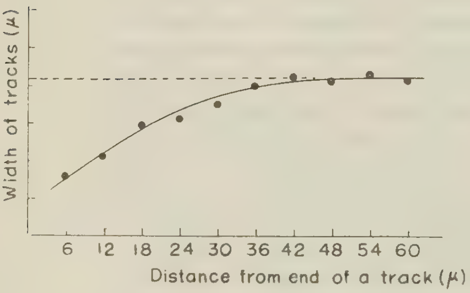

Fig. 3. Width of each division along a track.

for analysing short tracks. The fourth method also is not suitable to analyse tracks of comparatively low charged particles.

It is well known that as the velocity of the charged particles decreases passing through the emulsion, energies of δ rays emitted by it decrease also, while their density increases. When the velocity of the particle decreases to some extent and the density of δ rays becomes very large, their individual tracks can not be separated. For this reason, the width of the track increases, and this width varies with energies of δ rays.

Lonchamp[2)] examined the relationship between slow δ rays and the width of the tracks. In the present analysis we have examined also the width of tracks of stars to determine the nature of the particles which are emitted by disintegration of Ag or Br nuclei contained in the emulsion by cosmic rays.

The G5 emulsions 400 μ and 600 μ thick were exposed to cosmic rays at high altitude (25,000∼30,000 *m*) and the tracks in the emulsion were measured by the microscope with eyepiece micrometer. It was found that these tracks can be classified into six groups according to their width, and that the width of track was approximately proportional to $\sqrt{Z}$ ($Z$: atomic number).

## § 2. Experimental Procedure

The width of track is generally not uniform on account of clogging, so the mean width over 6 μ lengths was measured step by step along the track from its end point using an eyepiece with screw micrometer as shown in Fig. 1. In order to test whether the width may vary in the difierent layers of the same emulsion, the track widths of α particles from radiothorium stars located in all parts of the emulsion were measured. The results are shown in Fig. 2. It is shown in Fig. 2 that α ray tracks located between 20 μ and 380 μ (400 μ thick emulsion) or 580 μ (600 μ thick emulsion) from the surface of the emulsion have nearly the same width, provided that their angles of dip are less than 17°.

According to above results, the prongs which were selected to analyse were from among those which terminated in the emulsion, which were located more than 20 μ appart from the surface and from the bottom of the emulsion, and which lay within 17° of the angle of dip before processing. Moreover, since it was the intension to analyse stars from heavy nuclei (Ag or Br) contained in the emulsion, stars which had more than 9 prongs (grey tracks + black tracks) were selected.

An example of the measured width along a track is showed in Fig. 3. The curve shows a flat portion, the ordinate of which was designated as the width of the track. The ordinate of each track was measured, and the tracks were then classified. That is, the tracks which had nearly the same value of ordinate were considered as belonging to one group. The width of the tracks belonging to any one group definitely differed from that of the tracks belonging to any other group. The curves in Fig. 4 show the mean width of the tracks which belong to each group, at each 6 $\mu$ division along the tracks.

## § 3. Identification of Prongs

It is shown in Fig. 4 that all prongs are classified into six groups. The mean width of tracks which belong to the second and third groups amounts to 0.77 $\mu$ and 0.94 $\mu$ respectively. The former value agrees fairly well with 0.75 $\mu$ obtained from the width of forty-five $\alpha$ particle tracks from radiothorium stars contained in the emulsion, and the latter with 0.94 $\mu$ obtained from seven $Li^8$ tracks, known as hammer tracks. It seems to be possible to conclude that particles which belong to the second group have charge two, and those which belong to the third group have charge three. Hence, the particles of the first group may have charge one.

As for the particles of another groups, there was no direct method to identify them; but from the measurement of their thindown lengths, it seems to be probable that they have charge four, five, and six, respectively. Fig. 5 shows the relation between the thin-down lengths and the charges of the particles. Some more thicker tracks were observed. However, they showed steeper dip angles than 17°, therefore we have not made any further analysis. In Table I, the ratios of the width of each group to the width of the first group were compared with the ratios of $\sqrt{Z}$ ($Z$: atomic number). This comparison indicates that the width of tracks are approximately proportional to $\sqrt{Z}$. In Fig. 5, the thin-down track lengths are also shown to be approximately proportional to $Z$. Thus, the results of our experiment show same tendency with those of Hoang Tchang-Fong[3]. In addition, especially the longer tracks of lower charged particles were roughly examined by counting gap number, and the results of both measurements (width and gap) agreed well.

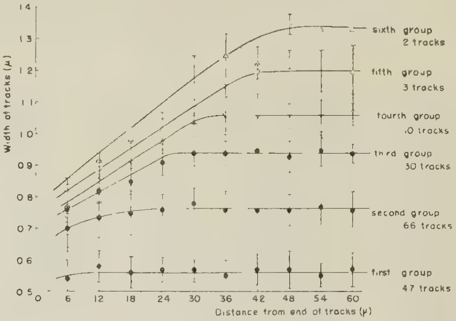

Fig. 4. Curves showing mean width of tracks belonging to each group, at each division along tracks.

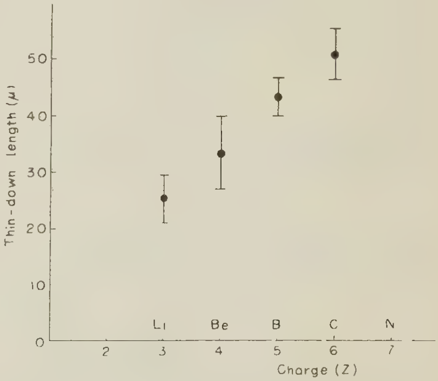

Fig. 5. Thin-down length versus charge of particle.

## § 4. Energy Distribution and Angular Distribution

The energies of tracks above analysed were obtained by measuring their ranges, and their energy distribution was examined. The energy distribution of a singly-charged group (proton group) is shown in Fig. 6. In this figure, the distribution in the higher energy region is not certain in as much as only tracks which stopped in the emulsion were selected. The full curve shows the calculated evaporation distribution, assuming that the mean temperature is 3 MeV and the mean Coulomb potential is 5 MeV. Fig. 7 shows the energy distribution histogram of particles of charge $Z=2$ with the curve calculated from the evaporation theory. The statistics are not adequate for describing the energy distribution of particles of charge $Z \geqq 3$.

To obtain the angular distributions of particles of each group, stars were selected in which the direction of incident particles was accurately observed. The results are presented

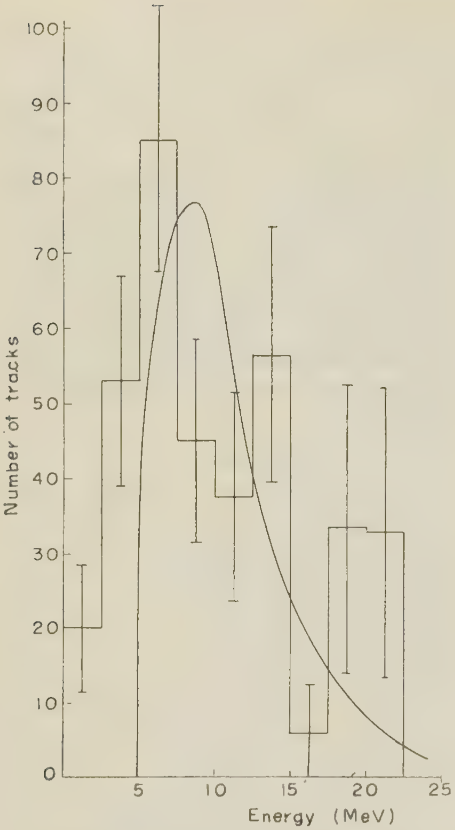

Fig. 6. Energy distribution of protons.
(Full curve was obtained from evaporation formula by assuming Coulomb barrier height 5 MeV and mean nuclear temperature 3 MeV.)

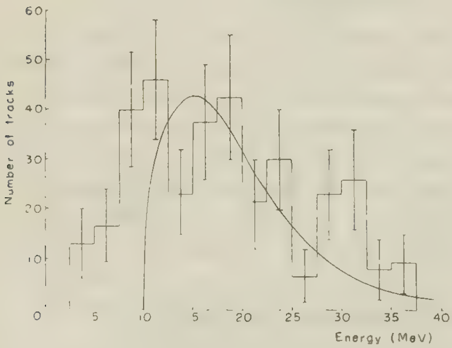

Fig. 7. Energy distribution of $\alpha$ particles.
(Curve: Coulomb barrier height—10 MeV, mean nuclear temperature—5 MeV).

in Figs. 8 and 9. In Figs. 8 and 9 are shown the angular distribution of protons and of $\alpha$ particles respectively. They show approximately isotropic distribution. As the measured number of the particles of charge $Z \geqq 3$ is comparatively small, we are now accumulating more data.

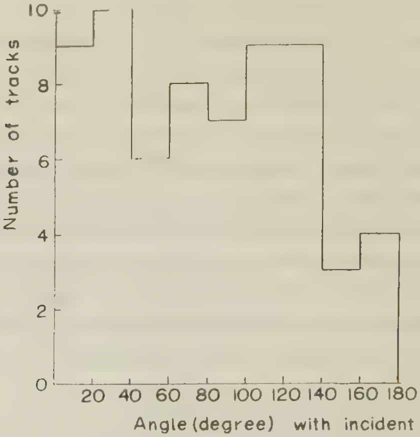

Fig. 8. Angular distribution of protons.

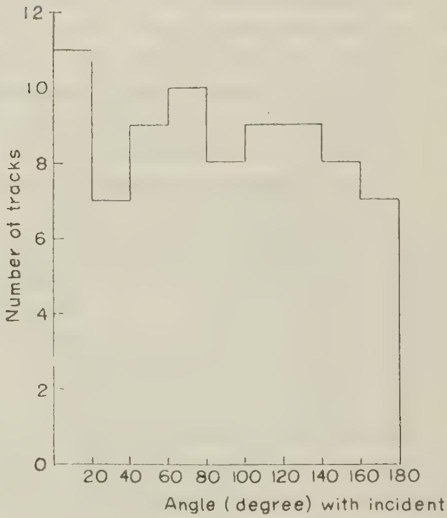

Fig. 9. Angular distribution of $\alpha$ particles.

Table 1.

| | group | width ($\mu$) | ratio of width | ratio of $\sqrt{Z}$ |
|---|---|---|---|---|
| 1 | first group | 0.55 | 1 | 1 |
| 2 | second group | 0.77 | 1.40 | 1.41 |
| 3 | third group | 0.94 | 1.72 | 1.73 |
| 4 | fourth group | 1.06 | 1.93 | 2 |
| 5 | fifth group | 1.2 | 2.18 | 2.23 |
| 6 | sixth group | 1.34 | 2.44 | 2.45 |

The measured energy spectra of protons and $\alpha$ particles nearly agree with those calculated, assuming the mean Coulomb barrier height V and the mean nuclear temperature T; although, on account of poor statistics, the excitation energies and potential barrier could not be analysed more precisely by classifying the star size.

In addition to the spectra, the angular distributions of these particles are nearly isotropic as mentioned above, so the mechanism of emission of particles may be mainly due to the evaporation process. In Fig. 7, however, it is shown that the number of slow $\alpha$ particles from heavy nuclei is considerably larger than expected by the evaporation process, as was reported by Harding, Lattimore and Perkins[4]. Therefore, the authors are now accumulating more data on these and also on heavy particles.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 11, No. 3, MARCH, 1956

# A High Pressure Cloud Chamber for Cosmic Ray Observation

By Saburo MIYAKE

*Institute of Polytechnics, Osaka City University*

(Received July 29, 1955)

A high pressure cloud chamber (50 cm in dia, 20 cm deep and used at 150 atm.) was built in the summer of 1952. The cloud chamber can be operated automatically by counter control with a recycling time of about 20 minutes. It was filled with 5.6 kg of nitrogen or 8 kg of argon gas in its illuminated space of about 30 litres, and it became much easier to observe some cosmic ray phenomena especially those events occuring in the gas nuclei in comparison with observations using the smaller type chamber (25 cm in dia, 7 cm deep and used at 100 atm.) which has been used previously.

## §1. Introduction

Observations using a high pressure cloud chamber are similar to those with photographic emulsions in a sense, although the density of the matter of the former case is about 1/15 of that in the latter. The chamber has the following advantages; there is a relatively larger mass of sensitive matter, the matter is simple, and the instrument may be controlled with the counters in the same manner of normal pressure cloud chamber.

To date, several high pressure cloud chambers have been constructed[1], and some of them have been used for cosmic ray observation recently. In an earlier paper (hereafter cited as "A") the smaller high pressure cloud chamber (25 cm in dia and 7 cm deep and used at 100 atm.) was reported in detail, and some experiments[2] were done with this equipment. It seemed too small, however, for investigating some important cosmic ray phenomena, especially hard showers produced in the gas. The large size chamber was therefore planned, expecting the following advantages;

(1) A long sensitive time (about 2–3 sec) and a mass of inner gas of about 5.6 kg for nitrogen and 8 kg for argon. These properties mean, for random expansions, that the efficiency is about 20 times as large as that for the small chamber.

(2) An increased number of events, occuring in the gas space, is favourable for the study of rare events.

(3) An increase in the stopping power, the multiple scattering angles and the number of knock-on electrons permit better estimation of the energy, mass etc.

On the otherh and, there are some disadvantages.

(1) A long recovering time is required for thermal equilibrium and uniform vapour distribution. It is about 20 minutes in this case.

(2) The thick metal wall of the chamber acts as the producer or the absorber of cosmic ray phenomena.

(3) The technical difficulties and the heavy weight of the equipment are not convenient.

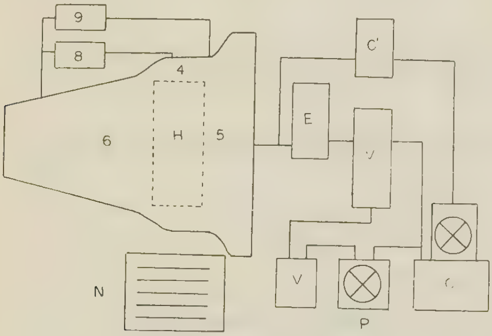

Fig. 1. Block diagram.

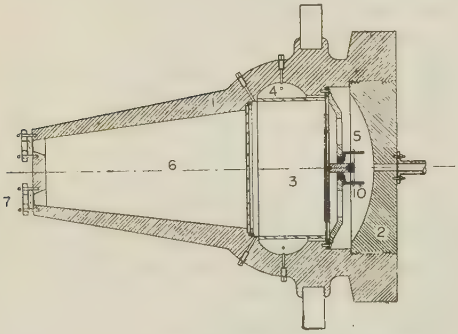

Fig. 2. Crosse Section (harizontal).

## §2. The Main Body of the Chamber

In the design of the chamber, the following conditions were considered;

(1) The weight of each separate piece of the chamber must not be more than about 2 tons for the purpose of transport to the mountain site.

(2) The volume of the chamber should be as large as possible, subject, of course, to limitations of the weight and the cost.

(3) The construction and handling should be simple.

(4) The illumination in the chamber must be kept uniform. The method of illumination is the same as that used in the former chamber, but more light is necessary. It was also desired to increase the transparency of the liquids through which light must pass.

Fig. 1 shows the block diagram of the main parts, H is the main body of the chamber, E is the expansion valve, V is the expansion vessel, P is the vacuum pump to pump the oil from the expansion vessel, C is the high pressure oil compressor and N is the multiplate cloud chamber to study the secondary particles from the upper chamber (sometimes a counter hodoscope is used for this purpose.)

Fig. 2 shows the cross section of main body of the cloud chamber. 1 is an iron case (pressure tight). It was made from cast steel of $17\ \mathrm{kg/mm^2}$ ultimate strength. 2 is a back plate, which was made from the same material and was set in the case 1 by a 1.4 cm pitch triangular saw-shaped screw. 3 is the cloud chamber space 50 cm in dia and 25 cm in deep. It is surrounded by the front glass, a glass cylinder and the back piston. The back piston is a rubber sheet sandwiched by aluminum plates, and held by its shaft as it moves in the axial direction. 10 is a slide rheostat which forms one arm of a bridge circuit so that the position of the piston can be shown from the out side. 5 is an oil space which is filled by ordinary spindle oil. At the expansion a part of this oil is allowed to flow into the expansion vessel. 6 is a water space, it is filled with transparent water of about 80 liters. Its inside surface is all painted with black vinyl paint to prevent corossion and rust. 5 to 10 g of NaOH was added to the water to clear it and to protect further colourization by iron rust. 7 is a glass window to permit photography. The diameter of this window is 4 cm and tempered glass of 2 cm thickness was put with steel fringe by bolts and nuts from the outside. The rubber gasket is used to protect the glass plate and made a leakproof seal.

8 and 9 are pressure balancers which balance the pressures between the water space 6, the

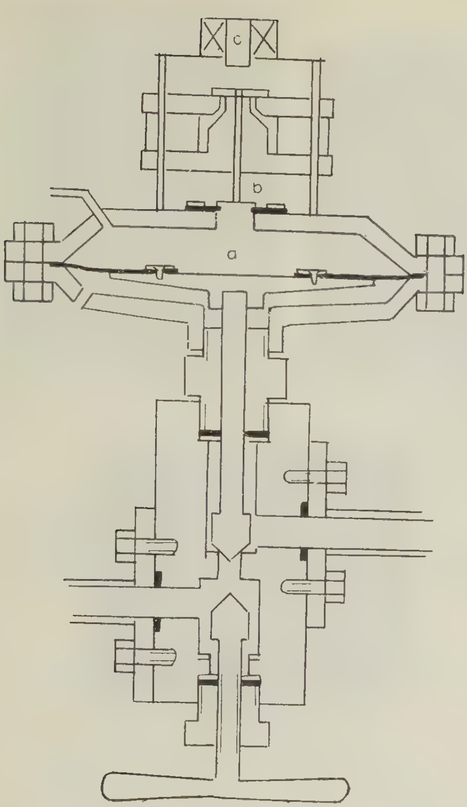

Fig. 3. Expansion valve.

light space 4 and the oil space 5 respectively. These are the vessels in which the boundaries between the water, the transparent oil and the oil of back space are separated by soft vinyl bags, and even at the fast expansion, pressures of spaces are reduced equally.

4 is the space for the light source, surrounding the cloud chamber. The iron wall is a nickel-plated parabolic mirror of 4 cm focal length. The circular flash lamp was set at the circular focal line, and the flash lamp surface facing the chamber was silvered to prevent direct illumination.

## § 3. Auxiliary Equipments

Fig. 3 shows an expansion valve. “a” is a compressed air space (about 2 atm.). The oil valve is closed by a force of about 400 kg. b is an air valve to reduce the pressure in “a” operated by a permanent magnet and demagnetizing coils as is usually done with chamber valves. The electro-magnet, c, keeps the valve open for about 2 sec. The hand valve, d, also adjusts the expansion velocities.

Fig. 4 shows the expansion vessel, the total volume of which is about 12 litres. The effective volume is varied by moving the center pipe, which has a check valve, at the top.

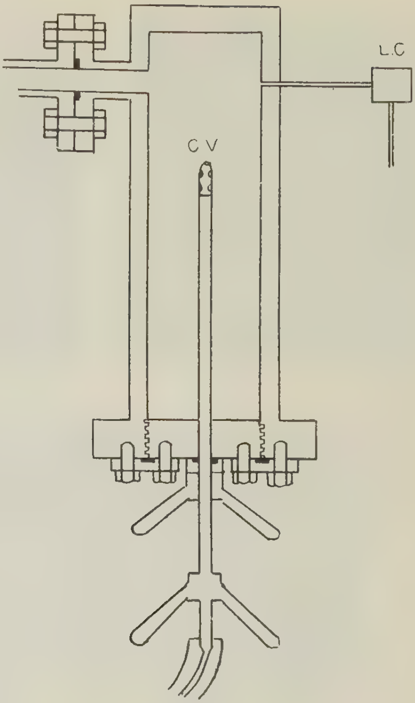

Fig. 4 Expansion vessel.

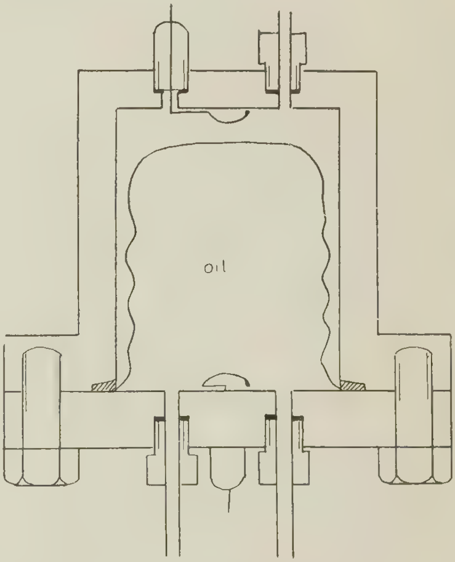

Fig. 5. High pressure oil tank.

The operation is as follows: fist, the entire space of the expansion vessel is filled with oil by an expansion of the cloud chamber and the check valve is, then, closed. After closing the expansion valve, the leak cock is opened and the pressure is reduced. Then the check valve is opened and oil is pumped out toward a vacuum pump until the oil level has gone down to the position of the check valve. The oil flows into the oil reservoir, b, and is pumped out slowly through a capillary tube. Most of the dust in the oil is deposited in the reservoir.

The oil compressor is driven by a 2 H.P. motor. The compressor has a capacity of 2 L/min. at 150 atm., the maximum available pressuae being about 300 atm. When the chamber is expanded, about 6–7 litres of the oil flow out. The time for pushing the chamber piston to the normal position is about 3 minutes. In order to shorten this time, the apparatus shown in Fig. 5 is used. Oil is stored in the vinyl bag at a pressure higher than that in the chamber the top relay being closed. The oil is pushed into the chamber by opening the valve (a valve similar to that of expansion valve). A gas tank of about 50 litres was used as the high pressure air reservoir to push the oil towards the chamber.

Two semicircular flash lamps are set along the focal line of the circular parabolic mirror. These are made by glass pipes of 4 mm inner diameter and 2 mm thickness. The aperture of the parabolic mirror is 18 cm of which about 15 cm is uniformly illuminated. Frequently the chamber is used without the glass cylinder. A circular solar silt is then used to avoid illumining the back plate. The electrical source for each lamp is 100 mf. condensors charged to 3000 volts. One of the electric leads is described in A, and the other leads are spark plugs of the common type for the gasonline engine. After a pressure test at 300 atm. they are painted to make them leak proof.

The gas cocks and oil cocks are not of special type, but the parts, connected to the chamber directly, are designed to have small gas spaces.

Sometimes, counters are set in the chamber for the purpose of triggering the chamber in favor of the showers which start in the gas. Glass tube counters of 2 cm diameter are used for this purpose. The end of the counter is carefully made in a spherical shape and these are used after the test up to 200 atm.

The main body is supported by its side shaft on a wooden rack and the entire assembly can be rotated by a chain block. The assembly of the chamber is done in a vertical position. Finally the back plate, held by a chain block, is screwed into the main body, and the whole assembly is rotated to a horizontal position. This work is done easily by two men. After that the spaces or water and oil are filled up and the vapour source and gas are pushed into the chamber up to 150 atm. driving the residual air off.

The time sequence circuits, the potentiometer circuits which shows the position of the piston and the thyratron relay circuits are described in " A ". The operating cycle is as follows

pulse in gate close —at once— cut the sweeping field
open the camera shutter
open the expansion valve

—0.5 sec.—light flash—0.5 sec

—apply the field
close the shutter—20 min.—gate open
close the valve

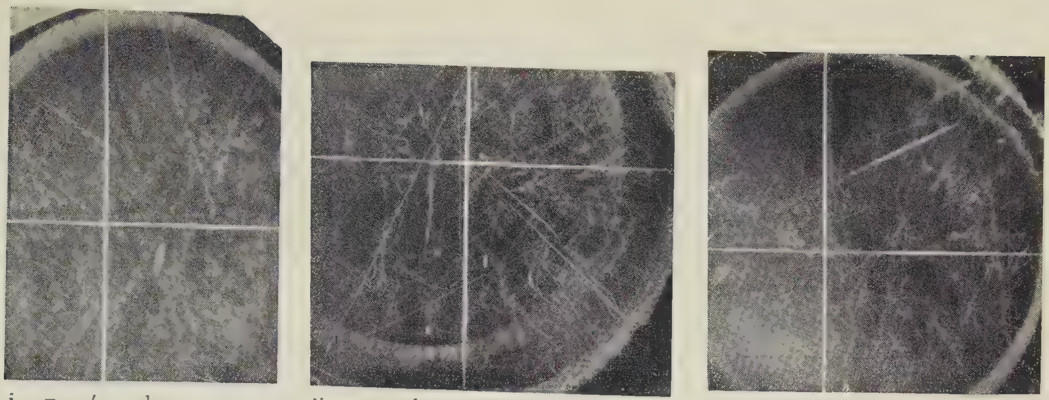
## § 4. The Operation and the Character of the Chamber

The uniformity of the illumination in the chamber are estimated by stereoscopic analysis of the photographs. Fig. 6 shows some examples of the photographs. The effective volume is about 50 cm in diameter and 15 cm in depth. The stopping power and the total weight for various gases in this effective volume are as follows;

| the sort of gas | stopping power per 50 cm | total weight |
|---|---|---|
| hydrogen (150 atm.) | 0.67 g/cm² | 400 g |
| nitrogen ″ | 9.4 | 5.6 k |
| argon ″ | 13.4 | 8.0 |

The purity of the inner gases were good, but a small amount of alcohol vapor and air were contained as impurities. The maximum content of such impurities was about 0.5%.

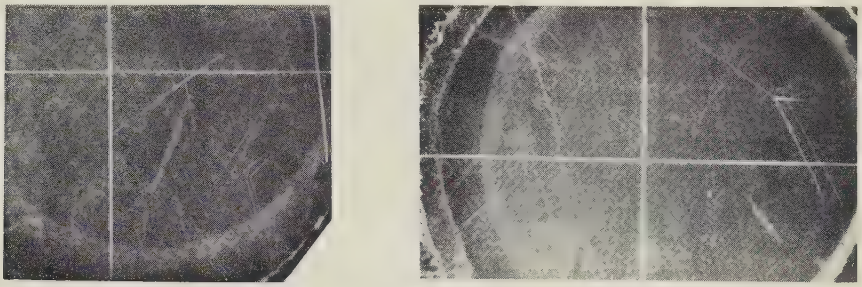
The following points have to be considered in selection of the vapour source. The pressure should not be high (to keep the gas impurity small), the resistance in liquid state should be high (to avoid the leakage of the electricity at the plugs when the vapor condences) and the required expansion ratio should be small and so on. In the case of one to 3 ethyl alcohol-propyl alcohol mixture,



i. $\pi-\mu'-e$ decay.

ii. $\mu-e$ decay and pair production by decay electron.

iii. decay of charged heavy meson.



iv. Production and decay of neutral heavy particle.

v. Neutron-proton and proton-proton collision.

Fig. 6. Examples of events in 92 atm. Hydrogen (these are observed by K. Hinotani, T. Matano, K. Nunogaki and Author).

the expansion ratios were 1.06 for argon, 1.13 for nitrogen and 1.14 for hydrogen (at 100 atm.)

The expansion time is adjustable from 0.5 sec to 0.2 sec by a hand valve. The expansion ratio depends somewhat upon the expansion time. A slower expansion requires larger expansion ratio.

The expansion time determines the width of the tracks. Although the expansion is rather slow, the diffusion of ions in high pressure gas is also slow. The chamber can be adjusted to have about 1 mm track width. The best condition is determined by looking at random cosmic ray tracks illuminated by a small lamp set in the chamber.

The sensitive time is longer than that in a low pressure cloud chamber because the sensitive time varies as the square root of the pressure. It is estimated to be about 2–3 sec. and varies with the kind of inner gas and expansion time. The track width, for the same expansion delay, varies inversely as the square root of the pressure.

When the photograph is taken about 0.5–1 sec. after the start of the expansion, about 50 tracks are seen in one expansion. These are random tracks of electrons and mu mesons. The age of these tracks are estimated from the sweeping separation and the track width. In the case of nitrogen the separation of plus and minus ions is about 4 cm/sec at the sweeping field of about 150 V/cm and the track width is proportional to $\sqrt{t}$, where $t$ is a time before expansion.

Two photographs are taken with the stereoscopic angle of about 20 degrees. The pictures are analysed after the correction was done for the deformation of images by the deflection of light path in the water. This deformation is not so large at the center of the chamber, but the image moves forward for about 2 cm at the edge and this has to be corrected in all cases.

The tracks are classified as thin, gray and black in a similar way as in emulsion works. But this classification is not so clear in this case, because the drops are so dense that they can not be counted. The tracks are seen as continuous lines. Therefore, they are

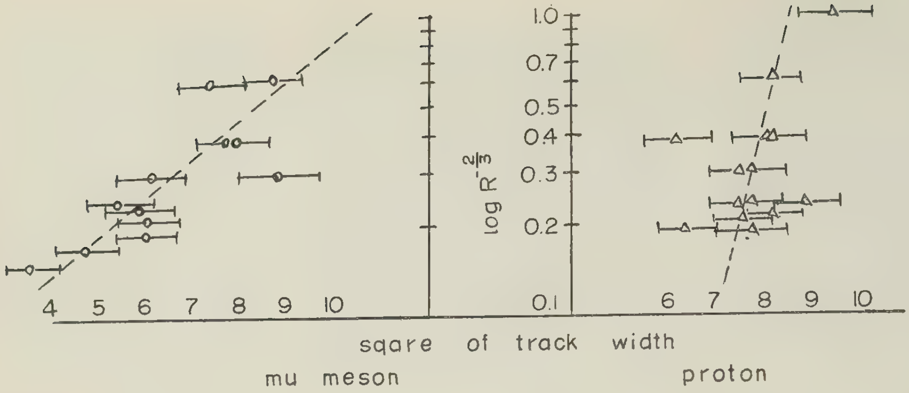


Fig. i.

discriminated by their width and knock-on electrons. Thin tracks are characterized by minimum ionization or by their production of knockon electrons. Black tracks are heavily ionizing tracks whose width is about twice the width of a thin track of the same age, and gray tracks comes between the above two. (see Appendix I) Momenta are easily measured by multiple scattering angle, for light particles especially for electrons. Momenta lower than 50 Mev/c for argon, 30 Mev/c for nitrogen and 4 Mev/c for hydrogen can be measured in this way. In these cases the average deflection angles are larger than about 2 deg./cm. This measurement can not be applied to high energy particles because of the distortion in the chamber and inaccuracy arising from track width. (see Appendix II)

The stopping powers of the inner gases are as follows:

| | energy for the range of 5 cm | | |
|---|---|---|---|
| | electron | mu meson | proton |
| argon | 2.7 Mev | 14 Mev | 36 Mev |
| nitrogen | 2.0 | 10 | 26 |
| hydrogen | 0.5 | 3.8 | 11 |

The masurements in the well known events, for instance the range of the mu meson in pi-mu-e decay etc. were used for checking these figures.

A range of 5 cm in nitrogen corresponds to about 3000 microns in emulsion. Such tracks, which correspond to about 60 microns in emulsion, as in the case of prongs from evaporation stars, are missed, because they are shorter than 1 mm in the nitrogen gas of 150 atm. Low energy stars from neutrons appear as only points of a few mm diameter.

Sometimes the lead plate of 1–2 cm thickness is placed in the chamber to distinguish the soft component.

It is very important to make the dead times in cycling operation as short as possible. For this purpose several methods have been tried., 1) Vapour sources were placed at many places in the chamber, 2) Vapour source were circulated by the variation of the pressure at the expansion and at the compression of the chamber, through the pipe which connect the top and the bottom of the chamber, 3) Slow expansions were repeated, 4) The inner gas was circulated by mechanical and thermal methods. All these procedures were effective in shortening the dead time, but the procedure (4) gave some disturbance, to the following cycle of observation.

## Acknowledgment

The authors are indebted to Professor Y. Watase for his valuable advice and encouragement and express their thanks to Mr. Nakamura for his aids in construction of the equipment.

## Appendix I

*Estimation of the mass from the ionization and the range*

The ionization density $I(x)$ at a distance $x$ from the track centre, after ions have diffused during $t$ sec, is given by

$$I(x)=(4Dt)^{-1/2}N_0 \exp(-x^2/4Dt)$$

and the track width is proportional to $(Dt)^{1/2}$. Where $D$ is a diffusion constant and $N_0$ is the number of ions per unit length and is proportional to the inverse square of the velocity of a particle. On the other hand, the range of a track is proportional to the cube of the velocity in low energy region. Thus log (range)$^{-2/3}$ is proportional to square of track width.

Fig. i shows this relation for mesons and protons and each curve is normarized at the end of the tracks.

The mass of each particle will be determined from the gradient of the curve in this figure.

## Appendix II

### *Scattering measurement*

Preliminary scrttering measurement was done for low energy electrons (about 2 Mev) in nitrogen, excepting the tracks inclined more than 30° to vertical plane.

There is a well known relation

$$\eta=\varphi R^{\alpha}$$

where $\varphi$ is the projected scattering angle, $R$, the residual range and $\alpha$ is a constant which is about 0.66 in this energy region.

Fig. ii A shows the distribution of $\eta$ and it is consistent with the expected value

$$g(\eta)=\frac{1}{\sqrt{2\pi}\rho}\exp\left(-\frac{\eta^2}{2\rho^2}\right)$$

with $\rho$ defined by

$$\rho=(4\pi r_e NZ^2A^{-1}tG)^{1/2}(m_e c^2 A)^{\alpha}(m_e/m)^{1-\alpha}$$

where $t$ is the cell length (0.5 cm in this case), $G$ is 4.22, $A_z$ is 1.32 cm/Mev and other notations are those usually used.

From the root mean square of $\eta$ or the average of the absolute value of $\eta$, the mass of the particles was given as $0.97^{+0.08}_{-0.06}$ electron mass.

Distribution of $\eta$ for each track is also shown together with computed distribution in Fig. ii B, but the accuracy of the result is not enough to decide whether there are other particles whose mass is different from that of electrons or not.

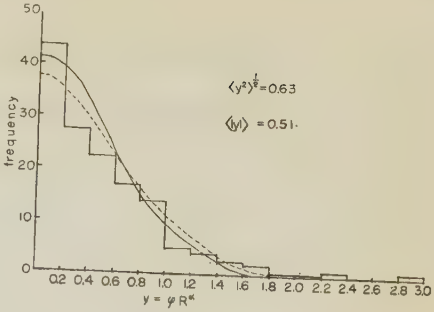

Fig. ii. A

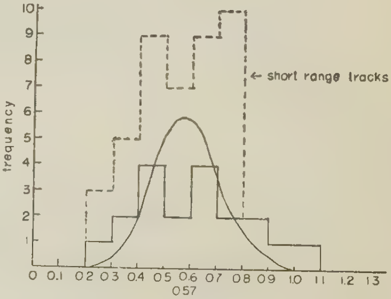

$$\xi=\left(\frac{1}{n-1}\sum_{i=1}^{n}\eta_i^2\right)^{1/2}$$

Fig. ii. B

# Statistical Theory of Phase Transition III

## Application to Vapor-Liquid-Solid Equilibrium

By Ikuro SHIMOSE

*Faculty of Literature and Science, Yamaguchi University*

(Received August 12, 1955)

Generalizing the idea of molecular-clusters introduced for a lattice gas with no sublattice in our paper, we calculate the equation of state for a lattice gas with many interstitial sublattices. Thus it is shown that the stable liquid phase, together with the vapor and solid phases, can exist in the above system. Furthermore, we make clear the relation between the two phase transitions, that is the vapor-liquid and the liquid-solid transitions, from the point of view of molecular-clusters.

### § 1. Introduction

In our previous paper[1]*, by extending the idea of order-disorder in the alloy theory to the case having many ordered parameters, we calculated the equation of state for a lattice gas with many interstitial sublattices in the degree of Bragg-Williams' approximation[2]. Thus we showed that the stable liquid phase, together with the vapor and solid phases, can exist in the above system, and we were able to make fairly clear the relation between the vapor-liquid and the liquid-solid transitions.

In this paper, by extending the idea of molecular-clusters introduced for a lattice gas with no sublattice in Parts I and II of this paper[3]** to the system with many sublattices, we deal with the same problem as in the previous paper[1]. Thus we wish to show that the stable liquid phase can exist in the above system, and to make still clearer the relation between the two phase transitions.

### § 2. Partition Function

We assume the potential energy $\varphi(r)$ between any two molecules to be of the following form;

$$\left.\begin{array}{ll}\text{(i)} & \varphi(r)=+\infty \quad \text{for} \quad 0\leqq r<a\,, \\ \text{(ii)} & \varphi(r)=-2\mathcal{E}\ (\mathcal{E}>0) \ \text{for}\ a\leqq r<\sqrt{2}\,a\,, \\ \text{(iii)} & \varphi(r)=0 \quad \text{for} \quad r\geqq\sqrt{2}\,a\,,\end{array}\right\} \qquad (1)$$

where $r$ is the distance between two molecules. Then we consider a square lattice composed of $sL$ lattice points, in which the distance between nearest neighbors is $a/s^{1/2}$, where $s$ is a integer. We can divide the above $sL$ lattice points into $s$ square lattices, in each of which the distance between nearest neighbors is $a$. We define each of the above $s$ lattices as "sublattice." A square lattice for $s=9$ is shown in Fig. 1.

The partition function $\Omega(T, L, s, N)$ of the system composed of $N$ molecules at the absolute temperature $T$ is given by

$$\Omega(T, L, s, N)=(2\pi mkT/h^2)^N(1/x)^{4N}s^N \times Q(T, L, s, N)\,, \qquad (2)$$

$$Q(T, L, s, N)=(1/s)^N\sum x^{N'}\,, \qquad (3)$$

$$x=\exp(-\mathcal{E}/kT)\,, \qquad (4)$$

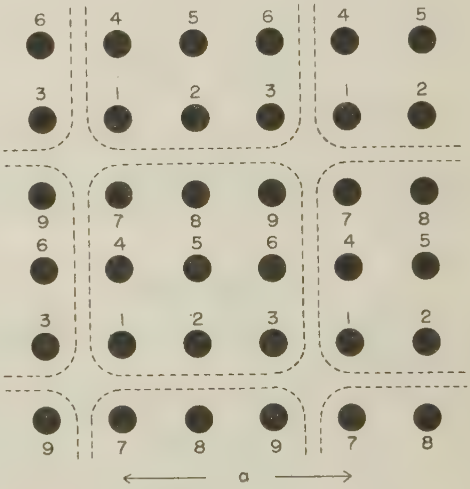

Fig. 1. Square lattice with 9 interstitial sublattices. The figure affixed to each lattice point shows the number of sublattice to which that lattice point belongs. The closed curves (dotted) show the l. p. groups (as will be stated in § 3).

---

* The paper "Equation of State for Vapor-Liquid-Solid system."

** The paper "Statistical Theory of Phase Transition" is denoted by "STPT" for short in the later articles.

where $\sum$ in Eq. (3) means the summation of $x^{N'}$ over all the possible cases, in which $N$ molecules are distributed among the $sL$ lattice points. $(4N-N')/2$ is the total number of $(r_1)$ pairs of any two molecules in one of the molecular configurations mentioned above, where "$(r_1)$ pair" of two molecules denotes the pair of two molecules existing at a distance $r_1(a\leqq r_1<\sqrt{2}\,a)$. $m$ is the mass of a molecule, $k$ Boltzmann's constant, $h$ Planck's constant.

## § 3. Molecular Configuration

As in STPT(1.3)***, we define a "molecular cluster" as the group of molecules in which every molecule either directly or indirectly is connected with each other at a distance $r_1$ $(a\leqq r_1<\sqrt{2}\,a)$. Then we divide all the lattice points into $L$ groups so that each group may contain $s$ lattice points, each of which belongs to each of $s$ sublattices respectively (such groups for $s=9$ are shown in Fig. 1). We denote such a group by "l.p. group", and a l.p. group with no molecule by "hole". Furthermore, we define a hole cluster as in STPT(1.3). Now we consider the following configuration types (viz. $A'$-, $B'$- and $C'$-types)[†] and the types including two or all of them (viz. $A'B'$-, $B'C'$-, $A'C'$- and $A'B'C'$-types).

($A'$) The configuration consisting of micro-molecular and macro-hole clusters,

($B'$) the configuration consisting of micro-hole and macro-molecular clusters,

($C'$)[††] the configuration consisting of micro-molecular and micro-hole clusters,

where micro- and macro- clusters (molecular and hole) are defined as in STPT(1.3). Then we can easily ascertain that the configuration consisting of macro-molecular and macro-hole clusters may give little contribution to the partition function. Furthermore, there may also exist intermediate (molecular and hole) clusters. However, we can deduce by the same consideration as in STPT(1.3) that intermediate clusters may be omitted in calculation, causing no alternation of the statistical properties.

## § 4. Calculation of Partition Function

Generalizing the method of STPT(I), we can calculate the contributions of the $A'$-, $B'$-, $C'$-, $A'C'$-, $B'C'$- and other type configurations to $Q_1(T, L, s, \rho)(=Q(T, L, s, N))$, where $\rho$ is molecular density and is given by $\rho=N/L$. We numerically calculate those contributions for $s=9$ and $x=0.3$. In low density region ($\rho\approx0$), the $A'$-type configuration gives a maximum contribution to $Q_1(T, L, s, \rho)$. This contribution is given by the curve $OAA'$ with a maximum in Figs. 2 and 3. In high density region ($\rho\approx1$), the $B'$-type configuration gives

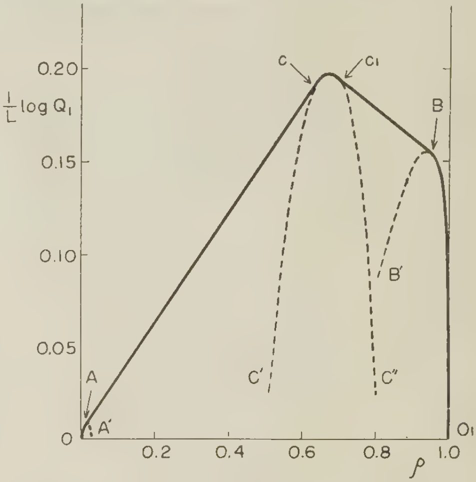

Fig. 2. $1/L\cdot\log Q_1-\rho$ curve for $s=9$ and $x=0.3$.

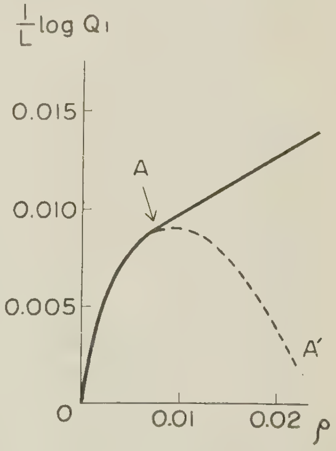

Fig. 3. $1/L\cdot\log Q_1-\rho$ curve for $s=9$ and $x=0.3$.

---

*** STPT (I.3) denotes § 3 of Part I in the paper "STPT".

[†] $A$- and $B$- types in STPT (I) and (II) correspond respectively to $A'B'$- and $A'$-types in this paper.

[††] In STPT (I) and (II), we considered without notice the configuration corresponding to the above $C'$-type one as the special case of $A$- and $B$-type configurations.

a maximum contribution to $Q_1(T, L, s, \rho)$ This contribution is given by the curve $O_1BB'$ with a maximum in Fig. 2.

The calculation of $C'$-type contribution is very difficult. We assume in order to simplify this estimation that each l. p. group with molecule at least has one adjacent hole. This assumption may hold in the molecular configuration for the small value of $m$, but it may not accurately hold in the configuration for the great value of $m$. Here $m$ denotes the greatest value of the number of holes constituting a hole cluster effective for the partition function. For the system with sublattices, owing to the great number of molecular configurations in a l.p. group and the form of potential in Eq. (1), the contribution per molecule to $Q_1(T, L, s, \rho)$ is several times as great as that for the system with no sublattice. Therefore, for the system with sublattices the $C'$-type contribution is effective for $Q_1(T, L, s, \rho)$ in temperature region ($x \gtrsim 0.3$) higher than a definite temperature. On the contrary, for the system with no sublattice the $C'$-type contribution is not effective for $Q_1(T, L, s, \rho)$ in the whole temperature region. This contribution for $s=9$ and $x=0.3$ is given by the curve $C'CC_1C''$ in Fig. 2. In this estimation, only the hole clusters consisting of single hole are taken into consideration to simplify the calculation. Then the l.p. groups having molecule but with no adjacent hole exist in the $B'$-type configuration. However, according to the above assumption every l.p. group with molecule has one adjacent hole at least in the $C'$-type configuration. Therefore, the contribution per molecule to $Q_1(T, L, s, \rho)$ for the $C'$-type case can be greater than that for the $B'$-type case.

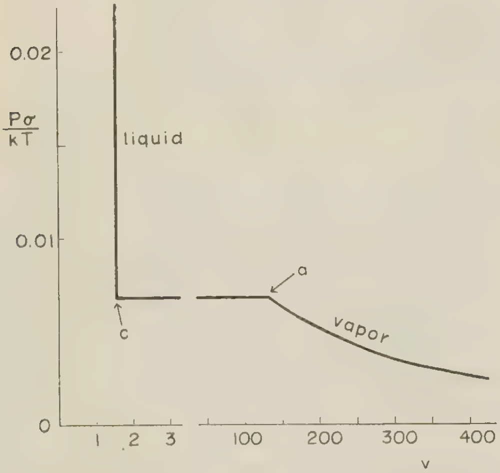

Fig. 4. $P\sigma/kT-v$ curve for $s=9$ and $x=0.3$.

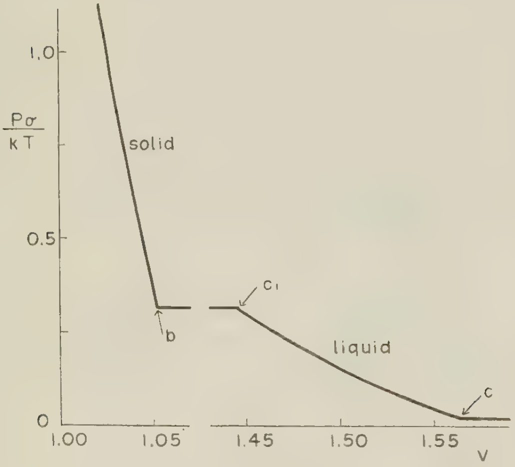

Fig. 5. $P\sigma/kT-v$ curve for $s=9$ and $x=0.3$.

In the comparatively low temperature region (for example $x=0.3$), by generalizing the theory of STPT(1·3·5) we can prove the following for the $A'C'$-type configuration in the intermediate region of the two densities, in the vicinity of which the $A'$- and $C'$-type contributions respectively become maximum. In this density region, (i) the $A'C'$-type contribution (for $x=0.3$) is exactly given by the common tangent $AC$ (in Figs. 2 and 3) to the $OAA'$ and $C'CC_1C''$ curves, which correspond respectively to $A'$- and $C'$-type contributions, (ii) the $A'C'$-type contribution is greater than any other type contributions. Furthermore, the same relation holds also for the $B'C'$-type configuration. The $B'C'$-type contribution (for $x=0.3$) is given by the common tangent $BC$ (in Fig. 2) to the $O_1BB'$ and $C''C_1CC'$ curves, which correspond respectively to $B'$- and $C'$-type contributions.

By the same consideration as in STPT(1·3·4), we shall see that the value of $1/L\cdot\log Q_1(T, L, s, \rho)$ is given by the greatest value of the contributions to $1/L\cdot\log Q_1(T, L, s, \rho)$ of all the possible type configurations. $1/L\cdot\log Q_1-\rho$ curve for $s=9$ and $x=0.3$ is shown in Figs. 2 and 3.

## §5. Equation of State

From the $1/L\cdot\log Q_1-\rho$ curve for $s=9$ and $x=0.3$ (Figs. 2 and 3), we can calculate the equation of state by using the theory of STPT

(1·4). The $P\sigma/kT-v$ curve (the isotherm) obtained is shown in Figs. 4 and 5, where $P$ is the pressure, $v$ the specific volume (two-dimensional) per molecule, and $\sigma$ the total volume (two dimensional) divided by $L$.
Particularly the two straight parts $AC$ and $BC_1$ in $1/L\cdot\log Q_1-\rho$ curve (in Fig. 2) correspond respectively to portions $ac$ (in Fig. 4) and $bc_1$ (in Fig. 5) parallel to $v$-axis ($P$=constant) on $P\sigma/kT-v$ curve. And these two portions represent respectively the two phase transitions that is the vapor-liquid and the liquid-solid transitions.

## § 6. Conclusion

For the lattice gas with many interstitial sublattices, we were able to calculate the equation of state from the point of view of moleculnr clusters, and theoretically show as in the previous paper[1] that the stable liquid phape, together with the vapor and solid phases, can exist in the above system. Though the degree of approximation for the method used was not so definite, we were able to obtain the reasonable result that the regions of two phase transitions (that is the vapor-liquid and the liquid-solid transitions) correspond respectively to the two portions parallel to the $v$-axis on the $P\sigma/kT-v$ curve (the isotherm) in the comparatively low temperature region.

The author wishes to express his sincere thanks to professor A. Harashima, Tokyo Institute of Technology, for his valuable discussions.

# Oriented Overgrowth of Evaporated Crystallites

## Fluoride Crystallites on Cleavage Surfaces of Single Crystals

By Jiro SHIGETA

*Department of Physics, Okayama University, Okayama, Japan*

(Received October 17, 1955)

The orientation of crystallites in fluoride films (LiF, NaF, $CaF_2$, $MgF_2$, $AlF_3$ and $Na_3AlF_6$) evaporated in vacuum onto the cleavage surfaces of several kinds of single crystals (galena, rocksalt, molybdenite and zincblende) were investigated by means of electron diffraction. The oriented overgrowth occurs even when the misfit is larger than 20%; for LiF and NaF on galena misfits are −33% and −23% respectively, for LiF on rocksalt misfit is −29% and for $CaF_2$ on molybdenite +23%. On the other hand, for $CaF_2$ on rocksalt the random orientation occurs though the misfit is only −3%. Therefore, the occurrence of orientation can not be predicted solely by the value of misfit. It is worth mentioning that in the present experiment no twin was observed provided the evaporated layer is thin, as previously stated by Uyeda [Proc. Phys.-Math. Soc. Jap. **26** (1942) 809]. This excludes the mechanism of oriented overgrowth which was proposed by Menzer [Naturw. **26** (1938) 385; Z. Krist. **A 99** (1938) 410] and later adopted by Frank and Merwe [Proc. Roy. Soc. **A 198** (1949) 205].

## § 1. Introduction

The oriented overgrowth of crystals has been studied extensively by many investigators. It is generally accepted that the fitting of lattices on the boundary surface is an important factor for the occurrence of oriented overgrowth. However, there are many examples[1] in which oriented overgrowth takes place even when the misfit is larger than 20%. For example, silver ($a_0$=4.08 Å) shows a definite orientaion on rocksalt ($a_0$=5.63 Å), where the misfit is −27%. This fact is not in accordance with the idea that the fitting of lattices is the only cause of the oriented overgrowth. To get rid of this difficulty Menzer[3][4] suggested the formation of a twinned structure in the initial layers of deposit. His suggestion, however, was denied by Uyeda's[2] experiment. Later, Frank and Merwe[5] proposed a mono-layer hypothesis which leads to the conclusion that the fitting is the only factor to cause the oriented overgrowth. Smollett and Blackman[6] criticized this theory and pointed out the disagreement of Frank-Merwe's theory with experimental facts. Recently, Schultz[7] and Raether[8] reported that Menzer's twin was not found in the initial deposit of alkali halides on substrates of alkali halides. More recently, Lüdemann[9] and Ogawa[10] also denied Menzer's twin by their experiments. In the present experiment the oriented overgrowth of crystallites in various fluoride films evaporated onto various substrates is studied with special attention to Menzer's twin.

## § 2. Experimental

Thin films of fluorides were prepared by evaporation on substrates in a vacuum furnace. Fluorides used in this experiment were LiF, NaF, $CaF_2$, $MgF_2$, $AlF_3$ and $Na_3AlF_6$ (cryolite); the substrates were cleavage surfaces of galena (PbS), rocksalt (NaCl), molybdenite ($MoS_2$) and zincblende (ZnS). Orientations were studied for all the combinations of the fluorides and the substrates.

The fluorides to be evaporated were preheated in a tungsten spiral long enough to exclude occuluded gas. When the vaporization started, the pressure in the bell jar was $1\sim2\times10^{-4}$ mm Hg. A few minutes later, it became $3\sim5\times10^{-5}$mm Hg. A shutter between the spiral and the substrate was then opened to make deposit. The evaporation of the sample in the spiral was generally completed in a few minutes. The temperature of the substrates during evaporation was kept at 15, 200, 300 and 400°C. For galena and rocksalt substrates the highest temperature was 400°C,

*Note.* The number in brackets indicates the orientation illustrated in Fig. 1. The mark × indicates no definite orientation. The mark ? is used when the pattern is not sharp enough to be analized although some definite orientations exist. The notation (2)>(3), for example, means that the orientation (2) prevails over (3).

while for molybdenite and zincblende substrates it was 500°C; above these temperatures the thermal etching became remarkable. For NaF deposit the highest temperature was 300°C for all the substrates because NaF re-evaporated above this temperature. The mean thickness of fluoride films was generally of the order of 60 Å. However, for LiF on galena at 200°C the mean thickness was varied from 6 Å to 740 Å to examine in detail the relation between orientation and thickness.

After the furnace was cooled, the samples thus prepared were taken out from the vacuum and was set in an electron diffraction camera as quickly as possible. Then they were examined by reflection method.

## § 3. Experimental Results

The main result of the present experiment is summarized in Table I and in Fig. 1. $MgF_2$ and $AlF_3$ shows no definite orientation, while all the other deposits show definite orientations above certain temperatures.

The result of LiF on galena is explained in detail below. The diffraction patterns for various temperatures are reproduced in Fig. 2, and those for various thicknesses in Fig. 3. On galena substrate LiF shows three types of orientations (1), (2) and (3) (Fig. 1).

Table II. The orientations of LiF deposit of various thickness on galena substrates at 200°C.

| Thickness of deposit | Orientation | Twin |
|---|---|---|
| 6 Å | (2), (1) both faint | no |
| 12 Å | (2)>(1), (3) | no |
| 52 Å | (2)>(1) both sharp | no |
| 100 Å | (2)>(1) | {111}, {012} |
| 300 Å | (2)≫(1), sharp, rather faint D. R. | {111}, {012} remarkable |
| 500 Å | (2), D. R. developed | {111}, {012} conspicuous |
| 740 Å | D. R. only | |

Remarks. (1), (2) and (3): Cf. Fig. 1.

At 15°C the type (2) is most predominant, the type (3) rather weak and the type (1) faint (Fig. 2a). No twin spots appear provided films are thinner than several tens Å (Fig. 2a). For films thicker than 100 Å {012} twin spots appear along circular arcs, but {111} twin spots do not appear.

At 200°C the type (3) becomes faint and the type (1) becomes so strong that it is comparable to the type (2) (Fig. 2b). At this temperature the variation of orientations with the thickness was examined in detail, the result being summarized in Table II. Both

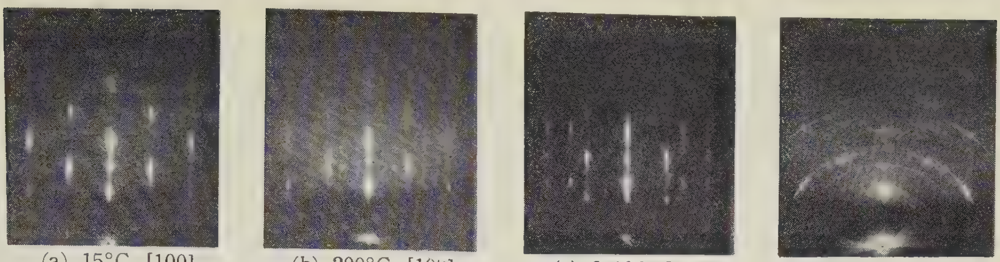
Fig. 1. Orientations of fluoride crystallites on various crystalline substrates. Miller's indices of the contact plane of fluoride crystallites are indicated in the figures. The mark ↻ indicates fiber structure. The numerals under the figures are the misfit values, the brackets for misfit values correspond to orientations which do not actually take place and the mark * indicates misfits larger than 15%. In all the figures thick lines represent the crystallite of the deposit and thin lines that of the substrate.

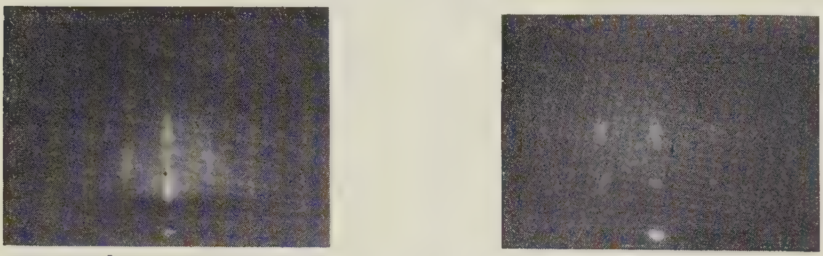
{111} and {012} twins do not appear in films thinner than several tens Å (Fig. 3a). They appear remarkably in the range 100～500 Å (Fig. 2b). As the thickness increases the type (2) prevails over (1) and at about 500 Å the type (1) disappears (Fig. 3b). When the thickness increases over 300 Å, weak Debye rings indicating random orientation are superposed on spot patterns (Fig. 3b), then the rings become gradually strong and finally at about 700 Å they mask the spot patterns.

At 300°C the types (1) and (2) are com-



(a) 15°C, [100] (b) 200°C, [100] (c) 300°C, [100] (d) 400°C. [110]

Fig. 2. Lithium fluoride on galena, temperatures and directions of the incident beam are indicated. The thickness for (b) is 150 Å and that for the others is 70 Å.



(a) 12 Å, beam//$[100]_{PbS}$ (b) 500 Å, beam//$[110]_{PbS}$

Fig. 3. Lithium fluoride of various thickness evaporated on galena at 200°C, thickness is indicated above. Cf. Fig. 2 b also.

(a) (b) (c)

Fig. 4. Calcium fluoride on various substrates at 400°C: (a) rocksalt, (b) galena and (c) molybdenite ($[120]_{azim.}$).

parably strong and the type (3) disappears (Fig. 2c). At 400°C the type (1) in which the diffraction spots spread along circular arcs becomes strong and the type (2) which was most predominant at lower temperatures disappears (Fig. 2d). The both types of twin spots do not appear at temperatures 300∼400°C.

For LiF on rocksalt the three types (1), (2) and (3) appear similarly as for LiF on galena. However, the change of orientations with substrate temperature is different for these two substrates. On rocksalt all the three types appear at 400°C and only the type (1) appears at 15∼200°C, while on galena all the three types appear at 15∼200°C and only the type (1) appears at 400°C.

On galena substrate NaF shows usually the type (1), and this is often accompanied by the type (2) or the type (4). On rocksalt substrate NaF shows only the type (1). On molybdenite substrate NaF and LiF show usually the type (6) and for LiF deposit the type (5) is superimposed as the temperature rises. On zincblende substrate NaF and LiF show different orientations as given in Table I.

The orientations of cryolite crystals appear only above about 300°C for all of the substrates. The orientation of cryolite on zincblende is very complicated. Besides seven types of orientations shown in Fig. 1c complicated diffraction patterns were often observed, separately or superimposed. Their appearance took place by chance and was uncontrollable.

On zincblende and molybdenite $CaF_2$ shows definite orientations, while on galena and rocksalt $CaF_2$ shows random orientation through the temperature range 15~400°C (Fig. 4a, b).

In all the experiments above mentioned, Menzer's twin never appears in the initial layers of deposits.

## § 4. Discussions

The misfit (or mismatch) $M$ between the deposit and the substrate on the contact plane is defined as $M=(b-a)/a$, where $a$ denotes the spacing of the substrate, $b$ that of the deposit. The oriented overgrowth occured very often even for misfit larger than 15% (Fig. 1). In Fig. 1a there are four examples indicated by stars * in which the misfit exceeds 15%. According to the theory of Frank and Merwe⁵⁾, the critical misfit value for stable orientations is ±9% and that for metastable orientations ±14%. The misfit of 15% mentioned above exceeds both of the critical values. For LiF on galena the misfit of the type (1) is −33%. It is noteworthy that for cubic crystals on cubic faces (Fig. 1a) the type (1) occurs generally in the temperature range 15~400°C, even though the misfit is the largest of the three possible orientations. This tendency is also observed for LiF on (100) faces of NaCl and KBr crystals, where the misfits are as large as −29% and −39% respectively. On the other hand, random orientation is observed through the whole temperature range 15~400°C for $CaF_2$ on rocksalt, where the misfit is only −3%.

As described in § 3 Menzer's twin was never observed in the present experiment provided films are thinner than several tens Å. This coincides with the experimental results by Uyeda²⁾, Schultz⁷⁾, Raether⁸⁾, Lüdemann⁹⁾ and Ogawa et al¹⁰⁾. Thus all the experiments are against Menzer's hypothesis and the values of misfit mentioned so far are regarded as the actual values of misfit. Therefore, Frank-Merwe's theory cannot explain definite orientations which take place with the misfit exceeding their critical values. In such a case the cause of the definite orientation may be found in the nucleus theory such as proposed by Uyeda²⁾ and Schultz¹¹⁾.

### Acknowledgement

The author wishes to express his sincere thanks to Prof. Ryozi Uyeda for suggesting the problem, his pertinent guidance and encouragement. He also thanks Miss F. Yamamoto and Mr. M. Hiramatsu for their helpful assistance. The expense for this research has been partly defrayed by the Ministry of Education Scientific Research Grant.

# On the Magnetic Anisotropy of $FeF_2$ and $CoF_2$

By Tôru MORIYA, Kazuko MOTIZUKI, Junjiro KANAMORI
and Takeo NAGAMIYA

*Department of Physics, Osaka University*

(Received September 26, 1955)

The magnetic anisotropies of $FeF_2$ and $CoF_2$ are studied in detail by calculating the crystalline field acting on their magnetic ions and considering the effect of the spin-orbit coupling. The electronic energy level splittings of the ions $Fe^{++}$ and $Co^{++}$ in the crystalline field are calculated assuming first that all the surrounding ions are point charges and then taking account of the overlapping of their $3d$ electrons with the electron clouds of the surrounding fluorine ions. The spin-orbit coupling is then introduced and the $g$-values are calculated. Further, introducing the exchange coupling in the approximation of molecular field, the parallel and perpendicular susceptibilities of $FeF_2$ are calculated and a reasonable agreement with experiment is found. For $CoF_2$, however, the calculated level splitting is not successful in explaining the observed susceptibilities. Discussions are given on the possible sources of this disagreement and the nature of the approximations made in this study.

## § 1. Introduction

Iron-group fluorides, $MnF_2$, $FeF_2$, $CoF_2$, etc., crystallize in the rutile type structure and their magnetic properties show tetragonal symmetry. Their magnetic anisotropies were studied experimentally by Stout, Griffel¹⁾ and Stout, Matarrese²⁾ over the temperature range 10°～340°K. They showed that the difference of the two principal values of the susceptibility, $\chi_{\parallel}-\chi_{\perp}$, is positive for $MnF_2$ and $FeF_2$ in their paramagnetic temperature range, except very near the Curie temperature, while for $CoF_2$, whose Curie point is 37.7°K, $\chi_{\parallel}-\chi_{\perp}$ changes sign at 140°K from positive to negative as temperature is decreased. The magnitude of $\chi_{\parallel}-\chi_{\perp}$ for $FeF_2$ and $CoF_2$ is about 100 times as large as that for $MnF_2$. Their low temperature measurements show that all these substances are antiferromagnetic and the spins prefer the c-axis as the easy direction of ordering. Measurements of the specific heat were carried out by Stout, Adams³⁾ and Stout, Catalano⁴⁾; they observed a sharp peak at the Curie temperature.

We confine our considerations to the magnetic anisotropy of these substances. For $MnF_2$, in which the $Mn^{++}$ ions are in the $^6S$ state and therefore the spin-orbit coupling is negligible, Keffer⁵⁾ has shown that the magnetic dipole-dipole interaction is the predominant origin of the anisotropy. For $FeF_2$ and $CoF_2$, however, their 100 times larger anisotropy should be attributed to other origin, namely, the spin-orbit coupling of the electrons in the $3d$ orbitals modified by the influence of the crystalline electric field. Theoretical investigations of this subject were undertaken by Niira and Oguchi⁶⁾ for $FeF_2$, and by Nakamura and Taketa⁷⁾ for $CoF_2$. They could give an explanation of the experimental results by adjusting several parameters contained in the crystalline field potential or in Pryce's effective spin Hamiltonian. These parameter theories could correlate various facts to each other, but it is desirable to look into the detail by studying directly the crystalline field itself and the resulting magnetic anisotropy. In this paper we attempt to make such a study, by making in part use of the crystaline field potential calculated in our previous paper⁸⁾. We make the following approximation. The crystal is assumed to be perfectly ionic. We consider the electronic structure of the cations to be that of an isolated cation we then take account of the effect of their environment. The latter is considered to be a static crystalline electric field. Exchange coupling between spins is approximated by a molecular field. One-body approximation is made for the electronic wave function of the cations, and other electronic states than those which result from the $3d$

electrons are neglected.

In § 2 we shall first give expressions for the energy level splittings of $Fe^{++}$ and $Co^{++}$ in an ortho-rhombic crystalline field, and then calculate their numerical values, making use of our previous results[8)] for the crystalline field obtained with the point charge model. The results, however, cannot explain the experimental fact. In § 3 we shall consider the effect of the overlapping of the $3d$ electron cloud with the surrounding fluorine electron clouds. This effect proves to be large and improves the results. In § 4 and § 5 are given calculations and discussions of the energy level splittings and paramagnetic susceptibilities of $FeF_2$ and $CoF_2$. For $FeF_2$ we find a reasonable result, but for $CoF_2$ we do not. Finally, in § 6, we discuss the nature of our approximation and possible sources of the discrepancy found for $CoF_2$.

## § 2. The Energy Level Splitting in the Crystalline Electric Field

Ions of the iron group elements have electrons residing in their incomplete $3d$-shells. The Hund rule tells us that the lowest lying electronic state has the maximum spin multiplicity and also the maximum orbital angular momentum consistent with this multiplicity; the ground states of $Fe^{++}$ and $Co^{++}$ are thus $^5D$ and $^4F$, respectively. These states are degenerate in their orbital states as well as in their spin states. When these ions are found in cystals, they are acted upon by the crystalline electric fiield and the degeneracy of their orbital states are lifted partly or perfectly according to the degree of symmetry of the field. The spin-orbit coupling, however, recovers a part of the orbital moment, which is carried by the spin so that the $g$-value becomes different from the spin only value 2. The $g$-value thus modified is generally anisotropic, namely it is a tensor. This is because the spin-orbit coupling, together with the action of the crystalline electric field on the $3d$ electrons, relates the spin to the crystalline axes. Therefore, the spin-orbit coupling lifts the spin degeneracy except for the Kramers doublets. These are the facts which underlie the anisotropic paramagnetic properties of the crystals.

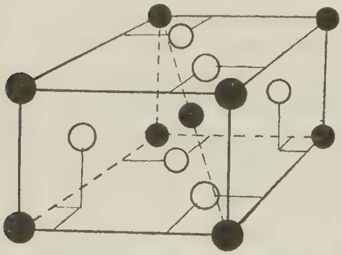

Fig. 1. The rutile type crystal structure of $FeF_2$ and $CoF_2$. Solid circles are cations, open circles anions.

There might be cases where some orbital levels lie closely above the non-degenerate ground level of the ion so that they obtain statistical populations which vary sensitively with temperature. In such cases the paramagnetic susceptibility of the substance will show unusual behaviours.

In this section, we shall first treat the general theoretical problem of the level splittings of $Fe^{++}$ and $Co^{++}$ ions in the orthorhombic crystalline electric field of their fluorides and then calculate the numerical values of the energy level splittings, basing our calculations on the 'point charge model' of the crystals which we studied earlier[8)]. We shall see, however, that this model does not give satisfactory results; we will modify the model in the next section.

Fig. 1 shows the rutile type crystal structure of $FeF_2$ and $CoF_2$, in which the cations form a body-centred tetragonal lattice and the anions surround each of the cations with an arrangement of orthorhombic symmetry. There are two kinds of sites for the cations, i.e. the corner and body-centre sites. Two of the principal axes of the crystalline field, perpendicular to the $c$-axis, are interchanged for these two kinds of sites. We shall take the [110], [$\bar{1}$10] and [001] directions as $x$, $y$ and $z$ axes for the body-centre sites and interchange the $x$ and $y$ axes for the corner sites. The electrostatic potential $V(\boldsymbol{r})$ around each cation can be developed in spherical harmonics as below, but we do not need terms beyond the fourth order, since we are dealing with $d$-electrons and the matrix elements of the higher order terms with respect to $d$-orbitals vanish. We have

$$\begin{aligned} V(\boldsymbol{r})=&A(r)\cdot(x^2-y^2)/r^2+B(r)\cdot(3z^2-r^2)/r^2\\ &+D(r)\cdot[(x^4+y^4+z^4)-3r^4/5]/r^4\\ &+F(r)\cdot[z^4-6(x^2+y^2)z^2+3r^4/5]/r^4\\ &+G(r)\cdot[-x^4+y^4+6(x^2-y^2)z^2]/r^4\,, \end{aligned} \tag{2.1}$$

where the third term has cubic symmetry, the second and fourth terms have tetragonal symmetry and the first and last terms orthorhombic symmetry.

The energy level splitting can be calculated in the first order perturbation, taking the free ion as the unperturbed system and the crystalline field potential as the perturbing Hamiltonian. We shall carry out this calculation separately for $FeF_2$ and $CoF_2$.

(i) The case of $FeF_2$

A free $Fe^{++}$ ion has the configuration $(3d)^6$ and the ground state, $^5D$, is the only quintet which results from this configuration. In this state, five electrons with parallel spinsform a closed shell and the remaining one with the reverse spin is in one of the five orbitals. The first five electrons can be neglected when we are concerned with the relative separations of the energy levels, because the crystalline potential is the sum of one-electron potentials, and a closed shell makes a constant contribution to the energy.

If the angular parts of the five orbital functions are taken to be proportional to

$$x^2-y^2,\ 3z^2-r^2,\ xy,\ zx,\ yz, \tag{2.2}$$

the first two of these mix in the crystalline field of the orthorhombic symetry but the remaining three are already the eigenfunctions. The matrix of $V(\boldsymbol{r})$ given by Eq. (2.1) with respect to the wave functions of the first two of (2.2) is calculated to be

$$\begin{pmatrix} \frac{4}{7}\langle B\rangle+\frac{4}{35}\langle D\rangle+\frac{16}{35}\langle F\rangle & -\frac{4\sqrt{3}}{21}(\langle A\rangle-\langle G\rangle) \\ -\frac{4\sqrt{3}}{21}(\langle A\rangle-\langle G\rangle) & -\frac{4}{7}\langle B\rangle+\frac{4}{35}\langle D\rangle+\frac{8}{105}\langle F\rangle \end{pmatrix} \tag{2.3}$$

where $\langle A\rangle$, etc. are defined by

$$\langle A\rangle=-e\int_0^\infty A(r)|\psi(r)|^2r^2dr\,,\quad \text{etc.,}\qquad (e>0) \tag{2.4}$$

$\psi(r)$ being the normalized $3d$ radial wave function. The eigenvalues of (2.3) are

$$\left.\begin{matrix}E_g\\E_h\end{matrix}\right\}=\frac{4}{35}\langle D\rangle+\frac{4}{15}\langle F\rangle\mp\frac{4}{7}\sqrt{\left(\langle B\rangle+\frac{1}{3}\langle F\rangle\right)^2+\frac{1}{3}\left(\langle A\rangle-\langle G\rangle\right)^2}\,. \tag{2.5}$$

The corresponding wave functions can be found in the usual way. The energy eigenvalues corresponding to the last three of (2.2) are calculated to be

$$\begin{aligned} E_{\mathrm{I}} &=-\frac{4}{7}\langle B\rangle-\frac{8}{105}(\langle D\rangle-\langle F\rangle)\,,\\ E_{\mathrm{II}} &=\frac{2}{7}(\langle A\rangle+\langle B\rangle)-\frac{8}{105}\langle D\rangle-\frac{32}{105}\langle F\rangle+\frac{8}{21}\langle G\rangle\,,\\ E_{\mathrm{III}} &=\frac{2}{7}(-\langle \mathrm{A}\rangle+\langle B\rangle)-\frac{8}{105}\langle D\rangle-\frac{32}{105}\langle F\rangle-\frac{8}{21}\langle G\rangle\,. \end{aligned} \tag{2.6}$$

(ii) The case of $CoF_2$

A free $Co^{++}$ ion has the configuration $(3d)^7$ from which quartet states $^4F$ and $^4P$ result. We may confine ourselves to these two multiplets. In this case, too, the orthorhombic crystalline field lifts the orbital degeneracy perfectly. We can confine ourselves to two $3d$ electrons of the cobalt ion outside the half-filled $3d$-shell. The wave functions of the $^4F$ and $^4P$ can be obtained by antisymmetrizing the following product of the one-electron spin-free functions since we are dealing with the state of the highest multiplicity:

$^4F$:

$$M=\pm3\qquad \phi_{\pm2}(1)\phi_{\pm1}(2)$$
$$M=\pm2\qquad \phi_{\pm2}(1)\phi_0(2)$$

$$\begin{array}{ll} M=\pm 1 & \sqrt{\frac{3}{5}}\,\phi_{\pm 2}(1)\phi_{\mp 1}(2)+\sqrt{\frac{2}{5}}\,\phi_{\pm 1}(1)\phi_0(2) \\ M=0 & \frac{1}{\sqrt{5}}\,\phi_2(1)\phi_{-2}(2)+\frac{2}{\sqrt{5}}\,\phi_1(1)\phi_{-1}(2)\;; \end{array} \tag{2.7}$$

$^4$P:

$$\begin{array}{ll} M=\pm 1 & \sqrt{\frac{2}{5}}\,\phi_{\pm 2}(1)\phi_{\mp 1}(2)-\sqrt{\frac{3}{5}}\,\phi_{\pm 1}(1)\phi_0(2) \\ M=0 & \frac{2}{\sqrt{5}}\,\phi_2(1)\phi_{-2}(2)-\frac{1}{\sqrt{5}}\,\phi_1(1)\phi_{-1}(2)\;. \end{array} \tag{2.8}$$

Here the suffixes of $\phi$ are the magnetic quantum numbers of the individual electrons. The antisymmetrized wave functions may be denoted as $\psi_{3M}$ ($M=\pm 3, \pm 2, \pm 1, 0$) and $\psi_{1M}$ ($M=\pm 1, 0$); they transform under rotation, as known well, in the same way as the surface harmonics of the third and first degrees. We combine them into such forms that are eigenfunctions for the field of orthorhombic symmetry (i.e. the bases of the irreducible representations of the group $V_h$). The third column of the following are such combinations:

$$\begin{array}{lll} A_1 & xyz & \frac{1}{\sqrt{2}\,i}(\psi_{32}-\psi_{3-2}) \\ B_1 1 & z\left(z^2-\frac{3}{5}r^2\right) & \psi_{30} \\ B_2 1 & y\left(y^2-\frac{3}{5}r^2\right) & \frac{1}{4}\{\sqrt{5}\,(\psi_{33}-\psi_{3-3})-\sqrt{3}\,(\psi_{31}-\psi_{3-1})\} \\ B_3 1 & x\left(x^2-\frac{3}{5}r^2\right) & \frac{1}{4i}\{\sqrt{5}\,(\psi_{33}+\psi_{3-3})+\sqrt{3}\,(\psi_{31}+\psi_{3-1})\} \\ B_1 2 & z(x^2-y^2) & \frac{1}{\sqrt{2}}(\psi_{32}+\psi_{3-2}) \\ B_2 2 & y(z^2-x^2) & \frac{1}{4}\{\sqrt{3}\,(\psi_{33}-\psi_{3-3})+\sqrt{5}\,(\psi_{31}-\psi_{3-1})\} \\ B_3 2 & x(y^2-z^2) & \frac{1}{4i}\{-\sqrt{3}\,(\psi_{33}+\psi_{3-3})+\sqrt{5}\,(\psi_{31}+\psi_{3-1})\} \\ B_1 3 & z & \psi_{10} \\ B_2 3 & x & \frac{1}{\sqrt{2}}(\psi_{11}-\psi_{1-1}) \\ B_3 3 & y & \frac{1}{\sqrt{2}\,i}(\psi_{11}+\psi_{1-1})\;. \end{array} \tag{2.9}$$

The second column gives in cartesian coordinates the functions which transform in the same way as the corresponding wave functions and the first column specifies the kinds of the irreducible representations; $A_1$, $B_1$, $B_2$, $B_3$ are all different irreducible representations, but since we have three wave functions for each of $B_1$, $B_2$, $B_3$, we number them as $B_1^1$, $B_1^2$, $B_1^3$, etc. For the perturbing potential $V(\boldsymbol{r})$ given by (2.1), each set of these three yields a three-dimentional energy matrix from which the energy eigenvalues and the corresponding wave functions can be obtained. These matrices were calculated, and the results are as follows. We write, in order to save the space, simply $A, B, \cdots$ for $\langle A\rangle$, $\langle B\rangle, \cdots$ and $(i, j)_k$ for the matrix element of $V(\boldsymbol{r})$ with respect to the wave functions of $B_k i$ and $B_k j$; then the matrix elements are:

$$(A_1|V(\boldsymbol{r})|A_1)=8D/35+8F/15; \tag{2.10}$$

$$(1,1)_1=4(2B-D-4F)/35\;,$$

&(3,3)_3=2(A+B)/5+(^4\mathrm{P})-(^4\mathrm{F})\ .
\end{aligned}\qquad(2.13)$$

In the above expressions for $(3,3)_k$, $(^4\mathrm{P})-(^4\mathrm{F})$ means the energy difference between the $^4$P and $^4$F levels of the free cobalt ion; its value is 14000 cm$^{-1}$.

We assume in this section the 'point charge model' of the crystals, for which the authors have reported numerical results for the crystalline electric potential[8]. In this model, the ions are replaced by point charges and the dipole-moments induced on the fluorine ions by point dipoles. The magnitude of these dipole moments has been determined by a self-consistent method using the value of the polarizability of the fluorine ion given either by Pauling[9] or Tessman, Kahn and Shockley[10]. We reproduce the result for the coefficients in (2.1) in Table I, in atomic units (abbreviated as A. U. in the following).

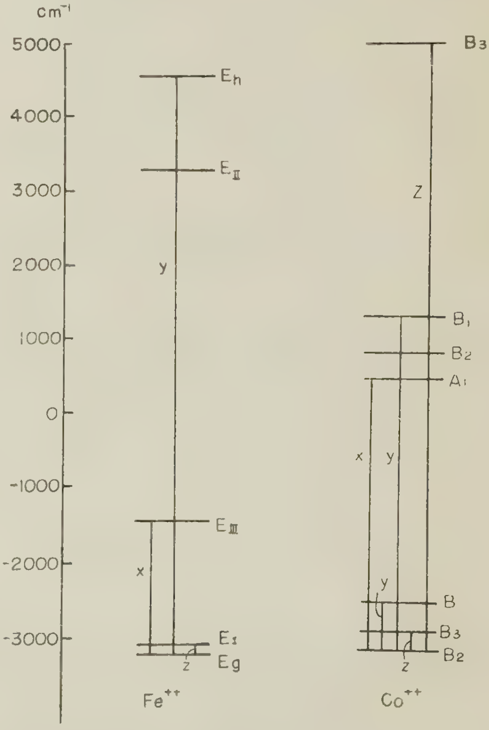

Fig. 2. Energy level splitting of Fe$^{++}$ ion in Fe$_2$F and Co$^{++}$ in CoF$_2$ calculated with the use of the point charge model. $x$, $y$ and $z$ represent the components of orbital angular momentum connecting the orbital ground and excited states.

Values of $\langle A\rangle$, $\langle B\rangle$, etc. defined by (2.4) can be obtained from the average values of $r^2$ and $r^4$ with respect to the 3$d$ radial function. We adopt Slater's[11] semi-empirical functions for the radial wave functions of Fe$^{++}$

and $Co^{++}$. They are hydrogen-like with effective nuclear charges $Z=6.25$ and 6.9 A. U., respectively for $Fe^{++}$ and $Co^{++}$. With these functions we obtain $\langle r^2\rangle=126Z^{-2}$ A.U. and $\langle r^4\rangle=25515\ Z^{-4}$ A.U., namely, we have

$$\langle r^2\rangle_{\mathrm{Fe}}=3.226\ \mathrm{A.U.} \qquad \langle r^2\rangle_{\mathrm{Co}}=2.647\ \mathrm{A.U.}$$

$$\langle r^4\rangle_{\mathrm{Fe}}=16.72\ \mathrm{A.U.} \qquad \langle r^4\rangle_{\mathrm{Co}}=11.26\ \mathrm{A.U.}$$

The values of $\langle A\rangle$, etc. thus calculated are enlisted in Table II, and the energy level splittings obtained with these values are shown in Fig. 2.

We see that both in $FeF_2$ and $CoF_2$ the first excited level liesly close to the ground level, the separation between them being of the order of 100 cm$^{-1}$, i.e. comparable with the magnitude of the spin-orbit coupling. Therefore, we are lead to conclude that the ground state posesses a considerable amount of orbital moment and so principal values of $g$ much different from 2. Also, the first excited state produces the $z$-component of the orbital angular momentum in both cases, so that $g_{\parallel}$ must be much greater than $g_{\perp}$ and consequently $\chi_{\parallel}$ much greater than $\chi_{\perp}$. The measurements of Stout and Mattarrese show, however, that although $\chi_{\parallel}$ exceeds $\chi_{\perp}$ above $T_c$ (except when close to $T_c$) in $FeF_2$, the values of $g$ in this substances are not much different from 2. Therefore the level separation must actually be much greater than that calculated here, i.e. 1000 cm$^{-1}$ or greater. Also, in the case of $CoF_2$, the measured $g$ values are not much different from 2. These facts show clearly the inadequacy of our point charge model. We shall therefore take account of the spatial extension of the electron clouds of the fluorine ions in the next section.

## § 3. Effect of Overlap Between Electron Clouds

We now wish to calculate the potential around a cation, taking account of the effect of the extension of the surrounding six fluorine electron clouds which inevitably overlap the cation $3d$ electron cloud. If this potential is expressed in the form (2.1), the coefficients $A(r)$, etc. are no longer proportional to $r^l$ ($l=2$ or 4). They must be determined by solving Poisson's equation. We shall denote the charge density of the $j$-th of the six fluorine ions at point $\boldsymbol{r}$ by $\sigma(x_j)$, where $x_j=|\boldsymbol{x}_j|=|\boldsymbol{r}-\boldsymbol{P}_j|$ ($j=1, 2\cdots, 6$), $\boldsymbol{P}_j$ being the position vector of the $j$-th fluorine ion, and for this we shall make use of the Hartree charge distribution modified by Benson and Wylie[12]).

Then the following potential must be added to the potential calculted with the point charge model:

$$\Phi_0(\boldsymbol{r})=\sum_{j=1}^{6}\phi(x_j) \tag{3.1}$$

where

$$\begin{aligned}\phi(x_j)&=-\frac{1}{x_j}\int_0^{x_j}\sigma(x)4\pi x^2dx\\&\quad-\int_{x_j}^{\infty}\frac{\sigma(x)}{x}4\pi x^2dx+\frac{ne}{x_j} \qquad (3.2)\\&=\frac{1}{x_j}\int_{x_j}^{\infty}\sigma(x)4\pi x^2dx-\int_{x_j}^{\infty}\sigma(x)4\pi x\,dx\ ,\end{aligned}$$

$n$ being the number of electrons in the fluorine ion so that $n=\int\sigma(x)4\pi x^2dx$. We shall consider in the following only six $2p$ electrons of the fluorine ion and neglect the two $2s$ electrons ($n=6$). This is because the $2s$ electron were neglected by Benson and Wyllie when they modified the Hartree charge cloud of fluorine ion so as to explain the observed diamagnetic susceptibility (they changed the linear scale of the Hartree $2p$ radial function in a suitable way) and this modification appears to take account to some extent of the effect of the $2s$ electron cloud. Moreover, we shall later arbitrarily change the overlap potential $\Phi_0(\boldsymbol{r})$ by multiplying it by a suitable factor not much different from unity so that the effect of the $2s$ electron will there again approximately be taken into consideration.

Expanding (3.1) in (normalized) spherical harmonics, we have

$$\begin{aligned}\Phi_0(\boldsymbol{r})&=\sum_m\varphi_{2m}(r)Y_{2m}(\theta,\varphi)\\&\quad+\sum_m\varphi_{4m}(r)Y_{4m}(\theta,\varphi)\ .\end{aligned} \tag{3.3}$$

$\varphi_{2m}(r)$'s and $\varphi_{4m}(r)$'s are related in a certain way to the overlap part $A_0(r)$, $B_0(r)$, etc. of $A(r)$, $B(r)$, etc. In calculating each contribution from $\phi(x_j)$ to $\varphi_{2m}(r)$ and $\varphi_{4m}(r)$, it is convenient to transform the coordinate axes in such a way that the new polar axis points to the $j$-th fluorine ion; then, since $\phi(x_j)$ has axial symmetry, we have only axially symmetric surface harmonics in the new system. This calculation is given in Appendix.

Lattice parameters for $FeF_2$ and $CoF_2$ are

$FeF_2$: $a=4.670$ Å $c=3.297$ Å $u=0.31$

$CoF_2$: $a=c=4.69$ $c=3.19$ $u=0.31$

and the values $P_1, P_2$ and $\theta$ in Fig. 3 are as follows:

| | $P_1$ | $P_2$ | $\theta$ |
|---|---|---|---|
| $FeF_2$ | 3.869,2 Å | 3.915,3 Å | 0.795,70 |
| $CoF_2$ | 3.885,7 | 3.841,6 | 0.619,95 |

The Hartree radial density distribution of the $2p$-electrons in a free fluorine ion can be fitted by an analytical expression of the form

$$R(r)=r\{A_1 \exp(-\alpha_1 r)+A_2 \exp(-\alpha_2 r)\},$$

and, as mentioned before, Benson and Wyllie changed the linear scale of this radial distribution so as to make the calculated diamagnetic susceptibility of the fluorine ion with $2p$ electrons only fit the observed value. The results were

$$A_1=16.445,9 \qquad \alpha_1=3.29$$
$$A_2=0.703,87 \qquad \alpha_2=1.18 \quad \text{(atomic units)}$$

We use these values and, after numerical calculations, obtain for the potential $\phi(x)$

$$\phi(x)=\sum_{i=1}^{3} D_i e^{-\delta_i x}\left[\frac{24}{\delta_i x}+18+6\delta_i x+\delta_i^2 x^2\right],$$

with

$$D_1=0.865,69 \quad D_2=0.347,94 \quad D_3=0.095,827$$
$$\delta_1=6.58 \quad \delta_2=4.47 \quad \delta_3=2.36\,. \quad \text{(atomic units)}$$

This potential is substituted in eq. (A. 3) of the Appendix, and the integrations were carried out graphically. In Table III we give the result for $\varphi_l(r; j)$ for $j=1$ in the case of $FeF_2$, where

$$\varphi_l(r;j)=\int \phi(x_j) Y_{l0}(\theta_j, \varphi_j) d\Omega\,. \qquad (3.4)$$

For $j=2$ of the case of $FeF_2$, we arrived at the following results:

$$\varphi_2(r;2)=0.90\varphi_2(r;1), \quad \varphi_4(r;2)=0.89\varphi_4(r;1).$$

For $CoF_2$, we assumed a relation $\varphi(r;j)_{Co}=k_j^{(l)}\varphi(r;j)_{Fe}$ and determined the ratio $k_j^{(l)}$ by calculating $\varphi_l(r;j)_{Co}$ at $r=2$ (A.U.) and comparing it with $\varphi_l(r;j)_{Fe}$ at $r=2$. The results were

$$k_1^{(2)}=0.97, \qquad k_2^{(2)}=1.06,$$
$$k_1^{(4)}=0.97, \qquad k_2^{(4)}=1.04.$$

Table III. (atomic units)

| $r$ | $\varphi_2(r;1)_{Fe}$ | $\varphi_4(r;1)_{Fe}$ |

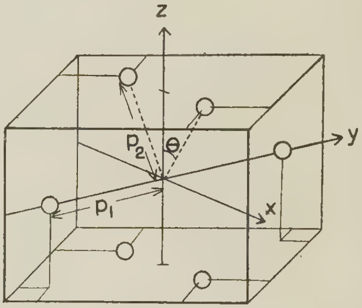

Fig. 3. Definition of coordinate axes, angle $\theta$ and lengths $P_1$ and $P_2$.

For the $3d$ wave function of the cation we tried a few possible ones, including that which is obtainable by modifying in a suitable way the Mn $3d$ function determined by neutron diffraction, but finally decided to adopt Slater's wave function[11]. After graphical integrations, we obtained the following result for the average of $\varphi_l(r;j)$ over the $3d$ electron cloud:

For $FeF_2$ $\langle\varphi_2(r;1)\rangle=0.034,89$

$\langle\varphi_4(r;1)\rangle=0.024,72$

For $CoF_2$ $\langle\varphi_2(r;1)\rangle=0.024,11$

$\langle\varphi_4(r;1)\rangle=0.014,95$

With all these results, we calculate the average values $A_0(r)$, $B_0(r)$, etc., the results of which are summarized in Table IV.

Finally, we might mention about another correction to the point-charge model. In this model, we tacitly assumed that the coefficients of the spherical harmonics of the second and fourth degrees of the potential are proportional to $r^2$ and $r^4$. This is valid only when $r$ is less than the radius of the sphere on whose surface lies one of the six neighbouring fluorine point charges; when $r$ exceed this radius these coefficient will no longer be proportional to $r^2$ and $r^4$. The actual $3d$ electron does not extend so far away and the correction due to this change is very small. Nevertheless, we took this small correction into account in the present calculation.

## § 4. Paramagnetic Susceptibility of FeF$_2$

The energy level splitting of the Fe$^{++}$ ion in FeF$_2$ obtained by the calculations described in the preceding sections is shown in Fig. 4. We adopted TKS's value of the polarizability $\alpha$ of the F$^-$ ion (the same for CoF$_2$, next paragraph). According to this result, the lowest excited level lies at about 1000 cm$^{-1}$ above the ground level, so that the ground state is predominantly populated at and below room temperature. In this temperature range, we are therefore allowed to confine ourselves to the ground state in calculating the paramagnetic susceptibility. Each of the split levels has five-fold degeneracy which, however, is lifted by introducing the spin-orbit coupling. The magnitude of the spin-orbit coupling constant is about $-100$ cm$^{-1}$, which is small compared to the energy level separations, so we can use Pryce's[13)] effective spin Hamiltonian for the ground quintet.

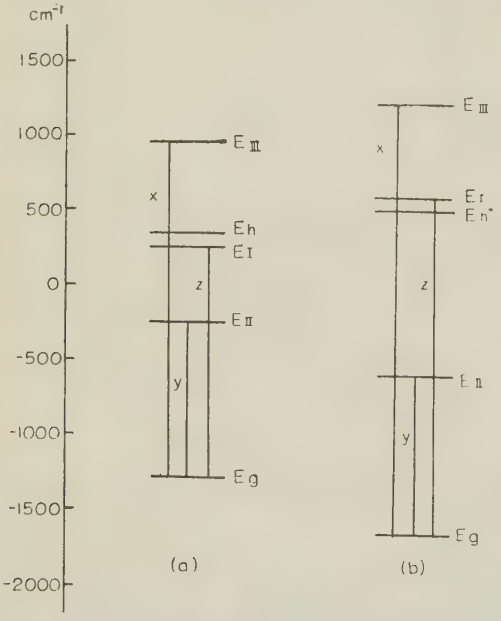

Fig. 4. Energy level splitting of Fe$^{++}$ ion in FeF$_2$. (a) is obtained taking account of the overlap effect calculated in § 3 and (b) increasing this effect by 10%. $x$, $y$ and $z$ represent the components of orbital angular momentum connecting the orbital ground and excited states.

We denote the spins on the body-centre sites by $\boldsymbol{S}^{(1)}$ and those on the corner sites by $\boldsymbol{S}^{(2)}$, and use the molecular field approximation to describe the exchange coupling among them. The effective spin Hamiltonian for the spins, say on the body-centre sites, is then written

$$\begin{aligned}\mathscr{H}^{(1)}=&-\lambda^2(\Lambda_x S_x^{(1)2}+\Lambda_y S_y^{(1)2}+\Lambda_z S_z^{(1)2})\\ &-\beta^2(\Lambda_x H_x^2+\Lambda_y^2 H_y+\Lambda_z H_z^2)\\ &+\beta(g_x H_x S_x^{(1)}+g_y H_y S_y^{(1)}+g_z H_z S_z^{(1)})\\ &-2J_1 z_1 \boldsymbol{S}^{(1)}\cdot\langle \boldsymbol{S}^{(2)}\rangle-2J_2 z_2 \boldsymbol{S}^{(1)}\cdot\langle \boldsymbol{S}^{(1)}\rangle\,, \quad (4.1)\end{aligned}$$

where $\lambda$ is the spin-orbit coupling constant ($\lambda=-100$ cm$^{-1}$ for the free Fe$^{++}$ ion[14)]), $\beta$ the Bohr magneton, $\boldsymbol{H}$ the external magnetic field, $J_1$, $J_2$ the exchange integrals between nearest neighbours and between second neighbours, $z_1(=6)$, $z_2(=2)$ the numbers of the nearest and second neighbours, and $\Lambda_x$, etc. are defined by

$$\Lambda_x=\sum_i \frac{(g|L_x|i)(i|L_x|g)}{E_i-E_g}\,,\ \text{etc.,} \quad (4.2)$$

where $\boldsymbol{L}$ stands for the orbital angular momentum and $g$, $i$, refer to the ground and excited orbital states; $g_x$, $g_y$, $g_z$ are the principal values of the $g$-tensor, the principal axes of which being the $x$-, $y$-, $z$-axes, and are related to $\Lambda_x$, etc. by

$$g_x=2(1-\lambda\Lambda_x)\,,\ \text{etc.} \quad (4.3)$$

The Hamiltonian for the ions on the corner sites is obtained by interchanging $\Lambda_x$, $g_x$ with $\Lambda_y$, $g_y$. The second term of the Hamiltonian (4.1), which is spin-independent and quadratic in $H$, corresponds to the second order interaction between the orbital magnetic moment and the external field, and gives a temperature-independent paramagnetic susceptibility. For a moment we drop this constant term from the Hamiltonian but will add it later. The third and fourth terms are to be regarded as small perturbations to the first term when we discuss the field-independent paramagnetic susceptibility above the Curie point, because then $H$ and $\langle S\rangle$ are small. So we write the Hamiltonian as

$$\mathscr{H}=\mathscr{H}_0+\mathscr{H}'\,,$$

where $\mathscr{H}'$ is the perturbing term. The matrices of $\mathscr{H}_0$ and $\mathscr{H}'$ in the representation diagonalizing $S_z^{(1)}$ can be obtained easily, and $\mathscr{H}_0$ can be diagonalized after transforming the spin functions of $S_z^{(1)}=1, -1$ by

$$\frac{1}{\sqrt{2}}\begin{pmatrix}1 & 1\\ 1 & -1\end{pmatrix}, \tag{4.4}$$

and the spin functions of $S_z^{(1)}=2, 0, -2$ by

$$\frac{1}{\sqrt{2}}\begin{pmatrix}\cos\theta & \sqrt{2}\sin\theta & \cos\theta\\ \sin\theta & -\sqrt{2}\cos\theta & \sin\theta\\ 1 & 0 & -1\end{pmatrix} \tag{4.5}$$

where

$$\tan 2\theta=\frac{\sqrt{3}\Lambda_-}{3\Lambda_z-\Lambda_+} \quad (\Lambda_\pm=\Lambda_x\pm i\Lambda_y)\,. \tag{4.6}$$

The diagonal elements of $\mathscr{H}_0/\lambda^2$ are then

$$\begin{aligned}
&1.\quad -\left(\Lambda_z+\frac{5}{2}\Lambda_++\frac{3}{2}\Lambda_-\right),\\
&2.\quad -\left(\Lambda_z+\frac{5}{2}\Lambda_+-\frac{3}{2}\Lambda_-\right),\\
&3.\quad -2(\Lambda_z+\Lambda_+)+\sqrt{4\Lambda_z^2+\Lambda_+^2+3\Lambda_-^2-4\Lambda_z\Lambda_+}\,,\\
&4.\quad -2(\Lambda_z+\Lambda_+)-\sqrt{4\Lambda_z^2+\Lambda_+^2+3\Lambda_-^2-4\Lambda_z\Lambda_+}\,,\\
&5.\quad -4\Lambda_z-\Lambda_+\,.
\end{aligned} \tag{4.7}$$

In this representation, the matrix of $\mathscr{H}'$ becomes as follows (the off-diagonal elements below the diagonal are omitted):

$$\mathscr{H}'=\begin{pmatrix}
0 & F_z^{(1)} & F_x^{(1)}(\cos\theta+\sqrt{3}\sin\theta) & F_x^{(1)}(\sin\theta-\sqrt{3}\cos\theta) & iF_y^{(1)}\\
 & 0 & iF_y^{(1)}(\cos\theta-\sqrt{3}\sin\theta) & iF_y(\sin\theta+\sqrt{3}\cos\theta) & F_x^{(1)}\\
 & & 0 & 0 & 2F_z^{(1)}\cos\theta\\
 & & & 0 & 2F_z^{(1)}\sin\theta\\
 & & & & 0
\end{pmatrix} \tag{4.8}$$

where

$$F_z^{(1)}=\beta g_zH_z-2J_1z_1\langle S_z^{(2)}\rangle-2J_2z_2\langle S_z^{(1)}\rangle\,, \quad \text{etc.}, \tag{4.9}$$

The paramagnetic susceptibility is given by the formula

$$\chi=\frac{1}{H}\frac{1}{Z_0}\sum_{nn'}\frac{\exp(-E_n/kT)-\exp(-E_{n'}/kT)}{E_{n'}-E_n}\frac{\partial}{\partial H}|(\mathscr{H}')_{nn'}|^2\,, \tag{4.10}$$

where $n$, $n'$ $(=1, 2, 3, 4, 5)$ refer to the eigen-state of $\mathscr{H}_0$ and $Z_0=\sum_n\exp(-E_n/kT)$. Taking the differentiation in (4,10) along the $z$-axis, $\chi_{\|}$ is obtained as

$$\chi_{\|}=\frac{\delta_1}{kT}\frac{1}{2H_z}\frac{\partial}{\partial H_z}F_z^2=\frac{\delta_1}{kT}\{g_z^2\beta^2+(2J_1z_1+2J_2z_2)\chi_{\|}\}\,,$$

where $\delta_1$ is given below by (4.14). The relation $g_z\beta\langle S_z\rangle=\chi_{\|}H_z$ was here used. It follows thus

$$\chi_{\|}=\frac{\delta_1\beta^2g_z^2}{kT-(2J_1z_1+2J_2z_2)\delta_1}\,.$$

The perpendicular susceptibility is obtained as the average of $\chi_x^{(1)}$ and $\chi_x^{(2)}$ $(=\chi_y^{(1)})$, which can be calculated in the same way as $\chi_{\|}$. With abbreviations

$$-(2J_1z_1-2J_2z_2)/k=\alpha\,, \qquad -(2J_1z_1+2J_2z_2)k=\gamma\,, \tag{4.11}$$

expressions for $\chi_{\|}$ and $\chi_{\perp}$, after adding the temperature-independent susceptibility, are obtained as

$$\chi_{\|}=N_0\beta^2\left[\frac{1}{k}\frac{\delta_1g_z^2}{T+\gamma\delta_1}+2\Lambda_z\right] \tag{4.12}$$

$$\chi_{\perp}=N_0\beta^2\left[\frac{\delta_2g_x^2+\delta_3g_y^2+\delta_2\delta_3\{(g_x-g_y)^2\gamma-(g_x+g_y)^2\alpha\}/2T}{k\{2T+(\delta_2+\delta_3)(\gamma-\alpha)-2\delta_2\delta_3\alpha\gamma/T\}}+\Lambda_x+\Lambda_y\right], \tag{4.13}$$

where

$$\delta_1=\frac{2kT}{Z_0}\left[\frac{\exp(-E_1/kT)-\exp(-E_2/kT)}{E_2-E_1}+\frac{\exp(-E_3/kT)-\exp(-E_5/kT)}{E_5-E_3}4\cos^2\theta\right.$$
$$\left.+\frac{\exp(-E_4/kT)-\exp(-E_5/kT)}{E_5-E_4}4\sin^2\theta\right]$$

$$\delta_2=\frac{2kT}{Z_0}\Big[\frac{\exp(-E_1/kT)-\exp(-E_3/kT)}{E_3-E_1}(\cos\theta+\sqrt{3}\sin\theta)^2 \tag{4.14}$$

$$+\frac{\exp(-E_1/kT)-\exp(-E_4/kT)}{E_4-E_1}(\sin\theta-\sqrt{3}\cos\theta)^2+\frac{\exp(-E_2/kT)-\exp(-E_5/kT)}{E_5-E_2}$$

$$\delta_3=\frac{2kT}{Z_0}\Big[\frac{\exp(-E_1/kT)-\exp(-E_5/kT)}{E_5-E_1}+\frac{\exp(-E_2/kT)-\exp(-E_3/kT)}{E_3-E_2}(\cos\theta-\sqrt{3}\sin\theta)^2$$

$$+\frac{\exp(-E_2/kT)-\exp(-E_4/kT)}{E_4-E_2}(\sin\theta+\sqrt{3}\cos\theta)^2\Big].$$

Next we turn to numerical evaluations. $\alpha$ can be estimated from the experimental value of the Curie temperature with the use of the relation $T_c=\alpha\delta_1$, which is given by the molecular field theory. $\gamma$ may be so chosen as to make the calculated susceptibilities fit their experimental values. For convenience, however, we estimate it from the powder susceptibility data[15] using the relation between $\Theta$ (paramagnetic Curie temperature) and $T_c$ given by the molecular field theory; then we obtain $\gamma=1.48\,\alpha$. $T_c$ is 78.3°K from the specific heat measurements.

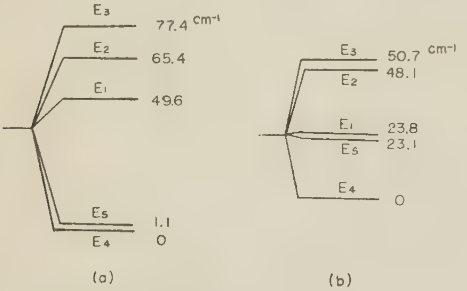

Fig. 5. Quintet separation of orbital ground state of Fe⁺⁺ ion.
(a) is obtained taking account of the overlap effect calculated in § 3 and (b) increasing this effect by 10%.

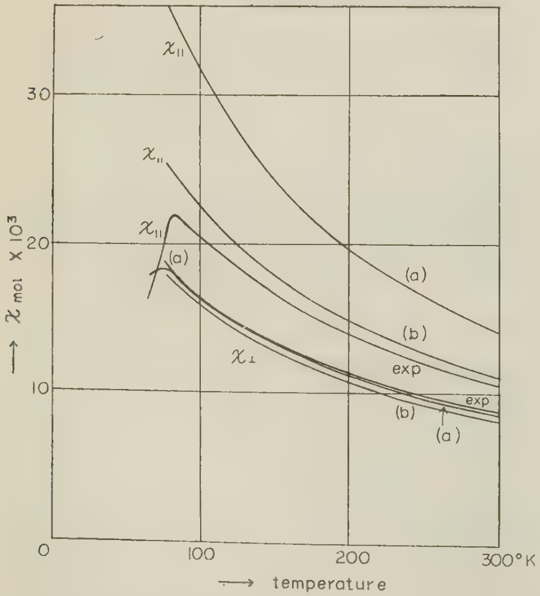

Fig. 6. Paramagnetic parallel and perpendicular susceptibilities of $FeF_2$.
(a) are obtained taking account of the overlap effect calculated in § 3 and (b) increasing this effect by 10%.

The results of the numerical computations are as follows. The $g$-tensor and $\alpha$ and $\gamma$ are

$$g_x=2.168,\quad g_y=2.063,\quad g_z=2.492;$$
$$\alpha=26.8,\quad \gamma=39.7.$$

The quintet separations are as shown in Fig. 5 (a), where we used for $\lambda$ the value of the free iron ion.

The obtained paramangetic susceptibility is shown by curve (a) in Fig 6; we see that, though its general feature and the order of magnitude of $\chi_{\parallel}-\chi_{\perp}$ are right, the quantitative agreement is poor.

In order to improve the agreement, we changed the overlap potential calculated in § 3 by multiplying it by a suitable constant factor. In § 3 we took account of the extension of the $2p$-electron cloud of the F⁻ ion but neglected those of the $1s$ and $2s$ cloud. There may be other effects such as a change in the radial distribution of the electron density of the fluorine ions when they are brought into the crystal and also exchange effect between fluorine ions and the iron ions. With a hope to take all these effects, we simply multiply the overlap potential factor by a constant numerical factor. When this is taken to be 1.10, we get the following values:

$$g_x=2.175,\quad g_y=2.013.\quad g_z=2.306;$$
$$\alpha=32.9,\quad \gamma=48.6.$$

The quintet separations become as shown in Fig. 5 (b) and the calculated paramagnetic susceptibility as shown in Fig. 6, curve (b). The agreement has now become much improved;

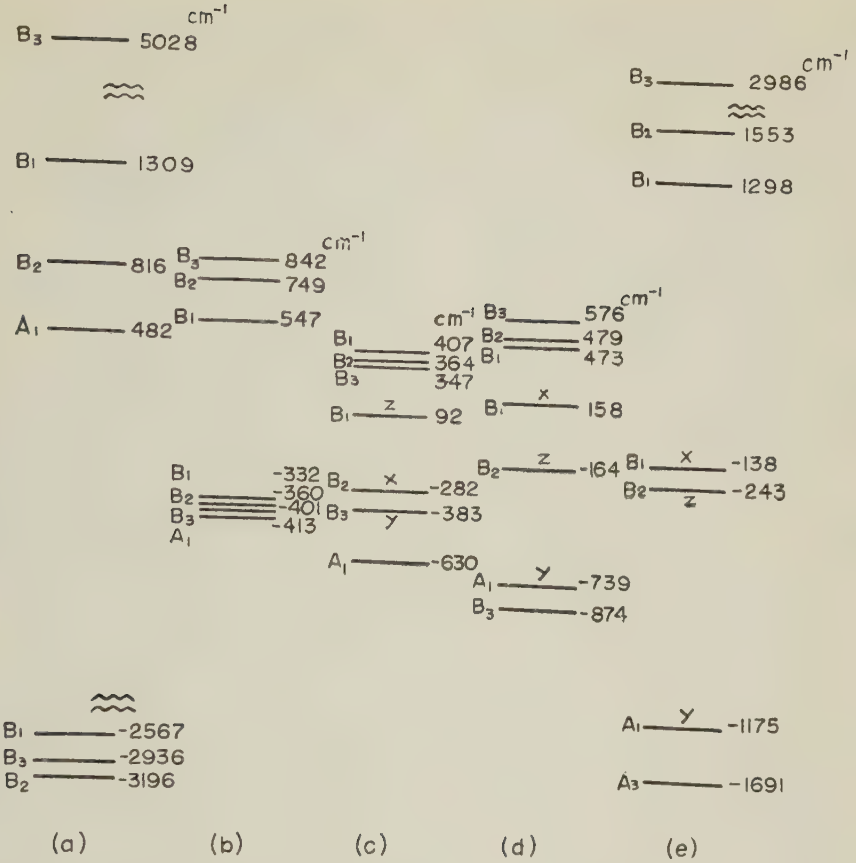

Fig. 7. Separation of orbital levels of $Co^{++}$ ion in $CoF_2$.
(a) is obtained with the use of the point charge model, (c) taking account of the overlap effect calculated in § 3, (d) and (e) increasing this effect by 10% and 50%, respectively, and (b) decreasing it by 20%. $x$, $y$ and $z$ represent the components of orbital angular momentum connecting the orbital ground state and the excited states indicated by them.

no better agreement could be obtained by taking other multiplicative factor.

## § 5. Calculation for $CoF_2$

The magnetic anisotropy of $CoF_2$ has been measured by Stout and Matarrese[2]. By combining their data with the powder susceptibility measurd by de Haas and Schultz[16], they have calculated the principal susceptibilities $\chi_\perp$ and $\chi_\parallel$. They found that the magnetic behaviours of $CoF_2$ differ much from those of $FeF_2$. According to the specific heat measurements by Stout and Catalano[4], $CoF_2$ has a Curie temperature of 37.7°K which is low compared with the Curie temperatures of other iron group fluorides. The magnetic anisotropy $\chi_\parallel - \chi_\perp$ of $CoF_2$ changes its sign at a temperature much higher than the Curie temperature, whereas in the case of $FeF_2$ this takes place just below the Curie temperature. The susceptibility perpendicular to the $c$-axis increases rapidly with decreasing temperature in the range between 100°K and 10°K; the susceptibility parallel to the $c$-axis does not tend to zero at 0°K. Though these anomalous behaviours of the principal susceptibilities are not yet confirmed by measurement with single crystal specimens, they make the study of $CoF_2$ very interesting.

We calculated the separation of the orbital levels of $Co^{++}$ using the potential calculated in § 2 and § 3. The results are shown in Fig. 7 (a)~(e). In these diagrams are indicated the components of the orbital angular momentum which connect the ground level to the corresponding upper levels. The magnitude of the matrix elements between these levels are nearly equal to 2 measured in units of $\hbar$. If we adopt the potential obtained by increasing the overlap effect by 10%, as we did in the case of $FeF_2$, the total energy separation of $^4F$ state of $Co^{++}$ is about 1450 $cm^{-1}$ and the separation between the ground level and the next level is only 140 $cm^{-1}$ as shown in Fig.7(d). Taking the spin-orbit coupling into account, each orbital state is split into two Kramers' doublets. When the energy separation between any two orbital levels is smaller than the spin-orbit coupling energy between them, the separations of doublets coming from these orbital levels are determined mainly by the spin-orbit coupling energy and there is a considerable mixing of the orbital wave functions of the doublets. If one of these doublets is the ground level and another of them lies closely to it, the orbital angular momentum will have a large effect on the magnetic behaviour of the substance. The absolute value of the coefficient $\lambda$ of the spin-orbit coupling energy is $-180$ $cm^{-1}$ for Co[14], which is larger than the separation between the ground orbital level and the next one shown in Fig. 7 (d), and the calculation with the spin-orbit interaction yields a separation as large as 300 $cm^{-1}$ between the lowest two doublets. We then have a large anisotropy of the $g$-factor, and the average $g$-value will exceed 3. Also the susceptibility will show an anomalous temperature dependence. However, the measurements of the powder susceptibility show that the average $\chi$ follows approximately the Curie-Weiss law and the $g$-value is about 2.4, and according to the measurements of the magnetic anisotropy at temperatures above 100°K, the anisotropy amounting only to 10% or less of the principal susceptibilities. Therefore we are led to conclude that the orbital angular momentum does not contribute so much to the magnetic property of $CoF_2$ as is expected from our potential. Moreover, with our potential, the population in the lowest doublet will always predominate below room temperature, so that it will be difficult to expect the change in sign of the anisotropy at a temperature considerably lower than room temperature. In § 4 we have obtained appropriate orbital levels for $FeF_2$ by increasing arbitrarily the overlap effect by 10%. So we expected to get a reasonable result also for $CoF_2$ by increasing or decreasing the overlap effect by a suitable percentage. This proved to be unsuccessful, however. In Fig. 7 (c) we show the levels when we adopt for the overlap effect the original value obtained in § 3. Other diagrams refer to cases where we assumed various percentage increases of the overlap effect. When we reduce the overlap effect, we cannot obtain a separation larger than 300 $cm^{-1}$ at any percentage between the ground orbital level and the next one. When we increase the overlap effect, we can obtain a larger separation, but in this case we see from the level separations and the value of the matrix elements that $\chi_\perp$ is always greater than $\chi_\parallel$. If we compare the cubic term, tetragonal term and orthorhombic term of the overlap potential calculated in § 3 with the corresponding ones of the potential calculated in § 2, we find that they are approximately equal in magnitude but have opposite signs to each other. So these two potentials have the same angular dependence. We therefore must conclude that this angular dependence cannot give a satisfactory explanation of the magnetic properties of $CoF_2$. There must be some other effects missing in our calculation which would give a different angular dependence of the potential energy of the cobalt $3d$ electrons. This point will be discussed further in the next section.

A consistent explanation of the magnetic properties of $CoF_2$ seems to have been given by Nakamura and Taketa. Their theory is based on the assumption that the energy differences between the ground orbital level and other levels are sufficiently large so that one can use safely the Hamiltonian derived by Pryce. Estimating phonomenologically the parameters included in the Hamiltonian, they showed that the orthorhombicity of the crystalline field is essential to the problem. The change in sign of the magnetic anisotropy with varying temperature was explained by the change in populations in two doublets into which the ground level is split by spin-orbit coupling. Qualitatively satisfactory explanations have been given of other properties. Though we cannot deny the possibility that these properties may come from a more complicated situation than those we considered in the present treatment, it is not yet clear where to find it.

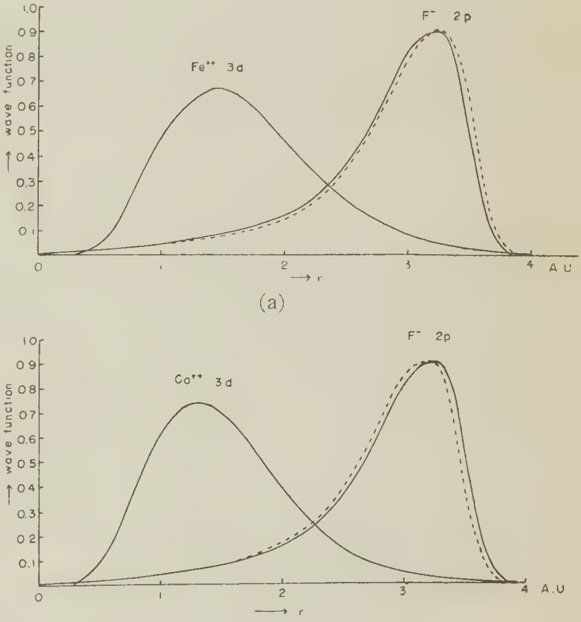
## § 6. Discussions

The result of our calculation proved to be reasonable for $FeF_2$ but not for $CoF_2$. Though we cannot see clearly at present wherein the discrepancy for the latter originates, we can imagine other possibilities than those taken into account in the present paper which might (or might not) improve the result for $CoF_2$ but preserve the good agreement obtained for $FeF_2$. We shall give below a brief discussion on this and the nature of the approximations made in our treatment.

We assumed at first that the crystal is purely ionic. We took into account only $(3d)^6$ and $(3d)^7$ configurations for $Fe^{++}$ and $Co^{++}$, respectively, and neglected all other higher configurations. From the standpoint of the perturbational treatment this means that we have calculated the first order correction to the free ion state. Therefore, if the actual crystal contains a considerable degree of covalency, our approximation will be poor. Even if the ionic model were correct, contraction and higher order deformations of the cation electron cloud due to a mixing of higher ionic configurations would have existed, but it seems that these deformations are less important than the covalent bonding because the energies of the ionic excited states are higher. As regards covalency, each of the $d$ orbitals split in the orthorhombic field will have different degree of covalency because each has different spatial distribution. Thus the split levels of $^4F$ of $CoF_2$ in crystalline field will have different degrees of covalency since they consists of different combinations of the split $d$ orbitals. Consequently one may expect that the relative separations of the energy levels suffer a considerable change when covalency is taken into account. Although we cannot see without calculation how large this effect is, a possible improvement might be found in it.

There are evidences of the existence of covalent bonding in ionic crystals. Kanda[17] found by means of nuclear magnetic resonance that some alkali halide crystals possess several percent of covalency. More recently, Owen[18] showed that the optical and magnetic data of hydrated iron group salts can consistently be explained by considering a partial covalency between the metallic $3d$ orbitals and the surrounding oxygen $2s$ and $2p$ orbitals. Assuming a partial covalency, he explained an apparent reduction of the spin-orbit coupling constant $\lambda$ and of the term separation observed in these crystals.

We can naturally consider the existence of a partial covalency also in iron group fluorides. However, the state of affairs to be considered is much more complicated in this case than in the hydrated salts because we have to seek wave functions appropriate to a less symmetrical arrangement of ions and moreover to consider them simultaneously for all the ions in the crystal. It is not clear, however, that the effect of covalency is important only for $CoF_2$.



(a)

(b)

Fig. 8. (a) Electron cloud density of a $3d$-electron of $Fe^{++}$ and that of a $2p$-electron of $F^-$ in $FeF_2$. $r$ measures (in atomic units) the distance from the nuclei of the $Fe^{++}$. Solid curve for $F^-$ represents the electron cloud of one of the two fluorine ions which contact with the iron in along the [110] direction and broken curve that of these which contact at above and below. (b) The same for $CoF_2$.

In our calculation of the overlap correction we neglected the exchange interaction between the $3d$ electrons of the metal ions and the closed shells of the surrounding $F^-$ ions. It appears, however, that, as the exchange integral is large when overlapping is large, a considerable part of this effect has been effectively included in the correction factor to overlapping which we rather arbitrarily introduced in § 4 and § 5. Thus the exchange interaction would probably not improve our result.

Effect of the polarization of $F^-$ ions (the displacement of their electron cloud) on the overlap potential was also neglected, but the estimation of its order of magnitude shows that it is negligible.

A possible error might have arisen in our calculations also from the use of the Slater function for the *d* orbital. We tried other functions as we mentioned in § 3. We did this for $FeF_2$ but found it rather unsatisfactory. Possibly, a more suitable wave function than Slater's will improve the result for $CoF_2$, but we do not know what is the better wave function. We show in Fig. 8 the radial charge distribution of a $3d$ electron of $Fe^{++}$ and $Co^{++}$ ion as well as that of a $2p$ electron of $F^-$ ion, of which we made use in this study.

In concluding, we would like to stress again on our conclusion that for iron group fluorides the simple point charge model is not enough for the crystalline field but the overlapping of the electron clouds is likewise important. Although we could not get a reasonable result for $CoF_2$ (since the effects of these two cancelled each other to a great extent), one cannot by any means deny that these two are of primary importance in considering the magnetic anisotropy of this salt and of other salt; there must be some minute effects in $CoF_2$ which we could not find in the present calculation.

The authors wish to thank Dr. K. Yosida for many valuable discussions. The present work has been supported in part by a Grant in Aid from the Ministry of Education.

## Appendix

### Calculation of the coefficients of the crystalline field due to the space charge of fluorine ions.

We donote by $(\beta_j, \alpha_j)$ the polar and azimuthal angles of $\boldsymbol{P}_j$ (vector drawn from the magnetic ion to the $j$-th neighbouring fluorine ion) referred to the $x$, $y$, $z$-axes defined in § 2 and by $(r, \theta_j, \varphi_j)$ the polar coordinates of point $\boldsymbol{r}$ taking $\boldsymbol{P}_j$ as the polar axis, then we have the relation[19)]

$$Y_{lm}(\theta, \varphi)=\sum_{m'} \mathfrak{D}^{(l)}(\{\alpha_j, \beta_j, 0\})_{mm'}{}^* Y_{lm'}(\theta_j, \varphi_j)\ , \tag{A.1}$$

where $\mathfrak{D}^{(l)}(\{\alpha, \beta, \gamma\})$ is the matrix of the $l$-th irreducible representation of the rotation group and $\alpha$, $\beta$, $\gamma$ are the Euler angles of the coordinate transformation from the $x$, $y$, $z$-system to a new system which, in the present case, is such that the new $z$-axis is along $\boldsymbol{P}_j$ and $\gamma$ is taken to be zero for convenience.

From eqs. (3.2), (3.3) and (A.1). we obtain

$$\begin{aligned}\varphi_{lm}(r)&=\int Y_{lm}{}^*(\theta, \varphi) \sum_{j=1}^{6} \phi(x_j) d\Omega \\ &=\sum_{j=1}^{6} \sum_{m'} \mathfrak{D}^{(l)}(\{\alpha_j, \beta_j, 0\})_{mm'} \int \phi(x_j) Y_{lm'}{}^*(\theta_j, \varphi_j) d\Omega_j\ .\end{aligned}$$

where $d\Omega$ and $d\Omega_j$ are the solid angle elements. Since $\phi(x_j)$ has an axial symmetry around the direction of $\boldsymbol{P}_j$, the integral in the above expression vanishes except for $m'=0$, so that

$$\varphi_{lm}(r)=\sum_{j=1}^{6} \mathfrak{D}^{l}(\{\alpha_j, \beta_j, 0\})_{m0} \varphi_0(r;\ j)\ , \tag{A.2}$$

where

$$\begin{aligned}\varphi_l(r;\ j)&=\int \phi(x_j) Y_{l0}(\theta_j, \varphi_j) d\Omega \\ &=\sqrt{2\pi} \int_{-1}^{1} \phi(\sqrt{r^2+P_j{}^2-2P_j r z})\, \Theta_{l0}(z) dz\ ,\end{aligned} \tag{A.3}$$

with

$$\Theta_{20}(z)=\sqrt{\frac{5}{8}}\,(3z^2-1)\,,$$
$$\Theta_{40}(z)=\frac{9}{8\sqrt{2}}\left(\frac{35}{3}z^4-10z^2+1\right). \tag{A.4}$$

Referring to Fig. 3, we have the following matrix elements appearing in (A. 2):

| | for $j=1, 2$ | $j=3, 4, 5, 6$ |
|---|---|---|
| $\mathfrak{D}_{\pm 20}{}^{(2)}=$ | $-\frac{\sqrt{6}}{4}$ | $\frac{\sqrt{6}}{4}\sin^2\theta$ |
| $\mathfrak{D}_{00}{}^{(2)}=$ | $-\frac{1}{2}$ | $\frac{1}{2}(3\cos^2\theta-1)$ |
| $\mathfrak{D}_{\pm 40}{}^{(4)}=$ | $\frac{\sqrt{70}}{16}$ | $\frac{\sqrt{70}}{16}\sin^4\theta$ |
| $\mathfrak{D}_{\pm 20}{}^{(4)}=$ | $\frac{\sqrt{10}}{8}$ | $\frac{\sqrt{10}}{8}(7\cos^2\theta-1)$ |
| $\mathfrak{D}_{00}{}^{(4)}=$ | $\frac{3}{8}$ | $\cos^4\theta-3\sin^2\theta\cos^2\theta+\frac{3}{8}\sin^4\theta$ . |

From these results we obtain the overlap part $A_0(r)$, $B_0(r)$, $\cdots G_0(r)$ of $A(r)$, $B(r)$, $\cdots G(r)$ follows:

$$A_0(r)=\frac{3\sqrt{5}}{4\sqrt{\pi}}[-\varphi_2(r;1)+2\sin^2\theta\varphi_2(r;2)]$$
$$B_0(r)=\frac{\sqrt{5}}{4\sqrt{\pi}}[-\varphi_2(r;1)+2(3\cos^2\theta-1)\varphi_2(r;2)]$$
$$D_0(r)=\frac{105}{16\sqrt{\pi}}[\varphi_4(r;1)+2\sin^4\theta\,\varphi_4(r;2)]$$
$$F_0(r)=\frac{15}{16\sqrt{\pi}}\left[\left(\frac{3}{4}-70\right)\varphi_4(r;1)+\left\{4\cos^2\theta-12\sin^2\theta\cos^2\theta-\left(2\sqrt{70}-\frac{3}{2}\right)\sin^4\theta\right\}\varphi_4(r;2)\right]$$
$$G_0(r)=\frac{15}{16\sqrt{\pi}}[\varphi_4(r;1)+2\sin^2\theta(7\cos^2\theta-1)\varphi_4(r;2)]\,. \tag{A.5}$$

# On the Superstructure of the Ordered Alloy $Cu_3Pd$ *
# I. Electron Diffraction Study

By Denjiro WATANABE and Shiro OGAWA

*The Research Institute for Iron, Steel and Other Metals,*
*Tohoku University, Sendai*

(Received October 24, 1955)

Ordered structures of copper-palladium alloys, chiefly of $\alpha''$ phase (18 ~28 atomic per cent Pd) were investigated by electron diffraction, using orientated, evaporated films. The elucidated structure of $\alpha''$ phase can be thought of as formed from the elementary face-centred tetragonal lattice, in which the atoms arrange themselves as in the ordered lattice of $Cu_3Au$ but the two kinds of step-shift occur at every definite distance along two directions parallel to the crystallographical axes, respectively. Thus, a two-dimensional anti-phase domain structure takes place, which is considered to have a large orthorhombic unit cell. The present model seems to be connected, not with that proposed by Geisler and Newkirk, but closely with that proposed by Schubert *et al.*

## § 1. Introduction

It has been known that two types of ordered alloy, CuPd and $Cu_3Pd$, are present in the copper-palladium alloy system[1]. The former has the CsCl type and is styled $\beta$ phase, as shown in Fig. 1, and the phase to which the latter belongs is subdivided into $\alpha'$ and $\alpha''$ phases. According to Jones and Sykes[2], $\alpha'$ phase has the $Cu_3Au$ type, while $\alpha''$ phase seemed to have a more complicated structure and it was only known that the lattice of $\alpha''$ phase is built up from face-centred tetragonal cells in terms of original disordered face-centred cubic cells, the lattice constants being $a=3.707$ Å, $c/a=0.986$ at 25 per cent Pd* after a slow cooling from 500 to 250°C in four months. The distributing manner of copper and palladium atoms in the lattice, however, could not definitely be determined by them. Recently, some experimental works on this ordered phase have been done. Jones and Owen[3] estimated by X-rays the temperature dependence of the long-range order of $\alpha''$ phase from values of $c/a$ measured in a polycrystalline alloy containing 25 per cent Pd, but reported none on the atomic arrangement of this phase. On the other hand, Geisler and Newkirk[4] analyzed by X-rays the ordered structure of the polycrystalline alloy, $Cu_4Pd$, which had been annealed at 450°C for three months, and concluded that the ordered phase is stable below 478°C and has a tetragonal unit cell of the modified $Ni_4Mo$ type, $a$ and $c$ being 5.826 Å and 7.328 Å respectively, and that a lattice of the $Cu_3Au$ type is produced by suitable introduction of some errors to this lattice.

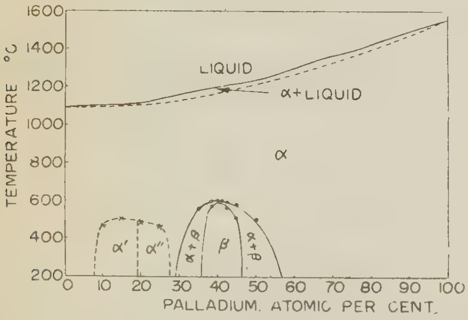

Fig. 1. Cu–Pd phase diagram.

The present work was undertaken to elucidate by electron diffraction the ordered structure of $\alpha''$ phase and also to examine the structure of the other ordered alloys, i.e., of $\alpha'$ and $\beta$ phases. Electron diffraction patterns of single-crystallike evaporated films of alloys give much informations to the problems of ordering, as proved in our previous work on the structure of CuAu II[5], because such a diffraction pattern nearly reproduces the intensity distribution on principal planes in reciprocal space, and hence informations concerning a crystal lattice can often intuitively be obtained. This method of observation was also adopted in the present work and the nature of the ordered phase $\alpha''$ has fully been elucidated, as shown in § 3 and 4. The results obtained are entirely different from those obtained by Geisler and Newkirk and show that this phase has a complicated two-dimensional anti-phase domain structure which contains a new type of out-of-step, besides a known type of out-of-step already found in $Cu_3Au$ and CuAu II. The change of sizes of these anti-phase domains with composition leads to the structural connection between $\alpha''$ and $\alpha'$ phase.

---

* A short note concerning this work has been published in Acta Cryst. **8** (1955) 510.

* Hereafter, a mere "per cent" will be used in place of "atomic per cent", since all compositions are expressed by atomic per cent of palladium in the present paper.

## § 2. Experimental Method

Single-crystallike films of copper-palladium alloys were formed in a usual way: copper and palladium were drawn to wires of 0.2mm in diameter, laid together in a tungsten filament and evaporated *in vacuo* on to cleavage surface of rocksalt heated at 300~350°C. The suitable thickness of films was 400~550 Å. Films mounted on a supporter of nickel were heated *in vacuo* in a silica tube and quenched by pouring water to the tube. This procedure of quenching seems to be nearly sufficient for copper-palladium alloys except $\beta$ phase, because the relaxation time for ordering is very large, especially, for $\alpha''$ phase, but the method may be considered to be insufficient, e.g., for drawing some conclusions from diffuse scatterings observed at superlattice reflection positions in patterns of films quenched from temperatures above the critical point. Such an investigation should be carried out by a high-temperature diffraction camera, the use of which is scheduled in a sequel of the present work. All results in the present work were obtained only from quenched films. After being homogenized at 600~800°C and quenched from the disordered state, films were annealed at various temperatures below the critical point for various durations. The composition of films was determined from the lattice parameter at the disordered state, using the X-ray data6) combining composition and lattice parameter. The used diffraction camera7) was of ED-C type made by Hitachi Co. and the applied voltage was about 50 KV. The majority of diffraction photographs was taken at normal incidence, i.e., the beam direction was parallel to a cube edge of disordered single crystal.

## § 3. Experimental Results

Alloy films of $\alpha'$ and $\alpha''$ phases were prepared, their palladium contents being 10, 13, 16, 18, 21, 25 (two specimens), 28 and 30 per cent, respectively, within the experimental error of ±1 per cent. Specimens whose compositions were planned to correspond to $\beta$ phase were also prepared, but their palladium contents were not determined, because the quenching of the disordered state was not successful owing to very quick formations of the ordered $\beta$ phase. In this section, experimental results obtained from specimens of $\beta$ phase will first be given and next those obtained from specimens of $\alpha'$ and $\alpha''$ phases will fully be described.

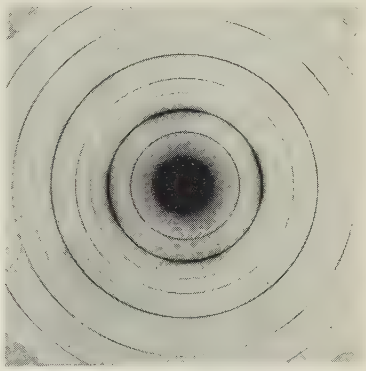

Fig. 2. $\beta$-phase, CsCl type.

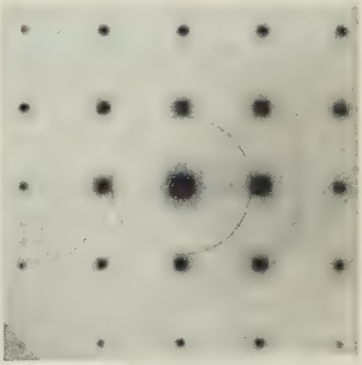

Fig. 3. Secondary diffraction from films containing Pd more than 25 per cent before homogenization.

### (1) *Specimens of $\beta$ phase*

From specimens whose compositions were planned to correspond to $\beta$ phase, both sharp body-centred cubic rings arising from a lattice of the CsCl type and weak face-centred cubic spots showing the orientation which follows that of the substrate were obtained before homogenization of films. The rings remained almost unchanged in their aspect even after being annealed at about 400°C for 10 hours, while the spots completely vanished, as shown in Fig. 2. Lattice spacings obtained from the rings nearly coincided with the X-ray data[6][8] for the ordered phase CuPd. But these X-ray data are somewhat different with different investigators and do not seem to permit the determination of compositions. It is noted that single-crystallike films of β phase were not formed by the present method.

(2) *Specimens of* α′ and α″ *phases*

Films containing palladium less than 25 per cent showed only face-centred cubic spots with weak superlattice reflections before homogenization, but those containing palladium more than 25 per cent exhibited, besides face-centred cubic spots with weak superlattice reflections, sharp body-centred cubic rings due to β phase. These rings often appeared also around intense normal spots, owing to the secondary diffraction as shown in Fig. 3. The body-centred rings, probably arising from places of high concentration of palladium before homogenization, became very faint after annealing above 350°C, and at the same time diffuse crosses and streaks appeared at superlattice reflection positions of the face-centred cubic pattern, just as in CuAu II. In such patterns (Fig. 4) faint spots were occasionally observed close to the direct spot and along two ⟨110⟩ directions passing through it. A discussion on this fact will be given in § 4. The body-centred rings completely vanished at 500°C, leaving the face-centred cubic spots with diffuse crosses and streaks. These crosses and streaks also appeared in patterns of films containing palladium less than 25 per cent and decreased their sizes with decreasing palladium content, finally transforming to spots at palladium content less than 18 per cent. The superlattice reflections remained, becoming faint and diffuse, even after quenching from any temperature between 500 and 800°C.

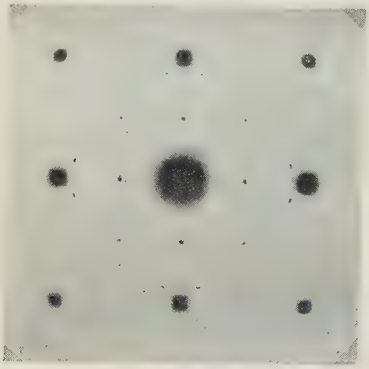

Fig. 4. Satellites flanking the direct spot due to secondary diffraction.

Detailed observations on patterns of alloys subject to various heat-treatments were carried out. After quenching from the disordered state seven samples were annealed *in vacuo* in such a manner as shown in Table I. These treatments seemed to be sufficient to develop a highly ordered structure, because the ordering process probably proceeds more rapidly in thin films, owing to the small grain size as well as the presence of a large number of dislocations and vacancies, than in bulk specimens. Specimens were quenched at the end of duration at each maintained temperature and, after observation of diffraction patterns, again subjected to a next heat-treatment. The results of observation are divided into the following two articles, the latter of which concerns α″ phase and is a main product in the present work.

Table I. Heat-treatments of samples of α′ and α″ phases.

| Sample. / Annealing Temp. (°C) | 25, 28, 30% Pd. | 18, 21% Pd. | 13% Pd. |
|---|---|---|---|
| 450 | 5～8 (hours) | 3 (hours) | 2 (hours) |
| 440 | 8 | ↓ | |
| 400 | 40 | 15 | ↓ |
| 380 | ↓ | ↓ | 10 |

and intense after annealing at 450°C for 2 hours, and the pattern did not change its aspect through the successive treatments at lower temperatures, except the further intensification of the superlattice reflections (Fig. 5). From the resemblance of the patterns the ordered structure of the present alloy is considered to be analogous to that of $Cu_3Au$. This result agrees with previous works[2)9)10)]. When the alloy film was again heated at higher temperatures, the pattern scarcely changed until 490°C, though the superlattice reflections were somewhat weakened. These reflections became faint and slightly diffuse at 510°C and still fainter above 530°C but did not advance in their diffuseness. The simple form of the superlattice reflections seems to reveal that anti-phase domains, such as observed in incompletely ordered $Cu_3Au$[11)], are absent in this composition below and above the critical temperature. Alloys of 10 and 16 per cent Pd were treated in a simpler way than the case of the alloy 13 per cent, and diffraction patterns similar to those of 13 per cent were observed.

### b) *Specimens of $\alpha''$ phase (palladium content more than* 18 *per cent)*

The ordered alloys of this phase were shown to have a face-centred tetragonal lattice in

terms of the disordered face-centred cell, as reported by Jones and Sykes[2], though a true unit cell is considered to be a large orthorhombic one, as will be described in § 4. The axial ratio of the tetragonal lattice decreased down to 0.993 at 25 per sent Pd and seemed to have a minimum in the neighbourhood of this content, increasing to unity with deviation of palladium content from 25 per cent. With the progress of ordering the superlattice reflections exhibited complex splits and satellites appeared around the normal spots including the direct spot. Details of these aspects are described about the sample of 25 per cent Pd as follows: After quenching from 500~750°C the alloy film showed diffuse crosses and doublets in its diffraction pattern, as seen in Fig. 6. These residual superlattice reflections looked far more distinct than those obtained from CuAu quenched from temperatures above the critical point[5]. They became very sharp and distinct after annealing at 440~450°C for some hours, as shown in Fig. 7a. Two splitting manners are seen in {100}* in this pattern. One of them occurs along a direction perpendicular to a line connecting the centre of the said reflection with the direct spot and is similar to that obtained from CuAuII or partially ordered $Cu_3Au$. The other splitting more faintly occurs along a direction parallel to the line connecting the centre of the said reflection with the direct spot and has not so far been observed. There are two values of separation, "$m$" and "$m'$", in these splittings, which are observed also in {110}, as illustrated in Fig. 7b. On further annealings at 440~450°C the complex splits in superlattice reflections became still sharper and more intense, and at the same time two kinds of satellites appeared around the normal spots including the direct spot, as illustrated in Fig. 7c, their separations being twice as large as those of corresponding splits of superlattice reflections respectively. At about 400°C splits of the normal spots of higher indices due to the tetragonality were clearly seen, and faint reflections appeared at positions along lines connecting {100} with neighbouring {110}. After such a long period of annealing at lower temperatures that it took full fifteen days before finishing of the treatment at 230°C, the superlattice reflections and the satellites flanking the normal spots fairly increased their intensities, so that details in their aspect were made clear. For example, two kinds of separation became clearer in {100} and {110} and a new kind of satellites appeared around the normal spots, its separation being half as large as that of the one kind of the satellites mentioned above. The axial ratio decreased to 0.993 at this stage. This value do not agree with the X-ray data, 0.986[2)3)12)]. The estimated error in the present experiment is not so large. The origin of this discrepancy is not clear. The aspect of the pattern mentioned above is well reproduced in Fig. 8a and illustrated in Fig. 8b.

---

* Miller's indices relevant to the ordered lattice are used in terms of the original disordered face-centred cubic lattice throughout the present paper.

When the film was again heated up, the pattern changed almost reversibly. At 450°C the superlattice reflections somewhat weakened and the satellites flanking the normal spots became extremely faint. The tetragonality seemed still to remain, but the axial ratio very closely approached to unity. At 470°C the pattern completely changed. The diffuse superlattice reflections in this pattern means the collapse of long range order, but their shapes similar to those in lower temperatures may mean that anti-phase domains of a definite size still persist. The critical temperature seems to lie between 450 and 470°C for 25 per cent Pd, if the quenching is satisfactory.

The aspects of patterns corresponding to compositions other than 25 per cent Pd are described as follows. For 28 and 30 per cent Pd the patterns were much similar to those of 25 per cent, as shown in Fig. 9, except that the separations of the splits of the superlattice reflections became larger and the critical temperature decreased to a value between 390 and 420°C. The satellites flanking the normal spots were observed for 28 per cent, but not for 30 per cent. For 21 per cent Pd the separations of the splits became smaller than those for 25 per cent. The superlattice reflections somewhat weakened but increased in sharpness at 470°C (Fig. 10) before they diffused at 510°C. The critical temperature seems to lie between 490 and 510°C for this composition. For 18 per cent the behaviour of the superlattice reflections was just like for 21 per cent and the critical temperature seems to lie very close to that for 21 per cent. The satellites were absent for 21 and 18 per cent.

## § 4. Interpretations and Discussions for the Results

The determination of the structure of $\alpha''$ phase is a chief subject in the present work, and discussions will be concentrated on this topic. Prior to this, however, some photographs will be called to account. In Fig. 4 faint satellites are observed at a small scattering angle. Satellites close to the direct spot were observed also in the patterns of CuAu II[5)] or of the ordered $\alpha''$ alloys in the present work (e.g., Fig. 8), but the positions of satellites are entirely different in Fig. 4. After some considerations they could be interpreted as due to the secondary diffraction, intense {200} spots acting as secondary incident spots and twin spots situated inside {200} spots being reproduced around the primary incident spot. Intensities in reciprocal space due to {111} twin formation lie along the body-diagonals of the reciprocal lattice, and hence twin spots cannot appear at the [001] incidence, if the crystal is perfect. In thin films considerable rotations of crystallites occur after removal of films from rocksalt substrates[7)13)], therefore twin spots are observed even at the [001] incidence.

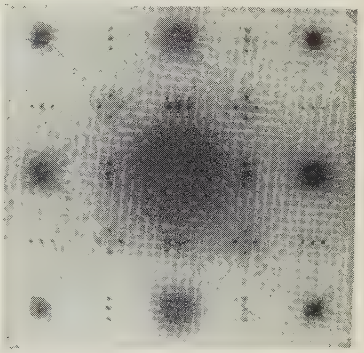

Fig. 9. Diffraction pattern from $\alpha''$-film containing 28 per cent Pd.

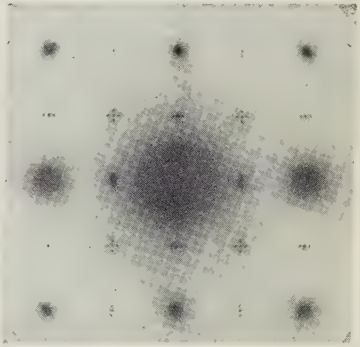

Fig. 10. Diffraction pattern from $\alpha''$-film containing 21 per cent Pd.

When the alloys of $\alpha''$ phases were quenched from temperatures above the critical points, weak diffuse crosses and doublets (or streaks) remained at superlattice reflection positions, as shown, e.g., in Fig. 6. It is suspected that these reflections are caused by the incomplete quenching. But, as the relaxation time for ordering is considerably large in the present alloys[2)], the aspect of superlattice reflections may probably reveal the actual state of the alloys above the critical point, that is, anti-phase domains of a nearly definite size may be present there. At any rate, this problem should be examined by direct observations at high temperatures.

Now, we shall closely examine the diffraction patterns of $\alpha''$ phase: The patterns shown in Fig. 7 and 8 resemble pretty well those obtained from CuAu II[5)], but the difference can be found in some respects, as already described in § 3. The main features in the present patterns are the splitting manner of {100} as well as {110} and the presence of two distinct values of separation. These features are difficult to discern just after quenching from temperatures above the critical point, but they distinguish themselves after a prolonged annealing. The tetragonality mentioned in § 3 is seen, in Fig. 8, not only in the fine splits of normal reflections of higher indices but also in the splits of superlattice reflections such as {100} and {110}. In such diffraction patterns it should be considered that a pattern corresponds to a superposition of orientations such that the tetragonal axis distributes into three directions of the original cubic axes. After a careful examination it is shown that the fundamental intensity distribution in reciprocal space can be induced from Fig. 8 and is depicted in Fig. 11, where separation "$m$" lies along the tetragonal direction and separation "$m'$" lies along another direction. The actual diffraction pattern corresponds to a sixfold superposition of this fundamental distribution, separation "$m$" taking three orientations and separation "$m'$" taking either orientation for a fixed orientation of separation "$m$". This superposition will later be discussed once more. Satellites around the main lattice points will also later be referred.

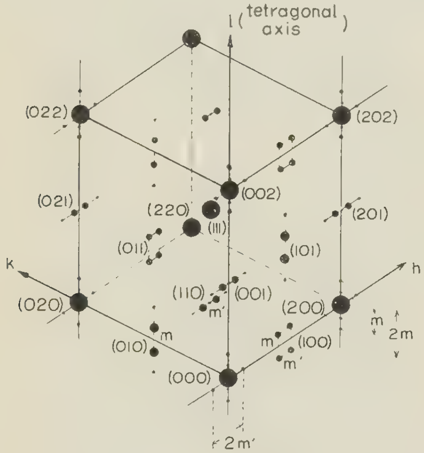

Fig. 11. Fundamental intensity distribution in reciprocal space induced from Fig. 8. Two symbols, •------• and •——•, are given to the two separations in superlattice reflections, $m$ and $m'$, respectively.

In Fig. 11 all the superlattice reflections with separation "$m$" or "$m'$" are thought of as formed by splitting of the reciprocal lattice points with mixed integers, $h_1, h_2$ and $h_3$. Hence the fundamental lattice of $\alpha''$ phase must be built up from face-centred cells with the atomic arrangement similar to that in $Cu_3Au$, and some kinds of out-of-steps must be introduced to this lattice. On the analogy of anti-phase domains in CuAu II or incompletely ordered $Cu_3Au$, the splits of the superlattice reflections of mixed $h_1$ and $h_2$ along $[00\,h_3]$ direction suggest that there is in a crystal a line-up of anti-phase domains with step shift $\pm(\boldsymbol{a}_1\pm\boldsymbol{a}_2)/2$ at every $M_3$-th atom along the $z$ direction[5)11)14)]. $\boldsymbol{a}_1, \boldsymbol{a}_2$ and $\boldsymbol{a}_3$ are the fundamental lattice vectors along $x, y$ and $z$ axes in terms of the fundamental cells. We shall call this type of out-of-step "the first kind of out-of-step". In reciprocal space the separation of the said split measured from its centre should be $(n_3/2M_3)a_3^*$, where $a_3^*$ is a reciprocal lattice constant corresponding to $\boldsymbol{a}_3$ and $n_3$ is an odd integer. On the other hand, the splits along $[h_1\,00]$ direction occur for mixed $h_3$ and $h_1$, with$_3$ a definite separation. This fact means a presence of anti-phase domains having a new kind of out-of-step with step shift $\pm(\boldsymbol{a}_3\pm\boldsymbol{a}_1)/2$ at every $M_1$-th atom along the $x$ direction. We shall call this "the second kind of out-of-step". In the above-mentioned consideration the number of anti-phase domains is assumed to be sufficiently large in every case. If the two kinds of out-of-step mentioned above occur in a crystal independently of each other, (100) in Fig. 11, e.g., should be split up from its centre along two directions, $[00\,h_3]$ and $[h_1\,00]$, forming a cross-like platelet as in CuAu II. Such a splitting manner is actually observed, faintly in Fig. 8, but in this figure as well as in Fig. 7 the oblique splits are distinctly visible. That is, the intensity distribution of (100) or (011) in Fig. 11 is mainly formed by double splits, which can be considered as follows: first, the original reciprocal lattice point is split up by either kind of out-of-step, and secondly, these splitted intensities are further split up by the other kind of out-of-step. The double splits mean both kinds of out-of-step not to be independent of but intimately connected with each other. These considerations lead to formation of a two-dimensional anti-phase domain structure, and a model of such a structure is proposed, as shown in Fig. 12(a), where $M_1$ and $M_3$ are assumed to be 5 and 4 respectively. If both $M$'s were definite throughout the crystal, an orthorhombic unit cell would be considered, as shown by the broad black lines.

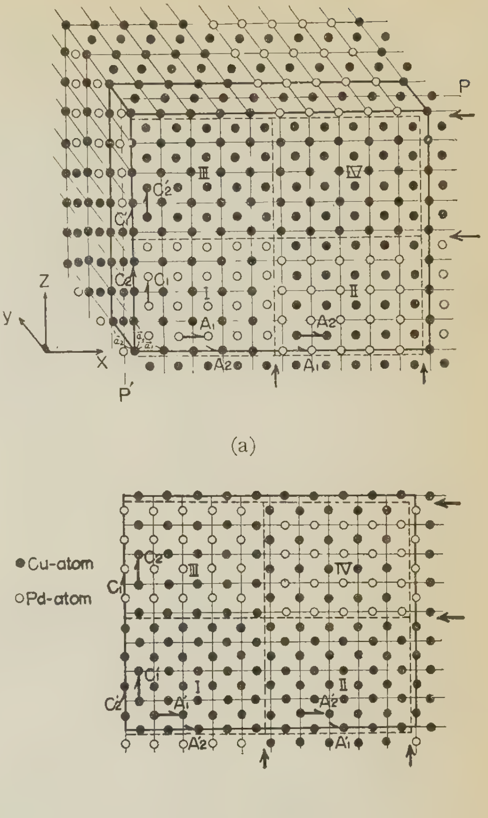

Fig. 12. Two-dimensional anti-phase domain structure. $M_1=5$ and $M_3=4$ are chosen in this model. Out-of-steps occur at places indicated by arrows.

(a) Orthorhombic unit cell is shown by the broad black lines.

(b) Distribution of atoms in the plane **PP′** situated immediately behind the front plane in (a).

Some explanations seem to be required about this model. Atom rows along the $z$ direction behave as follows: Any row of palladium atoms in the domain I, e. g. $\boldsymbol{C}_1$ row, has shifts, $(-\boldsymbol{a}_1+\boldsymbol{a}_2)/2$ and $(+\boldsymbol{a}_1-\boldsymbol{a}_2)/2$, alternately at every $M_3$-th atom, and any row of copper atoms in the domain I, e. g. $\boldsymbol{C}_2$ row, has shifts, $(+\boldsymbol{a}_1+\boldsymbol{a}_2)/2$ and $(-\boldsymbol{a}_1-\boldsymbol{a}_2)/2$, alternately at every $M_3$-th atom. Rows of copper atoms, $\boldsymbol{C}'_1$ and $\boldsymbol{C}'_2$ in Fig. 12(b), can be thought to have shifts $\pm(-\boldsymbol{a}_1-\boldsymbol{a}_2)/2$ and $\pm(\boldsymbol{a}_1-\boldsymbol{a}_2)/2$ respectively. Atom rows along the $x$ direction behave as follows: Any row of palladium atoms in the domain I in Fig. 12(a), e.g. $\boldsymbol{A}_1$ row, has shifts, $(-\boldsymbol{a}_3-\boldsymbol{a}_1)/2$ and $(+\boldsymbol{a}_3+\boldsymbol{a}_1)/2$, alternately at every $M_1$-th atom, and any row of copper atoms in the domain I, e.g. $\boldsymbol{A}_2$ row, has shifts, $(+\boldsymbol{a}_3+\boldsymbol{a}_1)/2$ and $(-\boldsymbol{a}_3-\boldsymbol{a}_1)/2$, alternately at every $M_1$-th atom. Rows of copper atoms, $\boldsymbol{A}_1'$ and $\boldsymbol{A}_2'$, can be thought to have shifts $\pm(-\boldsymbol{a}_3+\boldsymbol{a}_1)/2$ and $\pm(\boldsymbol{a}_3-\boldsymbol{a}_1)/2$ respectively. Thus, it will be seen that each of four basic atoms in the fundamental face-centred tetragonal cell has some of shifts, $\pm(\boldsymbol{a}_1\pm\boldsymbol{a}_2)/2$, at every $M_3$-th atom along the $z$ direction and also some of shifts, $\pm(\boldsymbol{a}_3\pm\boldsymbol{a}_1)/2$, at every $M_1$-th atom along the $x$ direction. These circumstances can be described in the following way: When the large orthorhombic unit cell is divided into four domains, as shown by the broken lines, sites of palladium atoms in these four domains correspond to four basic sites in the fundamental face-centred tetragonal lattice, respectively.

The structure amplitude for the lattice shown in Fig. 12, $|\boldsymbol{S}|$, is given by the following equation.

$$|S|=\left|\frac{\sin\pi N_1(2M_1)A_1}{\sin\pi(2M_1)A_1}\right|\cdot\left|\frac{\sin\pi M_1A_1}{\sin\pi A_1}\right|\cdot\left|\frac{\sin\pi N_2A_2}{\sin\pi A_2}\right|\cdot\left|\frac{\sin\pi N_3(2M_3)A_3}{\sin\pi(2M_3)A_3}\right|\cdot\left|\frac{\sin\pi M_3A_3}{\sin\pi A_3}\right|\cdot|\Phi|, \tag{1}$$

$$\begin{aligned}|\Phi|=|&[E_{Cu}\{1+\exp\pi i(A_1+A_2)+\exp\pi i(A_2+A_3)\}+E_{Pd}\exp\pi i(A_3+A_1)]\\&+[E_{Cu}\{1+\exp\pi i(A_1+A_2)+\exp\pi i(A_3+A_1)\}+E_{Pd}\exp\pi i(A_2+A_3)]\exp 2\pi iM_3A_3\\&+[E_{Cu}\{\exp\pi i(A_1+A_2)+\exp\pi i(A_2+A_3)+\exp\pi i(A_3+A_1)\}+E_{Pd}]\exp 2\pi iM_1A_1\\&+[E_{Cu}\{1+\exp\pi i(A_2+A_3)+\exp\pi i(A_3+A_1)\}+E_{Pd}\exp\pi i(A_1+A_2)]\exp 2\pi i(M_3A_3+M_1A_1)|,\end{aligned}$$

Table II. Calculation of $|\Psi|^2/|\Psi|^2_{(200)}$ for various splittings of superlattice reflections.
$M_1$ and $M_3$ are assmmed to be 5 and 4 respectively.
Splittings having $|\Psi|^2/|\Psi|^2_{(200)}$ less than $1.5\times10^{-4}$ and those corresponding to higher indices are omitted.

In this table, $|\Psi|^2/|\Psi|^2_{(200)}$ has been calculated under the following condition in order to simplify the calculation: $a=3.688$ Å, $c/a=1$.

where $A_1$, $A_2$ and $A_3$ are continuous variables in the reciprocal lattice, provided that the reciprocal lattice constants, $a_1^*$, $a_2^*$ and $a_3^*$, are considered in terms of the fundamental tetragonal cell, $N_1$ and $N_3$ are halves the numbers of anti-phase domains, i. e. the numbers themselves of orthorhombic unit cells, along the $x$ and $z$ directions respectively and assumed to be far larger than $M_1$ and $M_3$ respectively, $N_2$ is the number of unit cells, either tetragonal or orthorhombic, along the $y$ direction, and $E_{Cu}$ and $E_{Pd}$ are the atomic scattering factors for electron of copper and palladium respectively. $|\Phi|$ consists of sixteen terms corresponding to sixteen basic atoms in four fundamental face-centred cells, which represent the four domains in Fig. 12 respectively. There are such chances in equation (1) that $|S|$ has maxima at $A_1=h_1 \pm(n_1/2M_1)$, $A_2=h_2$, $A_3=h_3\pm(n_3/2M_3)$, where $h_1$, $h_2$ and $h_3$ are integers and $n_1$ and $n_3$ are 0 or odd integers. We shall calculate $|\sin\pi M_1A_1/\sin\pi A_1|\cdot|\sin\pi M_3A_3/\sin\pi A_3|\cdot|\Phi|\equiv|\Psi|$ to evaluate these maxima. At the said values of $A_1$, $A_2$ and $A_3$,

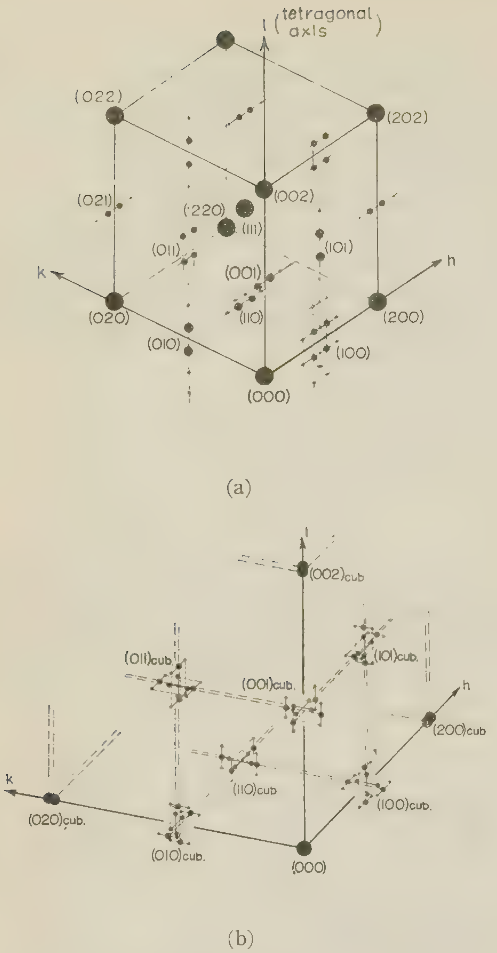
& \left.+E_{Pd}\exp\pi i\left(h_1+h_2\pm\frac{n_1}{2M_1}\right)\right]\cdot\exp\pi i(\pm n_3\pm n_1)\Bigg|. \qquad (2).
\end{aligned}
$$

---

$|\Psi|^2/|\Psi|^2_{(200)}$ is tabulated in Table II, $M_1$ and $M_3$ being assumed to be 5 and 4 respectively. On the basis of these estimated intensities the splitting manner of the superlattice reflections is depicted in Fig. 13a. The coincidence of this figure with Fig. 11 is fairly good, concerning the splits of the superlattice reflections. Since Fig. 13a or Fig. 11 represents the intensity distribution in reciprocal space corresponding to one orientation of the lattice, the intensity distribution in reciprocal space corresponding to an actual ordered alloy must be a sixfold superposition of the intensity distribution in Fig. 13a and is illustrated in Fig. 13b. The observed diffraction pattern is tolerably reproduced in the intensity distribution in the $hk$ plane in Fig. 13b. This tolerable reproducibility enables us to understand the propriety of the present model except some respects. There are some differences between the model and the observed facts as follows:

(1) The intensities cannot be expected at centres of the split superlattice reflections from the present model, while they were, in general, actually observed at some of centres, as in Fig. 11. In Fig. 8 the appearance of the centre spots of {100} groups may be explained from the model by assuming rotations of crystallites about the crystallographical axes, as often observed in thin films, but this manner of explanation does not apply to the centres of {110} groups. In Fig. 7, which corresponds to a state near the critical temperature, the centres of {100} groups are clearly visible, while the centres of {110} groups are very faint. This fact will be explained by assuming rotations of crystallities. In this



(a)

(b)

Fig. 13. (a) Fundamental intensity distribution in reciprocal space derived from the proposed model. Intensities corresponding to $|\Psi|^2/|\Psi|^2_{(200)}$ less than $2\times10^{-4}$ are omitted. The symbols, •------• and •——•, are used in the meaning similar to those in Fig. 11.
(b) Sixfold superposition of the intensity distribution in (a). This figure corresponds to the actual state of the ordered alloy.

sense, the model seems to have a better fitness to Fig. 7 than to Fig. 8. The appearance of the centre spots of {100} and {110} groups in the latter photograph suggests the increase of regions without the second kind of anti-phase domains at lower temperatures*. (In photographs from incompletely ordered $Cu_3Au$ intensities remain at centres of split maxima after formation of anti-phase domains.) The tendency that the centre spots of {110} become faint immediately below the critical temperature and become strong at lower temperatures was also observed in the specimens other than 25 per cent Pd. Higher order splits ($n_1, n_3=3$) which should be expected from the model are seen at some of the superlattice reflections in Fig. 11. They appear distinctly between {100} and {110} groups at lower temperatures (Fig. 8), but are not observed above about 400°C (Fig. 7). As the appearance of these reflections proves a high degree of development of the present anti-phase domain structure, the model seems to have a better fitness to Fig. 8 than to Fig. 7 in this sense. Thus, an ambiguity seems to be present, strictly speaking, about the propriety of the model, judging from the splitting manner of the superlattice reflections.

(2) Satellites flanking the intense normal spots cannot be derived from the present model. Three kinds of satellites are perceived in Fig. 11, and their separations from the relevant main reflections are $(a_1^*/M_1)$, $(a_3^*/M_3)$ and $(a_3^*/2M_3)$ in reciprocal space respectively. Satellites of a separation of the last value just appear after a long period of annealing, with a fainter intensity than the satellites of the other kinds. $|\Psi|$ has a finite value at $A_1=h_1\pm(n_1/2M_1)$, $A_2=h_2$, $A_3=h_3\pm(n_3/2M_3)$, where $h_1$, $h_2$ and $h_3$ are unmixed and $n_1$ and $n_3$ are odd integers. Some of these positions are only ones which can be expected in the neighbourhood of the main spots from the model, but they are entirely different from positions actually observed, and moreover, should belong, not to the normal reflections, but to the superlattice reflections, due to the term, $|E_{Cu}-E_{Pd}|$. Thus, the present model are not connected with the formation of the satellites.

Some discussions will be given of the origin of the satellites as follows. Two kinds of imperfection in a crystal lattice are considered as their causes, i.e., a periodic change of the scattering factor or a periodic change of the lattice constant[15]. For example, if the composition at each boundary between anti-phase domains would become different for some reason from that inside each domain in the course of the development of ordering, satellites should arise from the first cause. However, the observed satellites became strong and clear with the annealing time, i.e., proba-

---

* The presence of regions without both kinds of anti-phase domains cannot be considered, because only some of centres of split superlattice reflections have intensities in Fig. 11.

* These values are estimated, assuming $N$ to be smaller than $M$.

bly with the development of the two-dimensional anti-phase domain structure, and it is difficult at the present stage to consider that this structure should ultimately have a periodic change of composition. A remark should be made here. If the anti-phase domains characterized by the second kind of out-of-step are developed, as shown in Fig. 12, like atoms gather at each boundary between domains, the kind of atoms alternating. If the first kind of out-of-step would not occur, a periodic change of composition should be present and the scattering amplitude of the lattice should be modulated at a definite period, $2M_1a_1$, along the $x$ direction, the normal reflections being flanked with satellites of a separation $(a_1^*/2M_1)$. The existence of the first kind of out-of-step, however, compensates this periodic change of composition, and hence the normal reflections must be free from the effects of anti-phase domains. Next, if a periodic elongation or contraction of the lattice would occur at each boundary between anti-phase domains[5], satellites should arise from the second cause. In Fig. 12, an excess force cannot be considered to act at boundaries between domains along the $z$ direction characterized by the first kind of out-of-step, the circumstance being entirely different from that in CuAu II. On the other hand, a repulsive force might arise at boundaries between domains along the $x$ direction characterized by the second kind of out-of-step because of the gathering of like atoms. Thus, the origin of the satellites having a separation, $(a_1^*/M_1)$, might be found out here. An apparent expansion of the lattice along the $x$ direction should result from such a periodic error, but has not actually been detected. This condition, together with the complete lack of information about the origin of the stronger satellites having a separation, $(a_3^*/M_3)$, and of the faint satellites having a separation, $(a_3^*/2M_3)$, makes us give up a further research on this topic at the present stage. Satellites due to a periodic error of the scattering factor should be distinguished in the following point from those due to a periodic error of the lattice constant: The ratio of the intensity of satellites to that of the main reflection is independent of the order of reflection in the former case, while it increases with the order of reflection in the latter case. In thin films, however, the secondary diffraction often takes place and makes this criterion useless. In the previous work[5] the secondary diffraction effect increased the intensities of satellites flanking the normal spots other than the direct spot. Also in the present case the effect is probably present, though no distinct evidence for it has been given. The intensity of the satellites flanking the direct spot should be noticed, but its estimation is very difficult in Fig. 7 as well as in Fig. 8 owing to the intense background.

Although some corrections and replenishments to the present model may be necessary to explain completely not only the splitting manner of the superlattice reflections but also the origin of the saltellites flanking the normal spots, it will probably be safe to say that the two-dimensional anti-phase domain structure represents the actual state without serious error. In Fig. 12 the $y$ direction is equivalent to the $x$ direction with respect to the tetragonal axis, therefore, anti-phase domains characterized by the second kind of out-of-step might simultaneously be lined up also along the $y$ direction, that is, a three-dimensional anti-phase domain structure might be formed. The structure amplitude for such a lattice is easily calculated. The intensity distribution in reciprocal space derived from this structure amplitude, however, does not coincide with the observed results at all. Therefore, such a three-dimensional anti-phase domain structure is not thought to form actually.

The periods of occurrence of out-of-steps in the present structure, $M_1$ and $M_3$, were measured from separations of splits of the superlattice reflections as well as from separations of satellites flanking the normal spots and are given in Table III, together with the axial ratio of the fundamental tetragonal cell, for 18∼30 per cent Pd. The $M$ values are not integers in every concentration even after a long period of annealing. This fractional property is beyond experimental errors* and seems to suggest that some periodic fluctuation of the domain size is present within a coherent lattice, that is, that the structure shown in Fig. 12 is, strictly speaking, approximate and, in point of fact, a larger orthorhombic unit cell containing more than two domains of different size along the $x$ or $z$ direction may be considered. It is not certain whether the $M$ values settle in integers or remain fractional after a very long period of annealing.

According to the conception involved in the present work, there seems to be no discrete phase boundary between $\alpha'$ and $\alpha''$ phases. At 18 per cent Pd the separations in the splits of the superlattice reflections are so small that $M_3$ has a very large value, 10.5, and the axial ratio cannot be distinguished from unity. Thus, both the anti-phase domain structure and the tetragonality of the fundamental face-centred lattice, characteristic of $\alpha''$ phase, gradually fade away in the neighbourhood of 18 per cent Pd, and the structure is continuously changed to $\alpha'$ phase of the $Cu_3Au$ type with the decrease of palladium content. The present work has been carried out on the crystallographical standpoint, and the reason why the complicated anti-phase domain structure takes place in $Cu_3Pd$ should be explained from the standpoint of the electron theory of alloys.

## § 5. Conclusion

The present electron diffraction work on the ordered structure of $Cu_3Pd$ in thin orientated films has elucidated a complicated anti-phase domain structure present in $\alpha''$ phase. This structure can be thought of as formed from the elementary face-centred tetragonal lattice, in which the atoms arrange themselves as in the ordered structure of $Cu_3Au$ but the two kinds of step-shift, $\pm(\boldsymbol{a}_1\pm\boldsymbol{a}_2)/2$ and $\pm(\boldsymbol{a}_3\pm\boldsymbol{a}_1)/2$, occur at every $M_3$-th atom and $M_1$-th atom along the $z$ and $x$ directions respectively. Thus, the two-dimensional anti-phase domain structure is formed, which is considered to have a large orthorhombic unit cell, if $M_1$ and $M_3$ are sufficiently definite throughout the lattice. $M_1$ and $M_3$ are, however, not integers actually, even after a long period of annealing. The $M$ values monotonously decrease with the increase of palladium content. It is still better if the present model proposed on the basis of the experimental facts in thin films is confirmed in bulk specimens. This confirmation has recently succeeded in our laboratory, by taking X-ray stationary-crystal and oscillation photographs of ordered $\alpha''$ alloys of single-crystal. The detailed results will be reported in the second part of the present work.

The model of $\alpha''$ phase proposed by Geisler and Newkirk[4)] is entirely different from the present model. On the other hand, the structure reported by Schubert *et al*[16)], seems to be included in the present model. According to them ordered alloys of 18.5 to 25 atomic per cent Pd possess a one-dimensional anti-phase domain structure characterized by the first kind of out-of-step and ordered alloys of 25 to 29 atomic per cent Pd show a more complicated structure. It seems to the present authors that the last structure may be a two-dimensional anti-phase domain structure.

In conclusion, the present authors wish to express their sincere thanks to Mr. M. Hirabayashi for his kind discussions.

The present investigation has been supported

# Nuclear Magnetic Resonance Experiment on the Single Crystal of Lithium Sulfate Monohydrate, $Li_2SO_4H_2O$

By Eiji HIRAHARA and Miyuki MURAKAMI

*Department of Applied Physics, Faculty of Engineering,*
*Hiroshima University, Hiroshima*

(Received November 5, 1955)

Proton magnetic resonance absorption of water molecules in the single crystal of $Li_2SO_4 \cdot H_2O$ was observed, and the length and directions of the proton—proton line (p—p) of the water of crystallization were determined. The results obtained are as follows: there are two kinds of orientations of the p—p line in the unit cell, which contains two molecules of $Li_2SO_4 \cdot H_2O$, and they are symmetrically disposed with respect to the *ac*-plane, the plane of mirror, making the angles ±51° to that plane.

The angle between the projection of each p—p line on the *ac*-plane and the positive direction of *a*-axis is 94°, and the length of p—p line is 1.59 Å.

From the results obtained and the crystal structure by X-ray analysis, the bond angle of H—O—H is expected to lie between 106°50′ and 112°40′, and presumably some value nearer to 112°40′ may be taken to be favorable from the consideration of the bonding character.

The single crystals were prepared by a slow evaporation method from an aqueous solution in a water bath at 80°C.

## §1. Introduction

Nuclear magnetic resonance experiments on $Li_2SO_4 \cdot H_2O$ have been made by several workers[1]. Concerning the orientation of *the line joining the two protons of a water molecule* (say briefly p–p) in the crystal, however, their results are not consistent with the results of X-ray diffraction study by Ziegler[2]. Recently, Larson and Helmholz[3] have made a redetermination of the crystal structure by

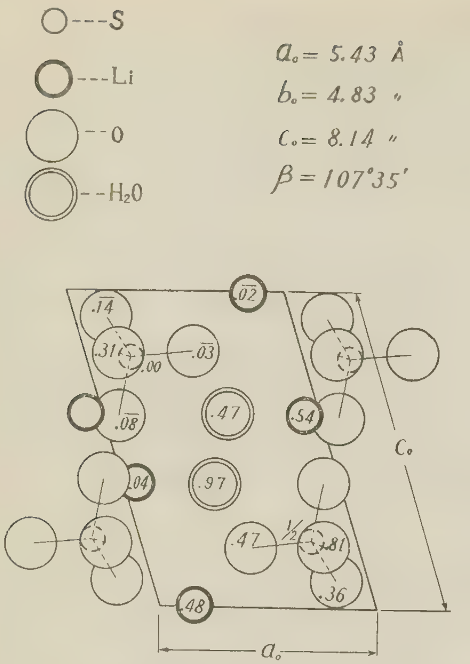

Fig. 1. Crystal structure of $Li_2SO_4 \cdot H_2O$. The projection of unit cell on the $b$-plane.

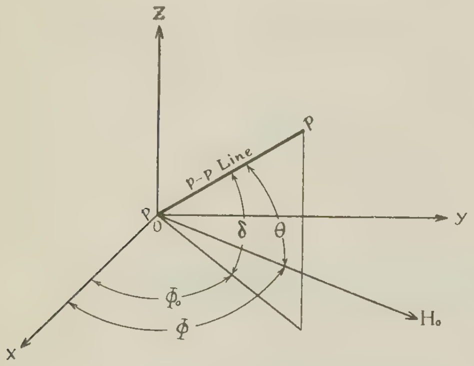

Fig. 2. Diagram defining various angles $\delta$, $\theta$, $\Phi$ and $\Phi_0$.

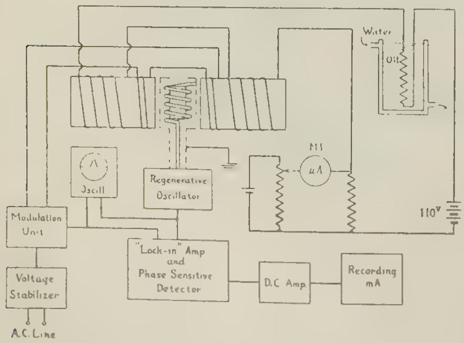

Fig. 3. Block diagram of apparatus and circuit system.

X-ray diffraction in order to check the work of Ziegler, and showed that their results are favorable for the orientation of the p–p line suggested by Pake[1]. In view of the situation, we have attempted to determine the orientation of the p–p line by means of nuclear magnetic resonance method and obtained the results somewhat different from Pake's in detailed respects.

According to Ziegler's results the crystal structure of $Li_2SO_4 \cdot H_2O$ is monoclinic and its space group is $C_2^2 - P2_1$. The dimensions of the unit cell are of $a_0 = 5.43$ Å, $b_0 = 4.83$ Å, $c_0 = 8.14$ Å, the angle between the $a$- and $c$-axes being 107°35′ $(=\beta)$, and the unit cell containing two molecules. Fig. 1 shows the projection of the unit cell on the $ac$-plane, and one of the two lithium ions in one molecule is seen to be situated nearer to a water molecule than the other.

According to the pioneer work by Pake[4] the shifts of the absorption lines of two-proton system from that of a free proton are represented as a function of the angle between the external field and the p–p line, by

$$\left.\begin{aligned} \Delta H &= \pm \alpha (3\cos^2\theta - 1) \\ \alpha &= \frac{3}{2}\mu r^{-3}, \end{aligned}\right\} \qquad (1)$$

under the assumption of rigid lattice. In these formulas $\mu$ is the magnetic moment of proton, $r$ the distance between two protons, $\theta$ the angle between the p–p line and the external field $H_0$, and $\delta$ the angle between the p–p line and its projection on the $xy$-plane (a plane perpendicular to the axis of rotation). A disposition of the p–p line with respect to the external field $H_0$ is shown in Fig. 2, from which the vector $\vec{H}_0$ is always on the $xy$-plane on rotating the crystal around $z$.

$\Phi$ is the angle between the external field $H_0$ and the reference line (say $x$-axis), and $\Phi_0$ the angle between the projection of the p–p line on the $xy$-plane and the reference line, of which a following relation holds

$$\cos\theta = \cos\delta \cdot \cos(\Phi - \Phi_0)\,. \qquad (2)$$

The orientation of the p–p line will be determined from the relations (1) and (2) observed at various values of $\Phi$.

## § 2. Preparation of Single Crystals and Experimental Arrangement

A single crystal of the hydrate was prepared from a solution of $Li_2SO_4$ by a slow evaporation method at constant temperature 80°C, through which the crystal grew up to the dimension of about $30 \times 15 \times 15\ \mathrm{mm}^3$ in a week. Then a sample was cut in a suitable shape, and the directions of the symmetry axes of crystal were examined with the aid of X-ray diffraction.

A block diagram of apparatus and circuit system is shown in Fig. 3. The oscillator used is an autodyne type detector, and the sample inserted in an oscillator coil is rotatable around the axis of the coil. A signal picked up from the oscillator coil is introduced to a narrow-band amplifier and detected by a phase-sensitive detector, from which the output is recorded by a recording milliammater through a d.c. amplifier. The electromagnet, with the pole face of 14 cm in diameter and the pole gap of 35 mm in length, yields the field strength of about 3800 gauss when it is excited by a d.c. current of about 4 ampere from a set of storage batteries.

A field modulation with a small amplitude at 60-c.p.s. is supplied from the commercial a.c. line through a voltage stabilizer and a modulation controller. A sweep of resonance line is attained by a slow changing of the magnet-coil current, which is realized as the result of Joule's heat generated in the magnet-coil. The current through the magnet-coil is measured by a potentiometric device as shown in Fig. 3, and the values of the magneticfield strength corresponding to the current are marked on the recording-milliammeter chart.

## § 3. Measurements and Results

The sample first measured (its dimension, $20 \times 10 \times 6\ \mathrm{mm}^3$) is shown in Fig. 4, in which (a) is its perspective diagram and (b) is its horizontal section cut perpendicularly to the *b*-axis. On rotating the sample around the *b*-axis in an external field the derivative curves of absorption obtained were shown in Fig. 5. The corresponding values of the angle between the external field $H_0$ and the line $x$ shown in Fig. 4 (b) are indicated beside each curve. The modulation width is indicated by the horizontal line at the upper left-side corner in the figure. The corresponding integral curves are shown in Fig. 6.

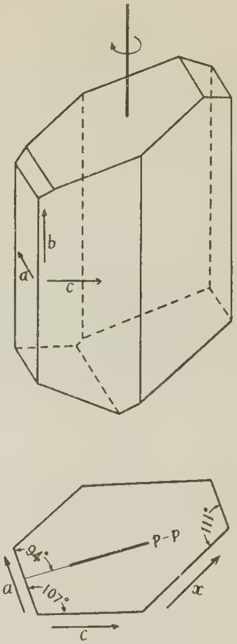

Fig. 4. Perspective diagram of the single crystal sample, and its horizontal section. The axis of rotation is *b*-axis.

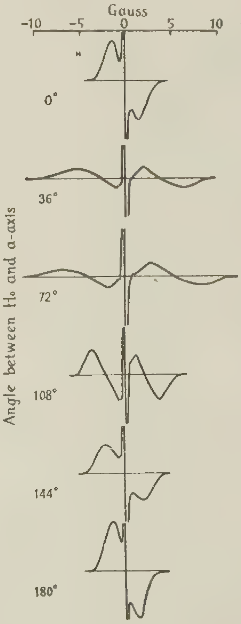

Fig. 5.

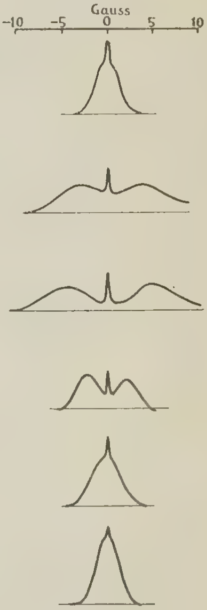

Fig. 6.

Fig. 5. Derivative curves of resonance lines at various angle positions. In this case the axis of rotation is *b*-axis. The width of modulation is indicated by a horizontal line at the upper left side of the figure.

Fig. 6. Integral curves of resonance derivative curves at the angles corresponding in Fig. 5. In Figs. 5 and 6, the sharp peak appearing in the center of resonance curve is the resonance line for free water molecules.

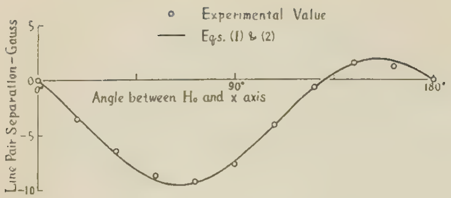

Fig. 7. $2\Delta H$, the twice of a separation of absorption lines from their center of gravity as a function of rotation angle $\Phi$. In this case, the rotation axis was $b$-axis, and angles of rotation were measured from $x$-line in Fig. 4. The solid line is the calculated line by use of Eqs. (1) and (2) with $\delta=51°$.

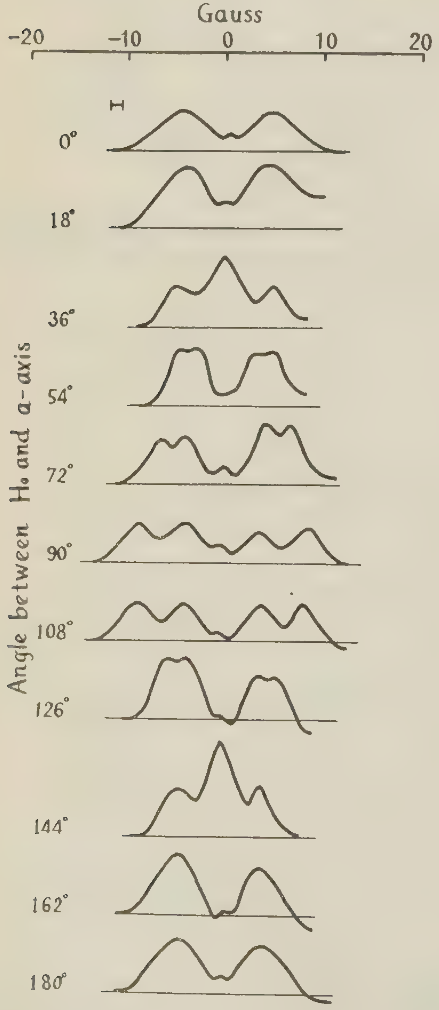

Fig. 8. Integral curves of resonance lines. The axis of rotation was the line nearly parallel to the one of two permitted p—p lines, and the angles of rotation were the angles between $H_0$ and $a$-axis. The width of modulation is indicated by a horizontal line at the upper left side of the figure.

The sharp peak in the center of each curve in Fig. 5 and 6 is attributed to the resonance line due to free water molecules contained in the cracks of the sample; and this attribution is justified by the facts that the sharp peak is as same as one from a little of water in an ampoule, and disappears after the sample is desiccated in a desiccator.

The observed separations of two component lines ($=2\Delta H$) in Fig. 5 or 6 are shown in Fig. 7 (open circles) as a function of the rotating angle $\Phi$ together the theoretical curve calculated by Eqs. (1) and (2). The value of $\cos\delta$ in Eq. (2) was determined by fitting the calculated one to the measured points in Fig. 7, which leads to $\delta=50°47'$ for the angle of inclination of a p–p line to the $xy$-plane ($ac$-plane). The curve in Fig. 7 has a minimum at 65° and a maximum at 155°, corresponding to $\Phi-\Phi_0=90°$ and 0° in Eqs. (1) and (2), respectively. From these data the angle between the projection of the p–p line and the positive direction of $a$-axis will be $94°\pm1°$ as shown in Fig. 4 (b).

The observed data can not uniquely determine the orientation of p–p line, as indicated by Eq. (1), but actually the permitted orientations of p–p lines in a unit cell containning two water molecules will have either only one group or two groups in accord with the observation mentioned above, in the latter case of which the $ac$-plane will bisect the angle of a pair of p–p lines belonging to each group, in other words, one permitted p–p line will be the mirror image of another permitted p–p line with respect to the $ac$-plane.

In order to settle the above alternative in p–p orientation, therefore, the following measurement was carried out. The sample was rotated around an axis parallel to the mentioned p–p line, and the external field $H_0$ was applied perpendicularly to it. When two permitted directions of p–p line exist, the values of $\Delta H$ from each permitted p–p should be different in such measurement, that is, $\Delta H$ from the p–p disposed parallel to the rotating axis will be constant at all angles $\Phi$, while, for another group of permitted p–p, $\Delta H$ will change with $\Phi$ as indicated by Eqs. (1) and (2).

The integral curves of the observed absorption are shown in Fig. 8. The angles between $a$-axis and the external field $H_0$ are indicated[3] beside each curve in the figure. The small peaks appeared at the center of several curves are the resonance lines from free water molecules contained in the crystal as seen in Figs. 5 and 6. The modulation width is indicated by the horizontal line at the upper left side corner in the figure.

In Fig. 9 are shown $2\Delta H$, the separation of the pair of lines for each group, as a function of the angle $\Phi$ between the external field $H_0$ and the $a$-axis. In the figure open circles show the measured values of $2\Delta H$, and the curves (1) and (2) are calculated by the use of Eqs. (1) and (2) with $\delta=90°$ and $\delta=-12°$, respectively. In the actual measurement, the rotating axis was deviated by 5° from the p–p line according to the circumstance of the crystal-cutting. Therefore, the minute deviations of the observed points from the curves (1) and (2) will be mainly ascribed to the exprimental conditions mentioned above, together with the effect of the interaction of the proton system with the other neighboring atoms such as Li- and H-ions.

From the observed value of $\alpha$ in Eq. (1), we have $r=1.59$ Å as the proton-proton distance, and assuming 0.99 Å for the bond length of O–H as in the case of ice, the bond angle of H–O–H is found to become of 106°50′.

## § 4. Discussion and Conclusion

In summing up our observed results mentioned above, it may be concluded that there exist two groups of permitted directions for the p–p lines of the water molecules in a unit cell, which directions are mutually related through mirror image with respect to the $ac$-plane and their inclinations with the $ac$-plane are about ±51°; The projection of a pair of p–p line on the $ac$-plane makes an angle of 94° with the positive direction of $a$-axis. The distance between two protons in each water molecule is 1.59 Å.

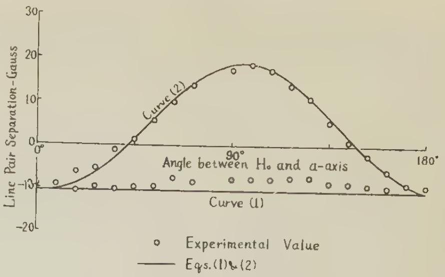

Fig. 9. $2\Delta H$, the twice of a separation of absorption lines from their center of gravity as a function of rotationg angles. The solid curves (1) and (2) are the calculated curves by the use of Eqs. (1) and (2) with $\delta=90°$ and $-12°$, respectively.

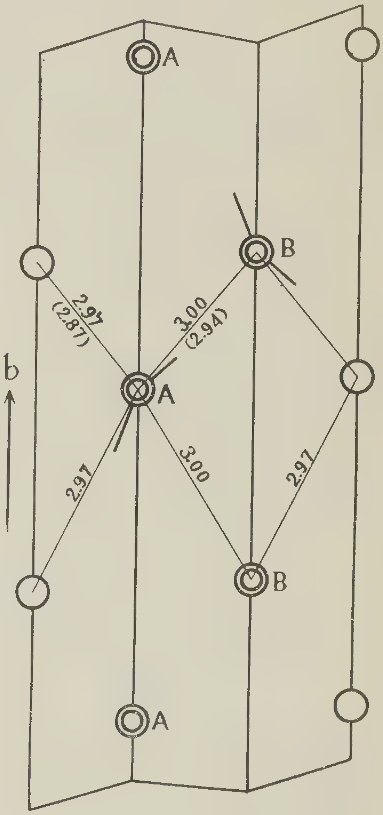

Fig. 10. The arrangement of the atoms in the neighborhood of the water molecules in the crystal lattice. The short heavy bars stretched from the double circle oxygen indicate the orientation of O—H.

The result of X-ray analysis by Larson and Helmholz[3] is in agreement with the one by Ziegler[2] in most essentials, from which the arrangement of the atoms in the neighborhood of the water molecules in the crystal lattice will be obtained as described in Fig. 10. The figure shows a projection of the crystal lattice on a plane perpendicular to the $a$-axis, in which double and single circles indicate the oxygen ions of water molecules and of the sulfate groups, respectively. Lithium ions are situated on the back of A-oxygen atoms and also in front of B-oxygen atoms. The distances (in Ångstrom) between the ions calculated from the data given by Ziegler are shown in the figure. The values in bracket denote the ones given by Larson and Helmholz[3)] in their X-ray measurement*.

As seen in ice, it may be suggested that a hydrogen atom stretches a covalent bond to the oxygen atom to which it belongs and simultaneonsly makes a hydrogen bonding with another neighboring oxygen atom. Since the shortest distance between the water molecule and the neighboring oxygen atom of sulfate group is 2.87 Å, using the X-ray data by Larson and Helmholz, the length of O–H···O in the substance is a little longer than in ice (2.76 Å). Therefore, the hydrogen bonding in this substance will be weaker than of ice, which, in turn, will have the hydrogen atom coordinate, by the covalent bonding, nearly on the line jointing the water molecule and a neighboring oxygen atom.

From the above considerations, it may be said that the water molecule will have a certain orientation of hydrogen bond under a slight restriction by the surrounding oxygen, consisting with the direction of p–p line determined in the analysis.

Next we shall go on to discuss the bond angle H–O–H of water molecule. As seen in the above discussion, the hydrogen bonding of H-ion in the crystal under consideration is taken to be weak and, its covalent bounding to be rather strong compared with those of ice. Thus, the length of O–H in the crystal will be expected to lie between 0.99 Å for ice and 0.955 Å for free gas molecule of water. Using the obtained value of 1.59 Å for the p–p distance and, further, the limiting values of O–H bond length mentioned above, the bond angle of H–O–H may be considered to take a certain value in between 106°50′ (corresponding to 0.99 Å) and 112°40′ (corresponding to 0.955 Å). In view of the rather small interaction of proton system with surrounding oxygens at large distance from the water molecule, the O–H length of water molecule in the crystal will presumably have more similar behaviour to that of a free gas in comparison with that of ice, the bond angle H–O–H being nearer to 112°40′.

So far we have confined ourselves to the discussion of the peak values of the proton resonance absorptions in $Li_2SO_4 \cdot H_2O$ in comparison with the calculated results based upon the rigid two-proton picture, as in the work of Pake. Although the observed data have been shown to be well understood theoretically, the analysis of the line width will be hardly carried through without taking into consideration the more distant interactions of the mentioned proton-system with the other protons and the neighboring Li-ions; the discussion of this problem shall be reserved till the more detailed measurements will be made.

Finally the authors wish to express their sincere thanks to Prof. T. Muto, University of Tokyo for his kind discussions. This work has been in part supported by the financial aid of the Educational Ministry.

# Determination of the End-to-End Distance of High Polymer Molecule in Solution

By Hiroshi MIZUTANI

*Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan*

(Received May 27, 1955)

Two convenient methods have been developed for calculating the end-to-end distance of the high polymer molecule in solution from the intrinsic viscosity and the angular distribution of the intensity of the scattered light, in which the volume-exclusion effect of the chain elements of the molecule and the effect of the interaction between chain elements and solvent molecules are taken into consideration. By making use of one of these methods, the determinations of the end-to-end distances of several kinds of polystyrenes in their solutions have been made.

## § 1. Introduction

In the present paper it is intended to consider the problem of determining the extension of high polymer molecules in solution. Inasmuch as the direct determination of this quantity is impossible, it must be derived through calculation from some measurable quantities such as the intrinsic viscosity $[\eta]$ or the angular distribution of the scattered light intensity $I(\theta)$[1][2]. Such calculation involves the assumption of the distribution function for the chain elements of the molecule. In the methods hitherto used it has been assumed that the chain elements are geometrical segments having no volume and there is no interaction between the elements and solvent molecules and further that their distribution is Gaussian, that is, the formula for the mean square end-to-end distance of the chain is given by

$$\langle r^2\rangle = b^2N\,, \tag{1}$$

where $N$ is the degree of polymerization and $b$ the effective bond length.

For the real high polymer molecule in solution, to which the above assumption does not actually correspond, the distribution function of the chain elements must be sought for by taking account of the volume-exclusion effect of the elements and the effect of the interaction between the elements and the solvent molecules. As yet, however, there has been obtained no correct distribution function that might be used for deriving molecular constants from experimental data. We therefore assume that, since all the theoretical formulas for $\langle r^2\rangle$ of high polymer molecules in vacuum can be rewritten, within a narrow range of $N$, approximately in the form

$$(\langle r^2\rangle)^{1/2} = CN^{\gamma} \quad \left(\gamma \geqq \frac{1}{2}\right), \tag{2}$$

the distribution function for the real high polymer in solution is of Gaussian type which gives Eq. (2) for $\langle r^2\rangle$. Thus, by making use of it, we can determine from the measurement of $[\eta]$ or $I(\theta)$ the constants $C$ and $\gamma$ which were primarily regarded as parameters, and consequently the mean square end-to-end distance $\langle r^2\rangle$. The detailed account of the method will be given below.

## § 2. Methods

### I. Method of Determining $\langle r^2\rangle$ from $[\eta]$

Eq. (2) can be rewritten as

$$(\langle r^2\rangle)^{1/2} = \alpha b N^{1/2}\,, \tag{3}$$

where $b$ is the effective bond length and $\alpha$ the factor meaning the expansion ratio of the real chain molecule as compared with the idealized one consisting of geometrical segments. It is to be noted that $\alpha$ is a function of $N$. Thus $\langle r^2\rangle$ can be determined, provided $\alpha$ and $b$ can be obtained in one way or another.

The method of obtaining $\alpha$ is as follows. It is required from thermodynamics that $\alpha$ is related to the molecular weight $M$ by

$$\alpha^5 - \alpha^3 = C'M^{1/2}\,, \tag{4}$$

where $C'$ is a constant. For $[\eta]$, on the other hand, we assume that the relation worked out by Debye and Bueche[1)]

$$[\eta]=\frac{4\pi}{3}\frac{R_s^3}{M}\phi(\sigma) \tag{5}$$

holds approximately. Here, $\phi(\sigma)$ is a certain function of the shielding ratio $\sigma$, and $R_s$ is the equivalent radius. If now we take it for granted that $R_s$ is related to $(\langle r^2\rangle)^{1/2}$ in the same way as calculated in the random-flight problem, namely

$$R_s=\sqrt{\frac{1}{6}}(\langle r^2\rangle)^{1/2}\,, \tag{6}$$

we obtain from Eqs. (3), (5) and (6)

$$[\eta]=K_0\phi M^{1/2}\alpha^3\,, \tag{7}$$

with

$$K_0=\frac{4\pi}{3}\left(\frac{1}{6m}\right)^{3/2}b^3\,, \tag{8}$$

in which $m$ is the mass of a monomer of the molecule. Eliminating $\alpha$ from Eqs. (4) and (7), we get

$$\frac{[\eta]^{5/3}}{(K_0\phi)^{5/3}M^{4/3}}-\frac{[\eta]}{K_0\phi M}=C'\,. \tag{9}$$

In so far as $K_0\phi$ and $C'$ vary only slowly with $M$, they may be regarded as constant in a narrow range of $M$, so that

$$\frac{d}{d([\eta]/M)}\left\{\frac{[\eta]^{5/3}}{M^{4/3}}\right\}=(K_0\phi)^{2/3}\,. \tag{10}$$

Thus, with the aid of Eqs. (7) and (10) we can obtain $\alpha$ for the given molecular weight $M$ of high polymer from its intrinsic viscosity $[\eta]$.

To obtain $b$ we employed the following procedure: For the intrinsic viscosity $[\eta]$, we have from Eqs. (2), (5) and (6) the relation

$$[\eta]=K_1N^{3\gamma-1}\phi\,, \tag{11}$$

in which $K_1$ is the quantity independent of $N$ and $\sigma$, and further we have for the same quantity an empirical relation

$$[\eta]=AN^{\varepsilon}\,. \tag{12}$$

$\sigma$ is, on the other hand, by definition and with the help of Eqs. (2) and (6), given by

$$\sigma=\left(\frac{27}{8}\right)^{1/4}\left(\frac{f}{\pi C\eta_0}\right)^{1/2}N^{(1/2)-(\gamma/2)}\,, \tag{13}$$

where $f$ is the frictional constant of the chain elements and $\eta_0$ the viscosity of the solvent. Thus, from Eqs. (11), (12) and (13), we get

$$\varepsilon=(3\gamma-1)+\left(\frac{1}{2}-\frac{\gamma}{2}\right)\frac{\sigma}{\phi}\frac{d\phi}{d\sigma}\,. \tag{4)^*$$

By the use of this equation and the relation for $\gamma$ given by

$$\gamma=\frac{1}{2}+\frac{dl_n\alpha}{dl_nN}\,, \tag{15}$$

we can determine $\phi$ with known values of $\alpha$ and $\varepsilon$, and hence $K_0$ from $K_0\phi$ given by Eq. (10). The final relation to be used for determining $b$, and consequently $\langle r^2\rangle$, is Eq. (8) rewritten as

$$b=\left(\frac{243}{2}\right)^{1/6}\pi^{-(1/3)}m^{1/2}K_0^{1/3}\,. \tag{16}$$

## II. Method of Determining $\langle r^2\rangle$ from $I(\theta)$

When the volume-exclusion effect of the chain elements and the effect of interaction between chain elements and solvent molecules are taken into account, and we can still assume the Gaussian distribution of the elements, the distribution function for the end-to-end distance of high polymer molecules with $Z$ chain elements, of which the mean square end-to-end distance takes the form

$$\langle r^2\rangle=C^2Z^{2\gamma}\,, \tag{17}$$

comes out to be

$$W(r)dr=\left(\frac{3}{2\pi C^2Z^{2\gamma}}\right)^{3/2}\exp\left(-\frac{3r^2}{2C^2Z^{2\gamma}}\right)4\pi r^2dr\,. \tag{18}$$

Consider that a parallel beam of light be incident upon a dilute solution of high polymer molecules, were $\nu$ molecules each consisting of $N$ elements are contained in volume $V$ of the solution. We define a distribution function $\rho(r)$ such that the probability of finding the center of some chain element within the volume element $d\tau$ at a distance $r$ from some other arbitrarily chosen element is $N\nu\rho(r)d\tau/V$. Let the wave-length of the light be $\lambda$, the unit vectors in the directions of incident and scattered light be $\boldsymbol{s}_1$ and $\boldsymbol{s}_2$ respectively, their difference be $\boldsymbol{s}=\boldsymbol{s}_1-\boldsymbol{s}_2$, and the angle between these directions be $\theta$, then we have for the intensity of the scattered light

$$I(\theta)=\frac{kN^2\nu^2}{V^2}\int\rho(r)\exp\left(\frac{2\pi i\boldsymbol{s}\cdot\boldsymbol{r}}{\lambda}\right)d\tau\,, \tag{19}$$

where $k$ is a constant factor. If we further define a probability function $W_{ij}(r)$ so that $W_{ij}(r)d\tau$ may give the probability of finding the $j$ th element in the volume element

---

* When $\gamma=1/2$ this relation reduces to that obtained by Debye and Bueche.[1)]

$d\tau$ at a distance $r$ from the $i$ th element, Eq. (19) turns out, according to Zimm[2], to be

$$I(\theta)=K(MP(\theta)c-2A_2M^2P^2(\theta)c^2) \tag{20}$$

with

$$\left.\begin{aligned} c&=\nu M/V\,,\\ K&=kN^2/M^2\,,\\ A_2&=-N_0N^2X/2M^2\,,\\ X&=\int\chi(r_{\kappa\lambda})d\tau\,. \end{aligned}\right\} \tag{21}$$

Here $\chi(r_{\kappa\lambda})$ is a function of the potential energy between the $\kappa$ th and $\lambda$ th element, and

$$P(\theta)=\frac{1}{N^2}\sum_i\sum_j\int W_{ij}(r)\exp\left(\frac{2\pi i\boldsymbol{s}\cdot\boldsymbol{r}}{\lambda}\right)d\tau\,. \tag{22}$$

In place of $W_{ij}(r)$ in this equation we may use Eq. (18) just by putting $Z=j-i$. Substituting Eq. (18) in Eq. (22) and replacing summation by integration, we obtain the formula

$$P(\theta)=\frac{2}{N^2}\int_0^N(N-Z)\exp(-uC^2Z^{2\gamma})dZ\,, \tag{23}$$

where

$$u=\frac{8\pi^2}{3\lambda^2}\sin^2\frac{\theta}{2}\,. \tag{24}$$

Thus from Eqs. (23) and (20) $I(\theta)$ becomes in the limiting case of infinitely dilute concentration:

$$\lim_{c\to 0}\frac{I(\theta)}{c}=\frac{2KM}{N^2}\int_0^N(N-Z)\exp(-uC^2Z^{2\gamma})dZ\,. \tag{25}$$

This is the formula for the intensity of the scattered light when the volume-exclusion effect and the effect of interaction between chain elements and solvent molecules are taken into account. By means of this formula, we can determine $C$ and $\gamma$ from the measurement of $I(\theta)$, and hence the end-to-end distance from Eq. (17).

## § 3. Experimental Results; Determination of $\langle r^2\rangle$ of High Polymer Molecule in Solution by the Method I

We prepared the benzene solutions of polystyrenes with three different molecular weights and measured their $[\eta]$ by the use of a capillary viscometer, of which the capillary had a length of 17 cm and inside diameter of 0.02 cm. The results are given in Table I. The values of $\mathcal{E}$ were determined from the values of $[\eta]$ given in Table I, by refering to the $\mathcal{E}$-values measured by R.A. Gregg and F. R. Mayo[3] at 30°C. Tables II～IV show the values of $\mathcal{E}$, $K_0\phi$, $\gamma$, $\phi$, $K_0$, $b$, $\alpha$ and $(\langle r^2\rangle)^{1/2}$, and Table V gives the expansion coefficients as calculated from Table IV.

Table I.

| M.W. | $[\eta]$ g$^{-1}$cm$^3$ | |
|---|---|---|
| | 20°C | 30°C |
| 388.000 | 183.8 | 181.0 |
| 355.000 | 163.1 | 161.2 |
| 195.000 | 110.8 | 110.2 |

Table II.

| Temp. | 20°C | 30°C |
|---|---|---|
| $\varepsilon$ | 0.728 | 0.720 |
| $K_0\phi$ | $0.664\times10^{11}$ | $0.738\times10^{11}$ |
| $\gamma$ | 0.572 | 0.564 |
| $\phi$ | 2.30 | 2.22 |
| $K_0$ | $0.29\times10^{11}$ | $0.33\times10^{11}$ |
| $b_0$ | $6.16\times10^{-8}$ | $6.42\times10^{-8}$ |

Table III.

| M.W. | $\alpha$ | |
|---|---|---|
| | 20°C | 30°C |
| 388.000 | 1.512 | 1.45 |
| 355.000 | 1.49 | 1.428 |
| 195.000 | 1.432 | 1.378 |

Table IV.

| M.W. | $(\langle r^2\rangle)^{1/2}=\alpha bN^{1/2}$ | |
|---|---|---|
| | 20°C | 30°C |
| 388,000 | $569\times10^{-8}$ | $566\times10^{-8}$ |
| 355,000 | 523 〃 | 521 〃 |
| 195,000 | 383 〃 | 382 〃 |

Table V.

| M.W. | Expansion coefficient |
|---|---|
| 388,000 | −0.0054 |
| 355,000 | −0.0039 |
| 195,000 | −0.0026 |

The measurement of $\langle r^2\rangle$ by the method II is now being carried on and will be reported in a subsequent paper.

## § 4. Remark

For comparison's sake, let us inquire into

Table VI.

| Temp. | 20°C | 30°C |
|---|---|---|
| $\varepsilon$ | 0.728 | 0.72 |
| $K_0\phi$ | $2.14 \times 10^{11}$ | $2.12 \times 10^{11}$ |
| $\phi$ | 1.225 | 1.26 |
| $K_0$ | $1.75 \times 10^{11}$ | $1.68 \times 10^{11}$ |
| $b_0$ | $11.18 \times 10^{-8}$ | $11.04 \times 10^{-8}$ |

Table VII.

| M.W. | $(\langle r^2\rangle)^{1/2}=b_0N^{1/2}$ | |
|---|---|---|
| | 20°C | 30°C |
| 388,000 | $694 \times 10^{-8}$ | $688 \times 10^{-8}$ |
| 355,000 | 636 〃 | 630 〃 |
| 195,000 | 468 〃 | 463 〃 |

the end-to-end distance of the chain corresponding to the simple formula $(\langle r^2\rangle)^{1/2}=b_0N^{1/2}$, in which $b_0$ is the effective bond length. For that purpose we first determine $\phi$ by means of Debye-Buche's method[1], and then determine $K_0$ from the formula for $[\eta]$, $[\eta]=K_0M^{1/2}\phi$. The value of $b_0$ can be obtained by the help of the relation

$$b_0=\left(\frac{243}{2}\right)^{1/6}\pi^{-1/3}m^{1/2}K_0^{1/3} .$$

The results are given in Tables VI and VII.

From comparison between Table IV and Table VII we see that the $\langle r^2\rangle$-value comes out different according as the assumed distribution function of the chain elements is different; in other words, in determining the value of $\langle r^2\rangle$, it is necessary to adopt the correct distribution function, taking into account the volume-exclusion effect and the effect of the interaction between chain element and solvent molecules.

## Acknowledgments

The author wishes to express his hearty thanks to Prof. T. Hori of the Institute of Low Temperature Science, Hokkaido University, Prof. J. Huruichi and other members belonging to the High Polymer Research Section of Hokkaido University, and Dr. S. Oka of Kobayashi Institute of Physical Research, Tokyo, for their kind discussions on the present subject.

# A Theoretical Analysis of the Magnetic Hyperfine Structure of the Microwave Spectrum of $C_{2v}$ Molecules

By Akira OKAYA

*Department of Physics, Faculty of Science, University of Kyoto*

(Received July 11, 1955)

A theoretical analysis of magnetic hyperfine structure due to the magnetic interaction between the spins of off or on axis nuclei and the molecular rotational magnetic field is developed for asymmetric $C_{2v}$ molecules in ${}^1A$ electronic and vibrational ground state.

This analysis is for the special case where two equivalent nuclei of spin 1/2 are off the molecular axis, one nucleus of spin zero and one nucleus of arbitrary spin are on the molecular axis.

This analysis predicts that a triplet will be observed for prolate rotational transitions for which $\Delta J=0$, $\Delta K_{+1}=-1$, and both initial and final $K_{-1}$ values are odd.

## §1. Introduction

The author has observed that the main line of the rotational spectrum of formaldehyde, $H_2CO$[1], is split into two lines. This doublet character is due to the magnetic interaction between the spin of two protons and the magnetic field caused by molecular rotation just as in the case of the ammonia molecule[2][3][4][5].

Theoretical calculations show that a triplet composed of three $\Delta F=0$ transitions can explain the observed doublet appearance as shown in a subsequent experimental report[1].

The above interaction is treated for asymmetric $C_{2v}$ molecules in a ${}^1A$ electronic and vibrational ground state, which includes formaldehyde as a typical example. We treat the case in which two equivalent nuclei of spin 1/2 are off the molecular axis, while one nucleus, $K_0$, of any optional spin value and another nucleus, $K_0'$, of spin zero are on the molecular axis.

This treatment can also be applied to such molecules as $H_2O$, $H_2S$, $CH_2O$, $CF_2O$, etc.

## §2. The Hamiltonian

The Hamiltonian[5][6] of a free prolate molecule in a ${}^1A$ electronic state is based on the Pauli approximation:

$$H=C(J_x-L_x)^2+B(J_y-L_y)^2+A(J_z-L_z)^2 \tag{1.0}$$

$$+(e\mu_0/c)\sum_{K,i} r_{Ki}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\{\boldsymbol{V}_i-[1+Z_KM_P/(g_KM_K)]\boldsymbol{V}_K\}\cdot g_K\boldsymbol{I}_K \tag{1.1}$$

$$-(e\mu_0/c)\sum_{\substack{K,L\\(K\neq L)}} Z_Lr_{KL}^{-3}(\boldsymbol{r}_K-\boldsymbol{r}_L)\times\{[1+Z_KM_P/(g_KM_K)]\boldsymbol{V}_K-\boldsymbol{V}_L\}\cdot g_K\boldsymbol{I}_K \tag{1.2}$$

$$+g_e\mu_0\mu_e\sum_{j,k} r_{jK}^{-5}[g_K\boldsymbol{I}_K\cdot\boldsymbol{S}_jr_{jK}^2-3g_K\boldsymbol{I}_k\cdot(\boldsymbol{r}_K-\boldsymbol{r}_j)\boldsymbol{S}_j\cdot(\boldsymbol{r}_K-\boldsymbol{r}_j)] \tag{1.3}$$

$$+\mu_0^2\sum_{\substack{K,L\\(K>L)}} r_{KL}^{-5}[g_K\boldsymbol{I}_K\cdot g_L\boldsymbol{I}_Lr_{KL}^2-3g_K\boldsymbol{I}_K\cdot(\boldsymbol{r}_K-\boldsymbol{r}_L)g_L\boldsymbol{I}_L\cdot(\boldsymbol{r}_K-\boldsymbol{r}_L)] \tag{1.4}$$

$$+H_Q \tag{1.5}$$

$$+(16/3)\pi\mu_0\mu_e\sum_{K,j} g_K\delta(\boldsymbol{r}_K-\boldsymbol{r}_j)\boldsymbol{S}_j\cdot\boldsymbol{I}_K \tag{1.6}$$

In (1.0) to (1.6), capital-letter subscripts refer to nuclei and small-letter subscripts to electrons. These particles have, respectively, position vectors $\boldsymbol{r}_k$, $\boldsymbol{r}_j$ and velocities $\boldsymbol{V}_k$, $\boldsymbol{V}_j$ relative to the molecular centre of mass which is assumed to coincide with the centre of mass of the nuclei only. The nuclei and electrons have charges $Z_ke$, $e$; spins $\boldsymbol{I}_k$, $\boldsymbol{S}_j$; and $g$-factors $g_k$, $g_e$, respectively. $\mu_0$ and $\mu_e$ are the nuclear and Bohr magnetons respectively, while $M_P$

is the proton mass and $M_K$ the mass of the $K$th nucleus. $C$, $B$ and $A$ are the transverse and axial rotational constants of the prolate $C_{2v}$ symmetry molecule exclusive of the electrons. $J_x, J_y, J_z$ are the components of the total molecular angular momentum exclusive of nuclear spin, and $L_x, L_y, L_z$ are the total electronic orbital angular momentum components.

## § 3. The Molecular Wave Function

Molecular rotational wave functions are classified by the irreducible representations of the rotation group $C_2$. The correspondence of the irreducible representations to the, $K_{-1}$, $K_{+1}$, rotational states are shown in Table I. The symmetries of nuclear spin functions are classified by the permutation group, $P_2$, and their irreducible representations are also shown in Table I. The total molecular wave function is represented by

$$\psi=\psi_{RA}(J, \tau, M, \gamma)\psi_0(\sigma_0)\psi(\sigma_1)\psi_2(\sigma_2) . \qquad (2)$$

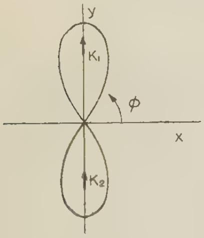

Fig. 1 (a).

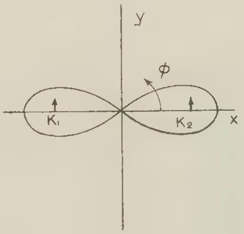

Fig. 1 (b).

The details of the rotational wave function, $\psi_{RA}$, for an asymmetric molecule are shown in Appendix I. $\psi_0$ is the spin function for nuclei on the molecular axis, while $\psi_1$ and $\psi_2$ are the spin functions for the two equivalent nuclei which are off the symmetry axis.

The permutation group, $P_2$, is homomorphic to the $C_{2v}$ rotation reflection group and forms a molecular rotational group by itself.

The total wave function belongs to the irreducible representation, $A$, or $B$[7], of the $P_2$ group according as the off axial nuclear spins are 0 or 1/2.

For the calculations of this paper, it is necessary to define the coupling scheme for angular momenta in the molecule. We can assume that the quadrupole coupling of the on-axis nucleus to the molecular rotation is stronger than the intra-molecular magnetic interaction. Then

$$\boldsymbol{I}_0+\boldsymbol{J}=\boldsymbol{F}_1 ,$$

and the spins of the equivalent nuclei are coupled to become $\boldsymbol{I}_1+\boldsymbol{I}_2=\boldsymbol{I}$. $\boldsymbol{I}$ is coupled further to $\boldsymbol{F}_1$ as

$$\boldsymbol{I}+\boldsymbol{F}_1=\boldsymbol{F} .$$

In this coupling scheme the total wave functions are

$$\begin{aligned}\psi_{E=W_0}&=|K, J, M, F_1, I_0, I=0>+(-1)^{\gamma}|-K, J, M, F_1, I_0, I=0>\\&=|\tau, J, M, F_1, I_0, I=0> ,\\ \psi_{E=W_0+W_1+f}=\psi_{E=W+f}&=|K, J, M, F_1, I_0, I=1>+(-1)^{\gamma}|-K, J, M, F_1, I_0, I=1>\\&=|\tau, J, M, F_1, I_0, I=1> ,\end{aligned}$$

where $W=W_0+W_1$ .

From the permutation $P_{12}$ of two equivalent nuclei, we can obtained the following relations:

$$P_{12}=P_{12}^{(z)}P_{12}^{(\sigma)}=P_{12}^{(z)}\{1/2+2(\boldsymbol{I}_1\cdot\boldsymbol{I}_2)\} ,$$

$$P_{12}^{(\sigma)}|F_1, I=1>=|F_1, I=1> ,$$

and

$$P_{12}^{(\sigma)}|F_1, I=0>=-|F_1, I=0> .$$

For the $P_{12}^{(z)}$ operation we can use the results of Mulliken[13] together with the fact that $P_{12}$ is homomorphic to the $C_{2v}$ group. Then we have

$$C_2^{(z)}\psi_{RA}=P_{12}^{(z)}\psi_{RA}=(-1)^{K_{-1}}\psi_{RA} \qquad \text{(prolate case)},$$

$$C_2^{(y)}\psi_{RA} \qquad =(-1)^{J+\gamma}\psi_{RA} \qquad \text{(oblate case)}.$$

The wave function symmetries are shown in Table I (a) for the prolate case ($I_1=I_2=1/2$ and $I_1=I_2=0$) and in Table I (b) for the oblate case ($I_1=I_2=1/2$ and $I_1=I_2=0$).

It may be helpful to give a simple physical argument for the magnetic interactions. The rotational wave function of a prolate asymmetric rotor* may be rewritten as:

---

* Underline shows the wave functions which are allowed.

$$\psi_{RA}=\psi_{MJ}(e^{iK_{-1}\phi}+(-1)^{\gamma}e^{-iK_{-1}\phi}) ,$$

where $\phi$ is the azimuthal angle about the molecular symmetry axis, and $\gamma$ is the parity which is uniquely determined by the rotational quantum numbers of each rotational level. According as the case $\gamma=1$ or $0$ applies, the the above wave function becomes:

$$\propto\psi_{MJ}\sin K_{-1}\phi \qquad (\text{for } \gamma=1),$$
$$\propto\psi_{MJ}\cos K_{-1}\phi \qquad (\text{for } \gamma=0).$$

A plot of the probability of a given value of $\phi$ is given in Fig. 1(a) and 1(b).

We can see that the interactions between nuclear spin wave functions and rotational wave functions are reasonably different for the two cases, $\gamma=0$ or 1, so clearly the interaction energies for these cases are different.

Then if we consider the cases of transitions between $\gamma=0$ and $\gamma=1$ levels[1], the triplet splitting of these lines are expected.

## § 4. Perturbation

Van Vleck's second order perturbation

method[5)6)] has been used.

(a) *Calculation of the first order effective Hamiltonian* ($G_1$).

The terms which are diagonal relative to ground electronic quantum number $l_0$ in Eq. (1) are shown below.

$$
\begin{aligned}
H_1 = {} & CJ_x^2 + BJ_y^2 + AJ_z^2 && (3.0)\\
& + (e\mu_0/c)\sum_{i,K} r_{iK}^{-3}(\boldsymbol{r}_i - \boldsymbol{r}_K)\times[1+Z_K M_P/(g_K M_K)]\boldsymbol{V}_K \cdot g_K \boldsymbol{I}_K && (3.1)\\
& - (e\mu_0/c)\sum_{K,L} Z_L r_{KL}^{-3}(\boldsymbol{r}_K - \boldsymbol{r}_L)\times\{[1+Z_K M_P/(g_K M_K)]\boldsymbol{V}_K - \boldsymbol{V}_L\}\cdot g_K \boldsymbol{I}_K && (3.2)\\
& + \mu_0^2 \sum_{\substack{K,L\\(K>L)}} r_{KL}^{-5}[g_K \boldsymbol{I}_K \cdot g_L \boldsymbol{I}_L r_{KL}^2 - 3 g_K \boldsymbol{I}_K \cdot (\boldsymbol{r}_K - \boldsymbol{r}_L) g_L \boldsymbol{I}_L \cdot (\boldsymbol{r}_K - \boldsymbol{r}_L)] && (3.3)\\
& + H_Q && (3.4)
\end{aligned}
$$

The term (3.0) can be calculated very accurately by the KHC method[8)]. The approximation formula of Bragg and Golden[9)10)] is applicable to (3.4). The coupling schemes in molecular and laboratory frames are shown in Figs. 2 and 3 respectively, in which we adopted the inverted spin quantum number[6)] $\bar{I}_0 = -I_0$, $\bar{I}_1 = -I_1$, and $\bar{I}_2 = -I_2$, in order to be able to use the same relations for angular quantum numbers in a laboratory frame and to use the matrix elements tabulated by Condon and Shortley[11)]. The notation for geometry of molecule in shown in Fig. 4.

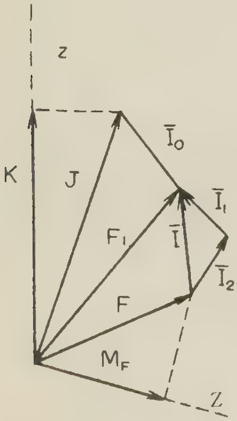

Fig. 2.

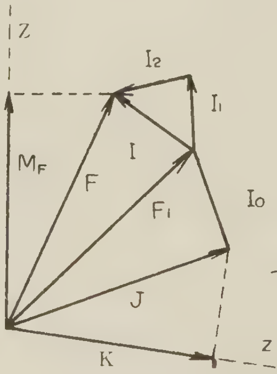

Fig. 3.

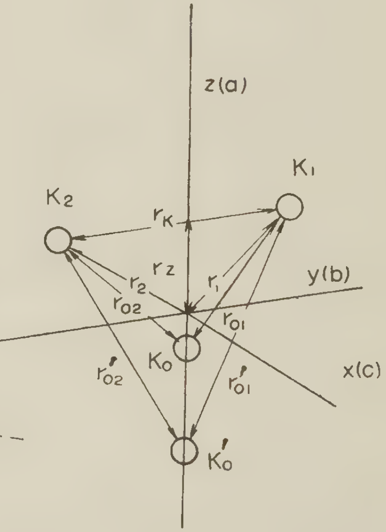

Fig. 4.

A part of (3.1) which is concerned with off-axial nuclei $K_1, K_2$ is reduced, after some calculations, to the following form:

$$-(\gamma_1 J_x \bar{I}_{1x} + \beta_1 J_y \bar{I}_{1y} + \alpha_1 J_z \bar{I}_{1z}) \,, \tag{4}$$

where

$$
\begin{aligned}
\gamma_1 = {} & -2(e\mu_0/c\hbar)C[1+Z_1 M_P/(g_1 K_1)]g_1\{r_z \langle l_0 | \sum_{i,K=1,2} r_{iK}^{-3}(\boldsymbol{r}_i - \boldsymbol{r}_K)_z | l_0 \rangle \\

\beta_1 = {} & -2(e\mu_0/c\hbar)Br_z[1+Z_1 M_P/(g_1 M_1)]g_1 \langle l_0 | \sum_{i,K=1,2} r_{iK}^{-3}(\boldsymbol{r}_i - \boldsymbol{r}_K)_z | l_0 \rangle \,,
\end{aligned}
$$

and

$$\alpha_1 = -2(e\mu_0/c\hbar)Ar_y[1+Z_1M_P/(g_1M_1)]g_1\langle l_0|\sum_{l,K=1,2} r_{iK}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)_y|l_0\rangle \,.$$

A part concerning nucleus $K_0$ in (3.1) is reduced to

$$-(c_1J_x\bar{I}_{0x}+b_1J_y\bar{I}_{0y}+a_1J_z\bar{I}_{0z}) \,, \tag{5}$$

where

$$c_1 = -2(e\mu_0/c\hbar)Cr_{0z}[1+Z_0M_P/(g_0M_0)]g_0\langle l_0|\sum_i r_{0i}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_0)_z|l_0\rangle \,,$$

and

$$b_1 = -2(e\mu_0/c\hbar)Br_{0z}[1+Z_0M_P/(g_0M_0)]g_0\langle l_0|\sum_i r_{i0}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_0)_z|l_0\rangle$$

$$a_1 = 0 \,.$$

A part which is concerned with $K_1, K_2$ in (3.2) becomes

$$-(\gamma_2J_x\bar{I}_{1x}+\beta_2J_y\bar{I}_{1y}+\alpha_2J_z\bar{I}_{1z}) \,, \tag{6}$$

where

$$\gamma_2 = -\frac{e\mu_0}{c\hbar}g_1C\left\{Z_1\left(2+\frac{Z_1M_P}{g_1M_1}\right)\frac{1}{r_{01}\sin\beta}+4\sum_{0,0'}\frac{Z_0}{r_{01}}\left[1+\frac{Z_1M_P}{g_1M_1}\left(\sin^2\beta+\frac{r_z}{r_{01}}\cos\beta\right)\right]\right\} \,,$$

$$\beta_2 = -\frac{4e\mu_0}{c\hbar}g_1B\sum_{0,0'}\frac{Z_0}{r_{01}}\left(\cos^2\beta+\frac{Z_1M_P}{g_1M_1}\frac{r_z}{r_{01}}\cos\beta\right) \,,$$

and

$$\alpha_2 = -\frac{e\mu_0}{c\hbar}g_1A\left\{Z_1\left(2+\frac{Z_1M_P}{g_1M_1}\right)\frac{1}{r_{01}\sin\beta}+4\sum_{0,0'}\frac{Z_0}{r_{01}}\left[\sin^2\beta+\frac{Z_1M_P}{g_1M_1}\left(\sin^2\beta+\frac{r_z}{r_{01}}\cos\beta\right)\right]\right\} \,.$$

A part concerning $K_0$ in the term (3.2) is reduced to

$$-(c_2J_x\bar{I}_{0x}+b_2J_y\bar{I}_{0z}+a_2J_y\bar{I}_{0z}) \,, \tag{7}$$

where

$$c_2 = -\frac{4e\mu_0}{c\hbar}Z_1g_0C\frac{1}{r_{01}}\left(1+\frac{Z_0M_P}{g_0M_0}\frac{r_z}{r_{01}}\cos\beta\right) \,,$$

$$b_2 = -\frac{4e\mu_0}{c\hbar}Z_1g_0B\frac{1}{r_{01}}\left(\cos^2\beta+\frac{Z_0M_P}{g_0M_0}\frac{r_z}{r_{01}}\cos\beta\right) \,,$$

and

$$a_2 = -\frac{4e\mu_0}{c\hbar}Z_1g_0A\frac{1}{r_{01}}\sin^2\beta \,.$$

The term in (3.3) which is concerned with the mutual interaction between equivalent off-axial nuclei does not vanish in the case when $I_1=I_2=1/2$, but has not been calculated in this paper, since it seems to be of small value. Those terms in (3.3) which involve interactions of $K_0$, with $K_1$ or $K_2$ are

$$\mu_0^2g_1g_0\sum_{0,0'}r_{01}^{-3}[(\bar{I}_0\,\bar{I})-3(\bar{I}_0\bar{I}_z\cos^2\beta+\bar{I}_{0y}\bar{I}_y\sin^2\beta)] \,. \tag{8}$$

This equation is rewritten as follows:

$$c_3\bar{I}_{0x}\bar{I}_x+b_3\bar{I}_{0y}\bar{I}_y+a_3\bar{I}_{0z}\bar{I}_z \,,$$

where

$$c_3 = \mu_0^2g_0g_1r_{01}^{-3} \,,$$
$$b_3 = \mu_0^2g_0g_1r_{01}^{-3}(1-3\sin^2\beta) \,,$$
$$a_3 = \mu_0^2g_0g_1r_{01}^{-3}(1-3\cos^2\beta) \,.$$

By using the general relation which was derived by Condon and Shortley11), the matrix elements in (8) are rewritten as:

$$\overline{I}_{0\nu}\overline{I}_{\nu}=\frac{(\boldsymbol{F}_1\cdot\boldsymbol{I})}{F_1(F_1+1)}\left(\frac{(\boldsymbol{I}_0\cdot\boldsymbol{J})}{J(J+1)}J_{\nu}^2+\overline{I}_{0\nu}^2\right), \tag{9}$$

where

$$\nu=x,\, y,\, z\,.$$

Furthermore, these are transformed by the following relations[5]

$$\langle\overline{I}_0,\, F_1,\, J,\, \tau\,|\,\overline{I}_{0\nu}^2\,|\,\overline{I}_0,\, F_1,\, J,\, \tau'\rangle=4\frac{(2I_0-1)}{J(J+1)}\frac{2JY}{2J+3}\langle J,\tau\,|\,J_{\nu}^2\,|\,J,\tau'\rangle\,,$$

where

$$Y=\frac{3(\boldsymbol{J}\cdot\boldsymbol{I}_0)^2+(3/2)(\boldsymbol{J}\cdot\boldsymbol{I}_0)-\boldsymbol{J}^2\boldsymbol{I}_0^2}{2J(2J-1)2I_0(2I_0-1)}\,.$$

By making use of (9) together with the above relations, the expression (8) is rewritten as:

$$\frac{(\boldsymbol{F}_1\cdot\boldsymbol{I})}{F_1(F_1+1)J(J+1)}\left\{(\boldsymbol{I}_0\cdot\boldsymbol{J})+\frac{8YI_0(2I_0-1)J}{2J+3}\right\}(c_3J_x^2+b_3J_y^2+a_3J_z^2)\,.$$

Moreover, $\overline{I}_{1\nu}$ and $\overline{I}_{0\nu}$ in the above expressions (4), (5), (6), (7) and (8) are rewritten by using the following relations:[11]

$$\overline{I}_{1\nu}=-\frac{(\overline{\boldsymbol{I}}\cdot\overline{\boldsymbol{I}}_1)(\boldsymbol{F}_1\cdot\boldsymbol{I})(\boldsymbol{F}_1\cdot\boldsymbol{J})}{I(I+1)F_1(F_1+1)J(J+1)}J_{\nu},\quad \overline{I}_{0\nu}=\frac{-(\boldsymbol{J}\cdot\boldsymbol{I}_0)}{J(J+1)}J_{\nu}\,.$$

If we use all of the above results (from (4) to the last relation), the expression for the effective Hamiltonian $G_1$ becomes

$$G_1=CJ_x^2+BJ_y^2+AJ_z^2 \tag{10.0}$$

$$+\frac{(\overline{\boldsymbol{I}}\cdot\overline{\boldsymbol{I}}_1)(\boldsymbol{F}_1\cdot\boldsymbol{I})(\boldsymbol{F}_1\cdot\boldsymbol{J})}{I(I+1)F_1(F_1+1)J(J+1)}(\gamma'J_x^2+\beta'J_y^2+\alpha'J_z^2) \tag{10.1}$$

$$+\frac{(\boldsymbol{J}\cdot\boldsymbol{I}_0)}{J(J+1)}(c'J_x^2+b'J_y^2+a'J_z^2) \tag{10.2}$$

$$+\frac{(\boldsymbol{F}_1\cdot\boldsymbol{I})}{F_1(F_1+1)J(J+1)}\left\{(\boldsymbol{I}_0\cdot\boldsymbol{J})+\frac{8YI_0(2I_0-1)J}{2J+3}\right\}(c_3J_x^2+b_3J_y^2+a_3J_z^2) \tag{10.3}$$

$$+2eQ\left\langle\frac{\partial^2V}{\partial z^2}\right\rangle_{\mathrm{AV}}Y\,, \tag{10.4}$$

where

$$\alpha'=\alpha_1+\alpha_2\,,\qquad \beta'=\beta_1+\beta_2\,,\qquad \gamma'=\gamma_1+\gamma_2\,,$$
$$a'=a_2\,,\qquad b'=b_1+b_2\,,\qquad c'=c_1+c_2\,.$$

### (b) *Calculation of the second order effective Hamiltonian* ($G_2$)

The terms which contribute to the second order effective Hamiltonian, $G_2$, are included in the following:

$$H_2=(CL_x^2+BL_y^2+AL_z^2)-2(CJ_xL_x+BJ_yL_y+AJ_zL_z) \tag*{(1.0)$'$}$$

$$+(e\mu_0/c)\sum_{K,i}[r_{iK}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)\times V_i]\cdot g_K\boldsymbol{I}_K \tag*{(1.1)$'$}$$

$$+(1.3)+(1.6)\,.$$

The terms (1.0)′ and (1.1)′ are off-diagonal relative to electronic orbital quantum numbers. Likewise the terms (1.3) and (1.6) are off-diagonal relative to electronic spin quantum numbers.

Now we are only concerned with the case where all spins are paired off so that the total spin is 0, and the terms (1.3) and (1.6) can be neglected. We can also neglect the cross terms between (1.3), (1.6) and (1.0)′ compared to cross terms between (1.0)′ and (1.1)′.

The relative magnitudes of these terms can be evaluated by referring to the results of Ref. 5. We can expect that only two terms contribute to $G_2$: namely, (1)$(G_2)_2$, the interaction between $I_0$ and the molecular rotational magnetic field and (2)$(G_2)_1$, interaction between $I$ and the molecular rotational magnetic field. Therefore, $G_2$ becomes

$$G_2=(G_2)_1+(G_2)_2=\frac{(\bar{\boldsymbol{I}}\cdot\bar{\boldsymbol{I}}_1)(\boldsymbol{F}_1\cdot\boldsymbol{I})(\boldsymbol{F}_1\cdot\boldsymbol{J})}{I(I+1)F_1(F_1+1)J(J+1)}(\gamma_3 J_x{}^2+\beta_3 J_y{}^2+\alpha_3 J_z{}^2) \tag{11.1}$$

$$+\frac{(\boldsymbol{J}\cdot\boldsymbol{I}_0)}{J(J+1)}(c_4 J_x{}^2+b_4 J_y{}^2+a_4 J_z{}^2)\,. \tag{11.2}$$

The coefficients of $(G_2)_1$ and $(G_2)_2$ in our case correspond to those of $(G_2)_4$ and $(G_2)_5$ respectively in Ref. 4. $a_4, b_4, c_4$ and $\alpha_3, \beta_3, \gamma_3$ are nearly the same with $a_3, b_3$ and $\alpha_3, \beta_3$ in Ref. 4, except that $c_4 \neq b_4$ and $\gamma_3 \neq \beta_3$. These terms are the contributions from excited electronic states.

## § 5. Secular Equation

For the convenience of the calculation the matrix $G$ shall be considered in the molecular frame

$$|M_F, F, \bar{I}, F_1, \bar{I}_0, J, \tau>\,.$$

In this frame the degeneracies of $I_0$ and $I$ are removed and therefore it is sufficient to consider only the elements which are concerned with $I_0$ and $I$.

The expression (3.0) becomes[8)]

$$CJ_x{}^2+BJ_y{}^2+AJ_z{}^2=\frac{A-C}{2}E(\kappa)+\frac{A+C}{2}J(J+1)\,,$$

where

$$\kappa=(2B-A-C)/(A-C) \qquad \text{(Ray's asymmetry parameter)}$$

and

$$A>B>C\,.$$

The terms $\gamma J_x{}^2+\beta J_y{}^2+\alpha J_z{}^2$ and $cJ_x{}^2+bJ_y{}^2+aJ_z{}^2$ which appear in the sum of Eq. (10) and Eq. (11) are calculated by the same method as that of Bragg and Golden[9)] which has been applied to the calculation of $\langle\partial^2 V/\partial Z^2\rangle_{\mathrm{AV}}$ for the asymmetric rotor.
Then we obtain, from Ref. 9, the following relation:

$$\gamma J_x{}^2+\beta J_y{}^2+\alpha J_z{}^2=\frac{1}{2}(\alpha+\gamma)J(J+1)+\frac{1}{2}(\alpha-\gamma)E(\kappa)$$
$$-\frac{1}{2}\{(\kappa+1)\alpha-2\beta-(\kappa-1)\gamma\}\frac{\partial E(\kappa)}{\partial\kappa}\,,$$

where $\alpha=\alpha'+\alpha_3,\ \beta=\beta'+\beta_3,\ \gamma=\gamma'+\gamma_3.$

The matrix elements which appear in this equation can be written as follows. The matrix elements of $(\bar{\boldsymbol{I}}\cdot\bar{\boldsymbol{I}}_1)$ which are labeled by $I=1,\ 0$ are

$$(\bar{\boldsymbol{I}}\cdot\bar{\boldsymbol{I}}_1)=\begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix}.$$

The matrix elements of $(\boldsymbol{I}.\boldsymbol{F}_1)$ for the case $I=1$ which are labeled by $F=F_1+1$. $F_1, F_1-1$ are

$$(\boldsymbol{I}\cdot\boldsymbol{F}_1)=\begin{pmatrix}F_1 & 0 & 0\\ 0 & -1 & 0\\ 0 & 0 & -F_1-1\end{pmatrix}.$$

The matrix elements of $(\boldsymbol{F}_1\cdot\boldsymbol{J})$ which are labeled by $F_1=J+I_0, J+I_0-1,\cdots, J,\cdots, J-I_0+1, J-I_0$ are

$$-(\boldsymbol{F}_1\cdot\boldsymbol{J})=\begin{pmatrix} J(J+1)+JI_0 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ \vdots & J(J+1) & \vdots \\ \vdots & \ddots & \vdots \\ 0 & \cdots & J(J+1)-JI_0-I_0 \end{pmatrix}.$$

The matrix elements of $(\boldsymbol{J}\cdot\boldsymbol{I}_0)$ which are labeled by $F_1=J+I_0,\cdots, J-I_0$ are

$$(\boldsymbol{J}\cdot\boldsymbol{I}_0)=\begin{pmatrix} JI_0 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ \vdots & 0 & \vdots \\ \vdots & \ddots & \vdots \\ 0 & \cdots & -JI_0-I_0 \end{pmatrix}.$$

Then as we can see from the angular momentum coupling scheme and the expressions for $G_1$ and $G_2$, the degeneracy relative to $F_1$ is removed first and that relative to $F$ second.

The off-diagonal eigenvalue of the Hamiltonian which are produced by wave functions $\psi(+K)$ and $\psi(-K)$ are to be found only in the element $\partial E(\kappa)/\partial\kappa$ and take different signs in the levels which have different parities, $\gamma$.

Now we can solve the secular equation completely. We take the energy levels as:

$$E=W_0+W_1+f,$$

where $W_0$ is the term which appears when only the $(\boldsymbol{I}_0\cdot\boldsymbol{J})$ coupling is considered, namely:

$$\begin{aligned} W_0= & \frac{A-C}{2}E(\kappa)+\frac{A+C}{2}J(J+1) \\ & +\frac{(\boldsymbol{J}\cdot\boldsymbol{I}_0)}{2J(J+1)}[(a+c)J(J+1)+(a-c)E(\kappa)] \\ & +eQ[(A'+C')J(J+1)+(A'-C')E(\kappa)]Y\,, \end{aligned}$$

where

$$a=a'+a_4,\quad b=b'+b_4,\quad c=c'+c_4\,.$$

$W_1$ represents the term when only the $(\boldsymbol{F}_1\cdot\boldsymbol{I})$ coupling is considered and is given by

$$\begin{aligned} W_1= & \frac{(\bar{\boldsymbol{I}}\cdot\bar{\boldsymbol{I}}_1)(\boldsymbol{F}_1\cdot\boldsymbol{I})(\boldsymbol{F}_1\cdot\boldsymbol{J})}{2I(I+1)F_1(F_1+1)J(J+1)}[(\alpha+\gamma)J(J+1)+(\alpha-\gamma)E(\kappa)] \\ & +\frac{(\boldsymbol{F}_1\cdot\boldsymbol{I})}{2F_1(F_1+1)J(J+1)}\left\{(\boldsymbol{I}_0\cdot\boldsymbol{J})+\frac{8YI_0J(2I_0-1)}{2J+3}\right\}[(a_3+c_3)J(J+1) \\ & +(a_3-c_3)E(\kappa)]\,, \end{aligned}$$

where

$$C'=\frac{2}{(J+1)(2J+3)}\frac{\partial^2V}{\partial x^2}\,,\qquad B'=\frac{2}{(J+1)(2J+3)}\frac{\partial^2V}{\partial y^2}\,,\qquad A'=\frac{2}{(J+1)(2J+3)}\frac{\partial^2V}{\partial z^2}$$

and $f$, which corresponds to the off diagonal $-K$, $+K$ states, has a value which is negative or positive depending on whether the parity, $\gamma$, is even or odd.

$f$ is

$$\begin{aligned} f=\Bigg[ & \frac{-(\boldsymbol{F}_1\cdot\boldsymbol{I})}{2F_1(F_1+1)J(J+1)}\left\{\frac{(\bar{\boldsymbol{I}}\cdot\bar{\boldsymbol{I}}_1)(\boldsymbol{F}_1\cdot\boldsymbol{J})}{I(I+1)}[(\kappa+1)\alpha-2\beta-(\kappa-1)\gamma]\right. \\ & \left.+\left[(\boldsymbol{I}_0\cdot\boldsymbol{J})+\frac{8YI_0J(2I_0-1)}{2J+3}\right][(\kappa+1)a_3-2b_3-(\kappa-1)c_3]\right\} \\ & -\frac{(\boldsymbol{J}\cdot\boldsymbol{I}_0)}{J(J+1)}[(\kappa+1)a-2b-(\kappa-1)c]-eQ[(\kappa+1)A'-2B'-(\kappa-1)C']Y\Bigg]\frac{\partial E(\kappa)}{\partial\kappa}\,. \end{aligned}$$

Then from the above results, we can see that

$$E=W+(-1)^{\gamma}|f| \, .$$

The signs before $|f|$ are shown in last column of Table I.

We can see from Table I and Ref. I that a triplet will occur in the case of $\Delta J=0$, $\Delta K_{+1}=-1$ transition between two levels of a prolate top for both of which $K_{-1}$ is odd.

Until now we only used the notations for prolate molecules, but for oblate molecules we must take care for the different notation for rotational constants between prolate and oblate molecules as shown in Appendix II.

The results of the above calculations are all valid even for the case of an oblate molecule and the change of notation from $A$, $B$, and $C$ to $C$, $B$, and $A$, are only to make the notation in this paper agree with that of Ref. 7, 8, 12.

### Acknowledgement

The author wishes to thank Professor I. Takahashi for his encouragement and helpful advice. The author's thanks are also due to Mr. H. Narumi for his kind advice in calculations and to Dr. Robert Poynter for his helpful comments and suggestions.

### Appendix I

#### *The asymmetric top wave function and its properties**

The asymmetric wave function $\psi_{\mathrm{RA}}(J, \tau, M, \gamma)$ is expressed as a linear combination of Wang functions:

$$\psi_{\mathrm{RA}}(J, \tau, M, \gamma)=\sum_{k} t_{K\tau} S(J, K, M, \gamma) \, . \quad \text{(A1)}$$

The summation over $K$ concerns only those $K$'s which occur as squares in main diagonals of the submatrixes. The values of $\gamma$ is fixed for each submatrix.

Since any $\psi_{\mathrm{RA}}$ belongs to one of the four species of $V$ group, only $S(J, K, M, \gamma)$'s of such particular species have non-vanishing $t_{K\tau}$'s in Eq. (A1). In general (i. e., for $J$ not very small), there exist several different $\psi_{\mathrm{RA}}$'s of the same species, characterized by different sets of $t_{K\tau}$'s: hence, the subscript $\tau$.

If two moments of inertia of an asymmetric top become nearly equal and if $S(J, K, M)$'s for the case of a nearly symmetric top are used in (A1), then one of the $t_{K\tau}$'s approaches unity and the remaining ones approach zero. Thus, for each $\psi_{\mathrm{RA}}(J, \tau, M, \gamma)$ of a slightly asymmetric top there is one particular $S(J, K, M, \gamma)$ to which it closely approximates, namely:

$$S(J, K, M, \gamma)=2^{1/2}[\psi^{*}(J, K, M) +(-1)^{\gamma}\psi(J, -K, M)] \, , \quad \text{(A2)}$$

where, $\gamma$, the parity, is odd or even, say 1 or 0. The parities corresponding to $J, K_{-1}, K_{+1}$ states are shown in Table 2.

Table II. Parities of Rotational Wave Function.

| $K_{-1}$ | $K_{+1}$ | $J+\gamma$ | $\gamma$ | |
|---|---|---|---|---|
| | | | $J$:*even* | $J$:*odd* |
| *e* | *e* | *e* | *e* | *o* |
| *e* | *o* | *o* | *o* | *e* |
| *o* | *e* | *o* | *o* | *e* |
| *o* | *o* | *e* | *e* | *o* |

This table has been taken from Ref. 8.

For $K=0$, only the case $\gamma=0$ exists and

$$S(J, O, M, O)=\psi^{*}(J, O, M) \, . \quad \text{(A3)}$$

Following the definition of Van Vleck**

$$\psi^{*}(J, K, M)=(-1)^{\beta}\psi_{J,K,M} \, , \quad \text{(A4)}$$

where $\beta$ denotes the larger of the two quantities $K$ and $M$, and $\psi_{J,K,M}$ is a symmetric top wave function*** which is given by

$$\psi_{J,K,M}(\theta, \phi, \chi)=\Theta_{J,K,M}(\theta)e^{iK\phi}e^{iM\chi}, \quad \text{(A5)}$$

with

$$\Theta_{J,K,M}(\theta)=N_{J,K,M}\chi^{1/2|K-M|}(1-\chi)^{1/2|K+M|} \times \sum_{0}^{n} a_{\nu}\chi^{\nu} \, .$$

### Appendix II

Following the notations of Ref. 7, 8, 12 the rotational constants $A$, $B$, and $C$, which are inversely proportional to the moments of inertia along the $a$, $b$, and $c$ axes are defined in any case as

$$A>B>C \, .$$

The axis of geometric symmetry is assigned as the $z$ axis at any time. Then the $a$, $b$, and $c$ axes coincide with the $z$, $y$, and $x$ axes for a prolate top molecule in which

*** C. H. Townes and A. L. Schawlow: Microwave Spectroscopy (McGraw-Hill Book Co. Inc., New York, 1955).

$$A>B\geqslant C \qquad \kappa=\frac{2B-A-C}{A-C}\geqslant -1\ .$$

On the other hand, the $a, b$, and $c$ axes coincide with the $x, y$, and $z$ axes for an oblate top molecule in which

$$A\geqslant B>C\ .$$

So the Hamiltonian of molecular rotation for each base becomes:

$$CJ_x^2+BJ_y^2+AJ_z^2 \qquad \text{prolate,}$$
$$AJ_x^2+BJ_y^2+CJ_z^2 \qquad \text{oblate}$$

# The Microwave Hyperfine Spectrum of Formaldehyde

By Akira OKAYA

*Department of Physics, Faculty of Science, University of Kyoto*

(Received July 11, 1955)

A hyperfine structure of the $4_{1,4}\rightarrow 4_{1,3}$ transition in the microwave spectrum of formaldehyde has been observed. The observed hyperfine features are mainly explained in terms of the interaction of the magnetic moments of the protons with the moleculer rotational magnetic field.

The main absorption lines were composed of three strong lines with total quantum numbers $F=3$, 4 and 5 respectively. The determined splitting frequency between the $F=5$ and the $F=3$ lines was $188\pm15$ kc. For a detailed explanation of this value, further information on electronic and magnetic properties of this molecule is required.

## §1. Introduction

The magnetic hyperfine structure of the microwave spectrum of the $NH_3$ molecule which is due to the interaction between proton spins and the molecular rotational magnetic field has been well investigated experimentally[1)3)] and theoretically[2)4)].

The author has observed and analyzed such magnetic hyperfine spectra in the formaldehyde molecule which is one of the typical molecules having $C_{2v}$ symmetry. A theoretical discussion of the general case of $C_{2v}$ asymmetric molecules has been described in a preceding paper[5)] by the author.

In the present paper, experimental results and their analysis will be described. Fortunately, the mirowave spectrum of this molecule has been well studied[6)7)8)] and this knowledge is of great use in interpreting the observed hyperfine structure in the spectrum.

The main rotational line in the $4_{1,4}\rightarrow 4_{1,3}$ transition has been resolved into a doublet.

The origin of this doublet is theoretically interpreted[5)] as the magnetic interaction between the two proton spins and the molecular rotational magnetic field. The results of detailed calculation show that the main line of $\Delta J=0$, $\Delta K_{+1}=-1$, $\Delta I=0$ transitions between $K_{-1}=1$ levels is composed of three strong $\Delta F=0$ lines and four weak $\Delta F=\pm1$ lines. Since the frequency splitting between $F=J-1$ and $F=J$ lines is smaller than the splitting between $F=J$ and $F=J+1$ lines, the triplet was not completely resolved but observed as a doublet.

Good agreement has been obtained between the experimental line shape and a theoretical line shape which can be obtained by assuming a definite splitting frequency relative to individual line breadths in the triplet. Then the absolute splitting frequency, $f_{SP}=188\pm15$ ks., between $F=5$ and $F=3$ lines of the $4_{1,4}\to4_{1,3}$ transition is obtained semi-empirically.

## § 2. Experimental Method and Results

The author has used a millimeter wave spectrograph consisting of a crystal frequency multiplier, *K*-band low loss Stark cell of 5 feet length and high sensitivity lock-in detector, all of which use new techniques[9)]. The millimeter wave radiation was obtained from a demountable crystal multiplier driven by a 2K33A klystron. A L. P. C. R. O. 5FP7 was used to display the absorption line at frequencies of 1/2 *c/s* to 1 *c/s*. Maximum resolution has not been achieved by mechanical recorder technique. The maximum sensitivity of this spectrograph was estimated to be about $5\times10^{-8}\text{cm}^{-1}$.

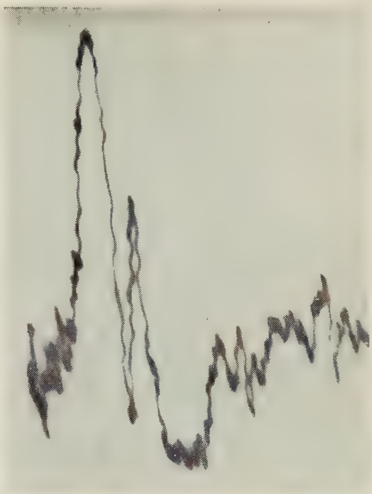

Fig. 1. The doublet spectrum of the $J_{K_{-1},K_{+1}}4_{1,4}\to4_{1,3}$ line. (Source modulation was used.)

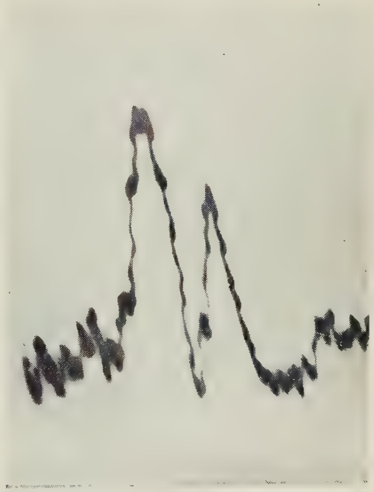

Fig. 2. The doublet spectrum of the $J_{K_{-1},K_{+1}}4_{1,4}\to4_{1,3}$ line. (Source modulation was used.)

Photographs of the observed $4_{1,4}\to4_{1,3}$ line doublet are shown in Figs. 1 and 2 for sample pressures of about $5\times10^{-4}$ mmHg. The doublet lines have been observed clearly both by 5 kc Stark and 5 kc source modulation spectrographs. Line shape distortion, which affects the accuracy of frequency measurements, has been minimized, but unfortunately, the distortion of the lower parts of the lines appearing in Figs. 1 and 2 was not completely eliminated due to the cut-off character of the amplifier tubes. In Fig. 2 the frequency scale is enlarged a little more than in Fig. 1.

## § 3. Comparison between Experimental and Theoretical Results

Theoretical calculations[5)] for $C_{2v}$ molecules, such as formaldehyde, yield for the total energy levels $W=W_0+W_1\pm|f|$, the following equations to first order

$$W_0=\frac{A-C}{2}E(\kappa)+\frac{A+C}{2}J(J+1)\,,$$

$$W_1=\begin{cases}\dfrac{-1}{4J}\{(\alpha+\gamma)J(J+1)+(\alpha-\gamma)E(\kappa)\} & M_{\mathrm{I}}=-1\,,\\[2mm] \dfrac{-1}{4J(J+1)}\{(\alpha+\gamma)J(J+1)+(\alpha-\gamma)E(\kappa)\} \qquad \text{for} & M_{\mathrm{I}}=0\,,\\[2mm] \dfrac{1}{4J(J+1)}\{(\alpha+\gamma)J(J+1)+(\alpha-\gamma)E(\kappa)\} & M_{\mathrm{I}}=+1\,,\end{cases}$$

and (1)

$$f=\begin{cases}\dfrac{1}{4J}\{(\kappa+1)\alpha-2\beta-(\kappa-1)\gamma\}\dfrac{\partial E(\kappa)}{\partial\kappa} & M_{\mathrm{I}}=-1\,,\\[2mm] \dfrac{1}{4J(J+1)}\{(\kappa+1)\alpha-2\beta-(\kappa-1)\gamma\}\dfrac{\partial E(\kappa)}{\partial\kappa} \qquad \text{for} & M_{\mathrm{I}}=0\,,\\[2mm] \dfrac{-1}{4(J+1)}\{(\kappa+1)\alpha-2\beta-(\kappa-1)\gamma\}\dfrac{\partial E(\kappa)}{\partial\kappa} & M_{\mathrm{I}}=+1\,,\end{cases}$$

where $I=1$.

Where $W_0$ is the rotational energy of molecule, $W_1$ is the diagonal term due to $(\boldsymbol{I}\cdot\boldsymbol{J})$ coupling, and $f$ is the off-diagonal term of the $(\boldsymbol{I}\cdot\boldsymbol{J})$ coupling.

The coefficients in the above equations (1) are

$$\alpha=\alpha_1+\alpha_2+\alpha_3\,,$$
$$\beta=\beta_1+\beta_2+\beta_3\,,$$
$$\gamma=\gamma_1+\gamma_2+\gamma_3\,,$$

where $\alpha_1$, $\beta_1$, $\gamma_1$ are to be determined from electronic orbital motions, $\alpha_2$, $\beta_2$, $\gamma_2$ are to be determined by nuclear orbital motions, and $\alpha_3$, $\beta_3$, $\gamma_3$ are to be determined by excited electronic states. The calculated results for the terms of the coefficients are shown below, except for $\alpha_3$, $\beta_3$, $\gamma_3$:

$$\alpha_1=-2\left(\frac{e\mu_0}{c\hbar}\right)g_1(1+1/g_1)Ar_y\langle l_0|\sum_{i,K=1,2}r_{iK}{}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)_y|l_0\rangle\,,$$

$$\beta_1=-2(e\mu_0/c\hbar)g_1(1+1/g_1)Br_z\langle l_0|\sum_{i,K=1,2}r_{iK}{}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)_z|l_0\rangle\,,$$

$$\gamma_1=-2(e\mu_0/c\hbar)g_1(1+1/g_1)C\{r_z\langle l_0|\sum_{i,K=1,2}r_{iK}{}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)_z|l_0\rangle\,,$$
$$+r_y\langle l_0|\sum_{i,K=1,2}r_{iK}{}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)|l_0\rangle\}\,,$$

and

$$\alpha_2=-\frac{e\mu_0}{c\hbar}g_1A\left\{\left(2+\frac{1}{g_1}\right)\frac{1}{r_{01}\sin\beta}+4Z_0\sum_{0,0'}r_{01}{}^{-1}\left[\sin^2\beta+\frac{1}{g_1}\left(\sin^2\beta+\frac{r_z}{r_{01}}\cos\beta\right)\right]\right\}\,,$$

$$\beta_2=-\frac{4e\mu_0}{c\hbar}g_1BZ_0\sum_{0,0'}r_{01}{}^{-1}\left(\cos^2\beta+\frac{1}{g_1}\frac{r_z}{r_{01}}\cos\beta\right)\,,$$

$$\gamma_2=-\frac{e\mu_0}{c\hbar}g_1C\left\{\left(2+\frac{1}{g_1}\right)\frac{1}{r_{01}\sin\beta}+4Z_0\sum_{0,0'}r_{01}{}^{-1}\left[1+\frac{1}{g_1}\left(\sin^2\beta+\frac{r_z}{r_{01}}\cos\beta\right)\right]\right\}\,,$$

where $A$, $B$, and $C$ are given by

$$A=\hbar^2/(2I_a),\qquad B=\hbar^2/(2I_b),\qquad C=\hbar^2/(2I_c),$$
$$A>B>C\,.$$

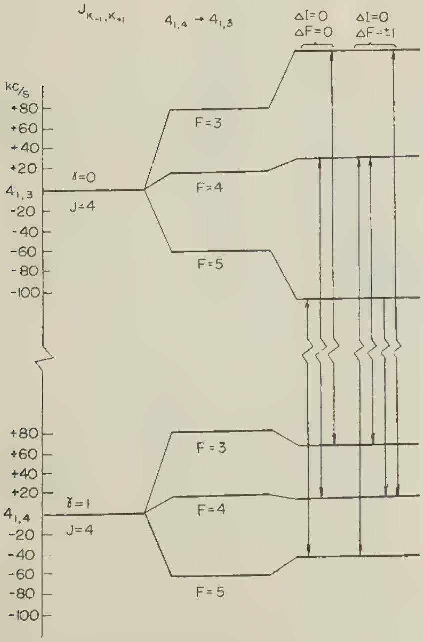

Fig. 3.

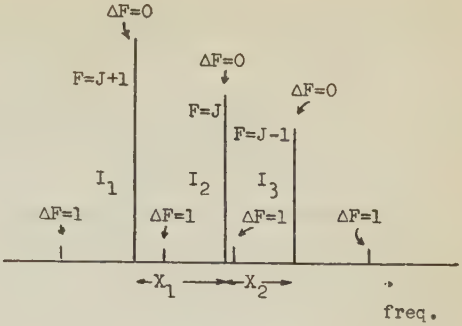

Fig. 4. The spectrum of $\Delta K_{+1}=-1$ transitions between $K_{-1}=1$ levels, where $X_1$. $X_2$ are relative splitting frequencies of the lines.

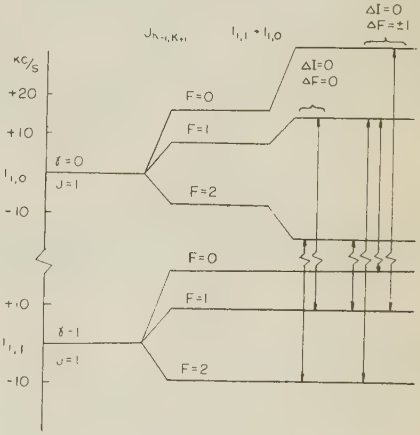

Fig. 5.

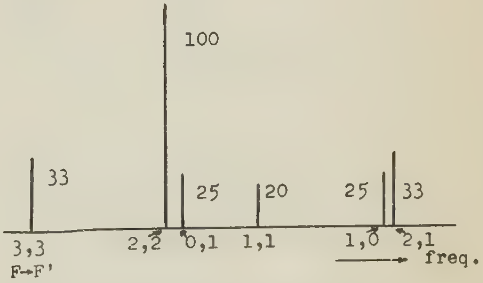

Fig. 6. The spectrum of $1_{1,1} \rightarrow 1_{1,0}$ line of which splitting frequency is calculated from the results of $4_{14} \rightarrow 4_{13}$ line.

$E(\kappa)$[10)] is the reduced energy for an asymmetric rotor and $\kappa$ is Ray's parameter defining its asymmetry.

The spectrum of $\Delta K_{+1}=-1$ transitions between $K_{-1}=-1$ levels, which is applicable to the cases of $2_{1,2} \rightarrow 2_{1,1}$, $3_{1,3} \rightarrow 3_{1,2}$, $4_{1,4} \rightarrow 4_{1,3}$, $5_{1,5} \rightarrow 5_{1,4}$, $\cdots$ transitions, is shown in Figs. 3 and 4 and Table 1. The weak $\Delta F = \pm 1$ lines are masked by strong $\Delta F=0$ lines within their line breadths, so they are not observed. On the other hand, the $1_{1,1}\rightarrow 1_{1,0}$ line is different from the lines of higher $J$, because the intensity of $F=0$, $\Delta F=0$ line is zero and the $\Delta F=\pm 1$ lines are of intensities comparable with that of $\Delta F=0$ lines as shown in Figs. 5 and 6 and Table 1. The values of $W_1$ in the upper and lower levels of the transition are almost equal within a few kc., because $J(J+1)$ is larger than $E(\kappa)$ and yet the values of $E(\kappa)$ in both levels are nearly equal when $\kappa=-0.9611$.

Then, from equation (1) above, we can obtain an approximate formula for frequency splitting between $F=J-1$ and $F=J+1$ levels for the triplet line of $K_{-1}=1$, $\Delta K_{+1}=-1$ transitions in general, namely:

$$f_{\mathrm{SP}}=|f|_{\mathrm{Up}}+|f|_{\mathrm{Low}}$$
$$=\frac{2J+1}{4J(J+1)}\left(\frac{\partial E(\kappa)_{\mathrm{Up}}}{\partial\kappa}+\frac{\partial E(\kappa)_{\mathrm{Low}}}{\partial\kappa}\right)$$
$$\times\{(\kappa+1)\alpha-2\beta-(\kappa-1)\gamma\} \qquad (2)$$

Here, the values of $E(\kappa)$ and $\partial E(\kappa)/\partial\kappa$ can be easily calculated by the interpolation from the table given in Appendix I of the paper[10] by King, Hainer, and Cross for the range of $J\leqslant 12$, and the values thus calculated are shown in Table 2.

Table II.

| Line assignment $J, K_{-1}, K_{+1}$ | $E(\kappa)$ | $\frac{\partial E(\kappa)}{\kappa}$ |
|---|---|---|
| $5_{1,5}$ | $-27.738$ | 6.74 |
| $5_{1,4}$ | $-27.177$ | 21.172 |
| $4_{1,4}$ | $-17.827$ | 4.305 |
| $4_{1,3}$ | $-17.438$ | 14.28 |
| $3_{1,3}$ | $-9.904$ | 2.453 |
| $3_{1,2}$ | $-9.671$ | 8.45 |
| $2_{1,2}$ | $-3.96$ | 1 |
| $2_{1,1}$ | $-3.84$ | 4 |
| $1_{1,1}$ | 0 | 0 |
| $1_{1,0}$ | 0.04 | 1 |

For the splitting measurement the author has adopted, instead of using standard frequency markers, the line breadth frequency as a frequency standard. Its reliability has been demonstrated in Ref. 3 and 11. First the theoretical line shape is plotted assuming a definite splitting frequency relative to the individual line breadths of the triplet and Gaussian line shape, and then drawing the first derivative as shown in Fig. 7. A comparison between the latter theoretical curve and the experimental curve of the $4_{1,4}\rightarrow 4_{1,3}$ line shows agreement as seen in Fig. 8.

The line broadenings by the Doppler effect and collisions[11] is calculated for the case of a $K$-band Stark cell at the temperature 290°K as shown below:

$$2\Delta\nu_D=107\ \mathrm{KC},$$

and

$$2\Delta\nu_W=28\ \mathrm{KC},$$

whence the total line breadth becomes

$$2\Delta\nu=2\sqrt{(\Delta\nu_D)^2+(\Delta\nu_W)^2}=110\ \mathrm{KC},$$

neglecting the modulation line broadining[11][12][13] due to source modulation since it is about 0.2% compared to the above total. $f_{\mathrm{sp}}$ is determined as

$$f_{\mathrm{sp}}=188\pm 15\ \mathrm{KC}.$$

We can obtain the value of $(\kappa+1)\gamma-2\beta-(\kappa-1)\alpha$ semi-émpirically from Eq. (2) and the result is

$$(\kappa+1)\gamma-2\beta-(\kappa-1)\alpha=-45.8\pm 4\ \mathrm{KC}.$$

On the other hand, we want to calculate the values of $\alpha$, $\beta$, $\gamma$ theoretically for comparison but we can only calculate the values of $\alpha_2$ $\beta_2$, $\gamma_2$ but not $\alpha_1$, $\beta_1$ $\gamma_1$ and $\alpha_3$, $\beta_3$, $\gamma_3$, because of the difficulty of establishing an electronic model, for which further theoretical and experimental considerations are needed. The calculated values of $\alpha_2$, $\beta_2$, $\gamma_2$ are

$$\gamma_2=-3.29-6.38\,Z_0-3.23\,Z_0' \qquad \mathrm{Kc},$$
$$\beta_2=-2.15\,Z_0-2.85\,Z_0' \qquad \mathrm{Kc},$$

and

$$\alpha_2=-27.3-41.5\,Z_0-8.48\,Z_0' \qquad \mathrm{Kc},$$

where $Z_0$ and $Z_0'$ are the effective charges of carbon and oxygen respectively. For the calculation of $\alpha_2$, $\beta_2$, $\gamma_2$ in Ref. 5, the following values for various constants have been used:

$\kappa=-1+2\delta=-0.96107$,
$r_{01}=(C-H)=1.12\pm 0.01\ A$,
$r_{01}'=(O-H)=2.02\ A$,
$I_C=14.864$ amu $A^2$,
$I_B=13.015$ amu $A^2$,
$I_A=1.792$ amu $A^2$,
$\beta=59°$, $\beta'=29°$,
$g_H=2\times 2.79255$,
$\mu_0=e\hbar/(2M_pc)=5.049\times 10^{-24}$ erg/gauss,
$c=3\times 10^{10}$ cm/s,
$e=1.602\times 10^{-19}$ coulomb.

## § 4. Discussion

As we can see in Fig. 7, the reason the theoretical triplet appears as a doublet is well understood, but the differences between ex-

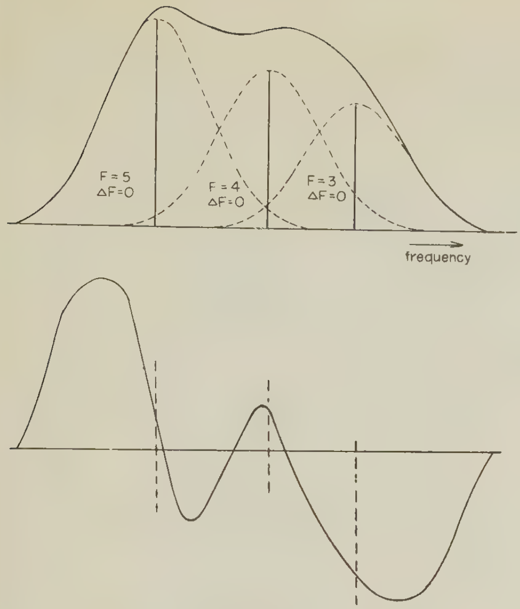

Fig. 7.

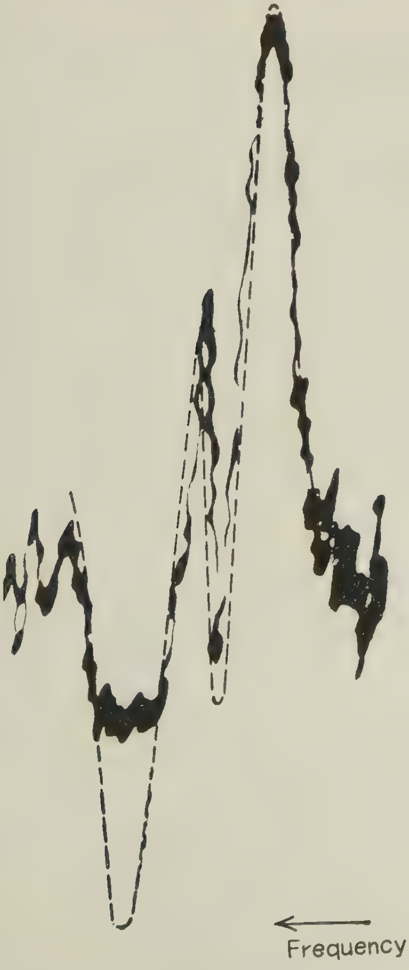

Fig. 8.

perimental and theoretical values are somewhat large and more detailed experiments are needed for the better understanding of this problem.

The author is now preparing experiments on other absorption lines in which the observation of multiplets can be expected.

The interpretation of the experimental values of $\alpha$, $\beta$, $\gamma$ depends on the model of the electronic orbits for which ionic characters, slipping effects, etc., should be taken into account. But it is very difficult to calculate these values definitely.

On the other hand, we can expect reasonable contributions from excited electronic states and spin spin interaction, and for the latter the calculations will be done elsewhere. The latter contribute to make the splitting frequency ratio $X_1/X_2$ and splitting frequency larger.

## Acknowledgement

The author wishes to thank Professor I. Takahashi for his encouragement and helpful advice.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 11, No. 3, MARCH, 1956

# Molecular Structure of Methylamine*

By Takashi ITOH

*Department of Physics, Faculty of Science, University of Tokyo, Tokyo*

(Received September 29, 1955)

The matrix elements of the Hamiltonian of a semiasymmetric internal rotor which have been given by Hecht and Dennison are rederived in a different way and in a form which is also applicable to more general semiasymmetric internal rotors. This theory together with a semi-empirical formula for the inversion splitting is applied to the analysis of the microwave spectrum of methylamine.

The barrier height of internal rotation is determined to be 691.1 cm$^{-1}$. The moments and product of inertia are obtained as $A=37.085$, $B=38.662$, $C=8.136$, $C_1=2.805$, $C_2=5.331$, $D=-0.120$ all times $10^{-40}$ g cm$^2$. The hypothetical inversion splitting in the absence of the coupling between inversion and internal rotation is determined to be 28604 Mc/sec for $n=0$ and 29358 Mc/sec for $n=1$. The molecular dimensions are obtained from the inertial constants as follows: $d_{CH}=1.093$ A (assumed), $d_{NH}=1.014$ A (assumed), $d_{CN}=1.474$ A, ∠HCH=109°30′, ∠HNH=105°50′, ∠CNH=112°10′, and the methyl axis passes through the $NH_2$ triangle making an angle of 3°30′ with the CN direction.

## § 1. Introduction

In the previous paper[1] a rather qualitative analysis of the microwave spectrum of methylamine has been given, and an approximate value of 680 cm$^{-1}$ for the barrier height of internal rotation was obtained from the starting points of $p_1$ and $p_2$ series.

On the other hand Lide[2] has assigned three inversion pairs of lines showing second-order Stark effects, which are pertinent to be used in the determination of inertial constants.

In this paper we will determine the precise values for the barrier height and molecular dimensions of methylamine by the combined use of the above experimental data.

## § 2. Theory of Semiasymmetric Internal Rotor

Theory of hindered internal rotation in $CH_3$-OH type molecule has been developed by Burkhard, Hecht and Dennison[3),4], and their theory is also applicabrele to $CH_3NH_2$. Here their formulas will be rederived in a different way and in a form which is also applicable to more general semiasymmetric internal rotors.

A semiasymmetric internal rotor is defined as a molecule with two mutually rotating groups, of which one is a symmetric rotor and the other is not[5]. Let the asymmetric and symmetric groups of a semiasymmetric internal rotor be called 1 and 2 respectively. Each of the two mutually rotating groups are assumed to be rigid, and the angle between the symmetry axis of group 2 and the principal axes of group 1 are assumed to remain constant during internal rotation. Then, the principal axes of the entire molecule are embedded in group 1, and the inertia tensor of the molecule, when referred to a coordinate system fixed in group 1, is constant during internal rotation. We denote by $x$ the angle of rotation of group 1 with respect to group 2. Then, the orientation of the molecule can be fixed by the Eulerian angles of group 1, which are also equal to the Eulerian angles of the entire molecule, and by the torsional angle $x$. The rotational motion of the molecule can be described by the angular velocity $\boldsymbol{\omega}=(\omega_\xi, \omega_\eta, \omega_\zeta)$ of group 1, which is also equal to the angular velocity of the ellipsoid of inertia of the entire molecule, and by the time derivative $\dot{x}$ of the torsional angle. The $\xi, \eta, \zeta$ axes are for the present arbitrary rectangular axes fixed in group 1.

The kinetic energy of the system may be derived as follows. Consider the $i$th constituent particle whose mass is $m_i$ and whose position vector is $\mathbf{r}_i$. We divide the velocity of this particle into three parts $\mathbf{u}_i$, $\mathbf{v}_i$, and $\mathbf{w}_i$

---

* A brief report has been given in J. Chem. Phys. **23** (1955) 1735.

as follows. $\mathbf{u}_i$ is the velocity when group 1 of the molecule stays at rest while group 2 rotates about its own symmetry axis with an angular velocity $\dot{x}$. $\mathbf{v}_i$ is the velocity when the entire molecule rotates rigidly as a whole with an angular velocity $\boldsymbol{\omega}_1$, such that $\mathbf{u}_i+\mathbf{v}_i$ gives zero resultant angular momentum of the entire molecule, i.e.

$$\sum_i m_i\mathbf{r}_i\times(\mathbf{u}_i+\mathbf{v}_i)=0 .$$

$\mathbf{w}_i$ is the velocity when the molecule rotates as a whole with an angular velocity $\boldsymbol{\omega}_2\equiv\boldsymbol{\omega}-\boldsymbol{\omega}_1$. The kinetic energy of the molecule is written

$$T=\tfrac{1}{2}\sum_i m_i(\mathbf{u}_i+\mathbf{v}_i+\mathbf{w}_i)^2=\tfrac{1}{2}\sum_i m_i\mathbf{u}_i^2$$
$$-\tfrac{1}{2}\sum_i m_i\mathbf{v}_i^2+\tfrac{1}{2}\sum_i m_i\mathbf{w}_i^2+\sum_i m_i(\mathbf{u}_i+\mathbf{v}_i)(\mathbf{v}_i+\mathbf{w}_i). \tag{1}$$

By using the relation

$$\mathbf{v}_i+\mathbf{w}_i=(\boldsymbol{\omega}_1\times\mathbf{r}_i)+(\boldsymbol{\omega}_2\times\mathbf{r}_i)=\boldsymbol{\omega}\times\mathbf{r}_i ,$$

the last term in (1) can be transformed as

$$\sum_i m_i(\mathbf{u}_i+\mathbf{v}_i)\cdot(\mathbf{v}_i+\mathbf{w}_i)=\boldsymbol{\omega}\cdot\sum_i m_i\mathbf{r}_i\times(\mathbf{u}_i+\mathbf{v}_i) .$$

Now, since $\mathbf{u}_i+\mathbf{v}_i$ represents an 'angular momentum less' motion, the right hand side of the above equation vanishes. So, the kinetic energy (1) becomes

$$T=\tfrac{1}{2}\sum_i m_i\mathbf{u}_i^2-\tfrac{1}{2}\sum_i m_i\mathbf{v}_i^2+\sum_i m_i\mathbf{w}_i^2 . \tag{2}$$

If we denote by $\mathbf{c}\dot{x}=(c_\xi\dot{x}, c_\eta\dot{x}, c_\zeta\dot{x})$ the three components of angular momentum produced by the motion $\mathbf{u}_i$ (i.e. $\sum_i m_i\mathbf{r}_i\times\mathbf{u}_i=\mathbf{c}\dot{x}$), then the following condition must be satisfied in order for $\mathbf{u}_i+\mathbf{v}_i$ to be an 'angular momentum less' motion:

$$\mathbf{c}\dot{x}+\mathbf{I}\cdot\boldsymbol{\omega}_i=0 ,$$

where $\mathbf{I}$ is the tensor of moment of inertia of the entire molecule. From the above condition, $\boldsymbol{\omega}_1$ is determined as

$$\boldsymbol{\omega}_1=\boldsymbol{\lambda}\dot{x},\ \boldsymbol{\lambda}=-\mathbf{I}^{-1}\cdot\mathbf{c}. \tag{3}$$

Therefore, the second term in (2) becomes

$$\tfrac{1}{2}\sum_i m_i\mathbf{v}_i^2=\tfrac{1}{2}\boldsymbol{\omega}_1\cdot\mathbf{I}\cdot\boldsymbol{\omega}_1=\tfrac{1}{2}\boldsymbol{\lambda}\cdot\mathbf{I}\cdot\boldsymbol{\lambda}\dot{x}^2 . \tag{4}$$

The first term in (2) is written

$$\tfrac{1}{2}\sum_i m_i\mathbf{u}_i^2=\tfrac{1}{2}C_2\dot{x}^2 , \tag{5}$$

where $C_2$ is the moment of inertia of group 2 about its own symmetry axis. The third term in (2) is written

$$\tfrac{1}{2}\sum_i m_i\mathbf{w}_i^2=\tfrac{1}{2}\boldsymbol{\omega}_2\cdot\mathbf{I}\cdot\boldsymbol{\omega}_2=\tfrac{1}{2}(\boldsymbol{\omega}-\boldsymbol{\omega}_1)\cdot\mathbf{I}\cdot(\boldsymbol{\omega}-\boldsymbol{\omega}_1)$$
$$=\tfrac{1}{2}(\boldsymbol{\omega}-\boldsymbol{\lambda}\dot{x})\cdot\mathbf{I}\cdot(\boldsymbol{\omega}-\boldsymbol{\lambda}\dot{x}) . \tag{6}$$

Putting (4), (5) and (6) into (2), we obtain the expression for the kinetic energy

$$T=\tfrac{1}{2}U\dot{x}^2+\tfrac{1}{2}\sum_{j,k} I_{jk}(\omega_j-\lambda_j\dot{x})(\omega_k-\lambda_k\dot{x}) , \tag{7}$$

where

$$U=C_2-\sum_{j,k} I_{jk}\lambda_j\lambda_k . \tag{8}$$

The components of the total angular momentum $P_\xi, P_\eta, P_\zeta$ conjugate to $\omega_\xi, \omega_\eta, \omega_\zeta$ are

$$P_j=\frac{\partial T}{\partial\omega_j}=\sum_k I_{jk}(\omega_k-\lambda_k\dot{x}) , \tag{9}$$

and the internal rotational angular momentum $P$ which is conjugate to $\dot{x}$ is

$$P=\frac{\partial T}{\partial\dot{x}}=U\dot{x}-\sum_{j,k}\lambda_j I_{jk}(\omega_k-\lambda_k\dot{x})$$
$$=U\dot{x}-\sum_j\lambda_j P_j . \tag{10}$$

Putting (9) and (10) into (7) we have

$$T=\tfrac{1}{2}U^{-1}\left(P+\sum_j\lambda_j P_j\right)^2+\tfrac{1}{2}\sum_{j,k} I^{-1}_{j,k}P_jP_k ,$$

where $I^{-1}_{jk}$'s are elements of the inverse inertia tensor. Adding the potential energy $V(x)$ to the above expression, we obtain the rotational Hamiltonian

$$\mathbf{H}_r=\tfrac{1}{2}U^{-1}\left(P+\sum_j\lambda_j P_j\right)^2+\tfrac{1}{2}\sum_{j,k} I^{-1}_{jk}P_jP_k+V(x) . \tag{11}$$

The potential $V(x)$ may, as usual, be assumed to be of the sinusoidal form

$$V(x)=\tfrac{1}{2}H(1-\cos 3x) . \tag{12}$$

Thus far, the coordinate axes $\xi, \eta, \zeta$ have been chosen arbitrarily. Now we take a new system of coordinate axes in the following way: we take the $\bar{\zeta}$ axis in the direction of the vector $\boldsymbol{\lambda}$, while take $\bar{\xi}$ and $\bar{\eta}$ axes arbitrarily under the restriction that they are perpendicular to the $\bar{\zeta}$ axis and to each other. The Hamiltonian then have the form

$$\mathbf{H}_r=\tfrac{1}{2}U^{-1}(P+\lambda P_{\bar{\zeta}})^2+\tfrac{1}{2}\sum_{\bar{j}\bar{k}}\bar{I}^{-1}_{\bar{j}\bar{k}}P_{\bar{j}}P_{\bar{k}}+V(x) , \tag{13}$$

where $\lambda=|\boldsymbol{\lambda}|$, and $\bar{\mathbf{I}}$ denotes the inertia tensor referred to the new coordinate axes.

In quantum mechanics, we replace $P^{-}$, $P_{\bar{\eta}}$ and $P_{\bar{\zeta}}$ by matrices whose elements are

$$\begin{cases}(P_{\bar{\eta}}\mp iP_{\bar{\xi}})^{JK}_{JK\pm1}=\hbar\sqrt{(J\mp K)(J\pm K+1)} , \\ (P_{\bar{\zeta}})^{JK}_{JK}=\hbar K ,\end{cases} \tag{14}$$

and replace $P$ by $\frac{\hbar}{i}\frac{\partial}{\partial x}$.

The merit of using $\bar{\xi}, \bar{\eta}, \bar{\zeta}$ axes lies in that, if we adopt the basic wave functions which diagonalize $P_{\bar{\zeta}}(=\hbar K)$ and

$$\frac{\hbar^2}{2}U^{-1}\left(\frac{1}{i}\frac{d}{dx}+\lambda K\right)^2+V(x), \tag{15}$$

then the off-diagonal elements of the Hamiltonian (13) do not contain any terms involving $P$ or $P^2$. Since the magnitudes of terms involving $P$ and $P^2$ are of the orders of $\sqrt{h\nu_r\cdot h\nu_t}$ and $h\nu_t$, where $h\nu_r$ and $h\nu_t$ are rotational and torsional energies respectively, and since in most cases $h\nu_t$ is much larger than $h\nu_r$, the elimination of the terms involving $P$ and $P^2$ from the off-diagonal elements of the Hamiltonian usually facilitates the calculation of energy levels. This will be an improvement on the method of Burkhard and Dennison.

The eigenfunction of the internal rotational Hamiltonian (15) can be expanded in the Fourier series

$$Q(x)=\sum_m a_m e^{imx}, \tag{16}$$

where $m$ takes every third integral values. We may introduce an internal rotational quantum number $\mu(=0, 1, -1)$ by the definition $\mu=m\,(\mathrm{mod.}\ 3)$. Then the eigenstates of the Hamiltonian (15) are designated by $\mu$ and the torsional quantum number $n$. It can be shown that $\mu$ is related to $\tau$ of Burkhard and Dennison⁴⁾ by the equation

$$K+\tau+\mu=1\ (\mathrm{mod.}\ 3)\,. \tag{17}$$

The use of $\mu$ will be more convenient than $\tau$, because the energy matrix factors into three submatrices belonging to $\mu=0$, $\mu=1$ and $\mu=-1$, and also the selection rule for the spectral transition becomes simply $\Delta\mu=0$ instead of $\Delta(K+\tau)=0$.

By the way, it can be easily shown that the eigenvalue $E^{K\mu n}$ of the internal rotational Hamiltonian (15) is a periodic function of $\gamma=\frac{2\pi}{3}(\lambda K+\mu)$:

$$E^{K\mu n}=\alpha_n-\beta_n\cos\gamma-\beta_n'\cos 2\gamma-\cdots. \tag{18}$$

The method of numerical evaluation of $E^{K\mu n}$ has been devised by Koehler and Dennison⁶⁾.

## § 3. CH$_3$NH$_2$ Type Molecules

The theory of the preceding section applies to all the semiasymmetric internal rotors. In the present section, we consider a somewhat specialized type of semiasymmetric rotor, i.e. a semiasymmetric rotor with a plane of symmetry. CH$_3$NH$_2$ and CH$_3$OH are sush molecules.

In this type of molecules, if we take the $\xi$ axis to be the normal to the plane of symmetry, two products of inetia $-I_{\xi\eta}$ and $-I_{\xi\zeta}$ vanishes, and only $-I_{\eta\zeta}$ remains non-vanishing. So the inertia tensor is written

$$\mathbf{I}=\begin{pmatrix} A & 0 & 0 \\ 0 & B & -D \\ 0 & -D & C \end{pmatrix}, \tag{19}$$

where $A, B, C$ are moments of inertia about $\xi, \eta, \zeta$ axes and $D$ is the product of inertia with respect to $\eta$, and $\zeta$ axes ($I_{\eta\zeta}=-D$). We may take $\zeta$ axis to be parallel to the symmetry axis of group 2 (symmetric group). Then the above $A, B, C, D$ are just those defined in I.

The vectors $\boldsymbol{\lambda}$ and $\mathbf{c}$ defined in §2 are written explicitly

$$\mathbf{c}=-\begin{pmatrix} 0 \\ 0 \\ C_2 \end{pmatrix}, \tag{20}$$

$$\boldsymbol{\lambda}=-\mathbf{I}^{-1}\cdot\mathbf{c}=\begin{pmatrix} 0 \\ \dfrac{DC_2}{BC-D^2} \\ \dfrac{BC_2}{BC-D^2} \end{pmatrix}, \tag{21}$$

from which we obtain

$$\lambda=|\boldsymbol{\lambda}|=\frac{C_2\sqrt{B^2+D^2}}{BC-D^2}, \tag{22}$$

and

$$U=C_2-\boldsymbol{\lambda}\cdot\mathbf{I}\cdot\boldsymbol{\lambda}=C_2\frac{BC_1-D^2}{BC-D^2}, \tag{23}$$

where $C_1=C-C_2$.

The coordinate transformation $\xi, \eta, \zeta\to\bar{\xi}, \bar{\eta}, \bar{\zeta}$ can be achieved by a rotation about $\xi(=\bar{\xi})$ axis by an angle

$$\theta=-\tan^{-1}\frac{D}{B}. \tag{24}$$

The inertia tensor referred to the new coordinate axes is

$$\bar{\mathbf{I}}=\mathbf{S}\mathbf{I}\tilde{\mathbf{S}}, \tag{25}$$

where

$$\mathbf{S}=\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & \sin\theta \\ 0 & -\sin\theta & \cos\theta \end{pmatrix}, \qquad (26)$$

and $\tilde{\mathbf{S}}$ is the transposed matrix of $\mathbf{S}$. From (19), (24), (25) and (26), the inverse inertia tensor referred to the new coordinate axes is obtained as

$$\bar{\mathbf{I}}^{-1}=\mathbf{S}\mathbf{I}^{-1}\tilde{\mathbf{S}}=\begin{pmatrix} \frac{1}{A} & 0 & 0 \\ 0 & \frac{B}{B^2+D^2} & \frac{D}{B^2+D^2} \\ 0 & \frac{D}{B^2+D^2} & \frac{B+C}{BC-D^2}-\frac{B}{B^2+D^2} \end{pmatrix}. \qquad (27)$$

The matrix elements of the Hamiltonian (13) is obtained as

$$\left\{\begin{aligned} (\mathbf{H}_r)^{JK\mu n\pm}_{JK\mu n\pm}&=\frac{\hbar^2}{4}\left(\frac{1}{A}+\frac{B}{B^2+D^2}\right)[J(J+1)-K^2]+\frac{\hbar^2}{2}\left(\frac{B+C}{BC-D^2}-\frac{B}{B^2+D^2}\right)K^2+E^{K\mu n}\,, \\ (\mathbf{H}_r)^{JK\quad\mu n\pm}_{JK+1\mu n'\pm}&=\frac{\hbar^2}{2}\frac{D}{B^2+D^2}(K+\tfrac{1}{2})\sqrt{(J-K)(J+K+1)}\,I^{K\quad\mu n}_{K+1\mu n'}\,, \\ (\mathbf{H}_r)^{JK\quad\mu n\pm}_{JK+2\mu n'\pm}&=-\frac{\hbar^2}{8}\left(\frac{1}{A}-\frac{B}{B^2+D^2}\right)\sqrt{(J-K)(J-K-1)(J+K+1)(J+K+2)}\,I^{K\quad\mu n}_{K+2\mu n'}\,, \end{aligned}\right. \qquad (28)$$

where

$$I^{K\mu n}_{K'\mu n'}=\int_0^{2\pi} Q^{K\mu n}(x)^*Q^{K'\mu n'}(x)dx\,. \qquad (29)$$

We have included in the above expressions a superfluous index ± which designates the sublevels of inversion doubling described in the following section. It is to be mentioned that the formulas of (28) have also been derived by Hecht and Dennison[4] in a different way independently.

## § 4. Inversion Doubling

In $CH_3NH_2$, inversion takes place in addition to the internal rotation, and there occurs a very complicated interaction between inversion and internal rotation. To avoid the difficulty involved in the rigorous treatment of this two dimensional internal motion, we have proposed in I a simple semiempirical formula for the inversion splitting, and it will be also used in this paper. The summary of I will be given in the following with some complementary remarks.

When the $NH_2$ group turns over from one side to the opposite side of the $CH_3$ group, the minima and maxima of the torsional potential are reversed. Therefore, the internal rotational state undergoes a transition $Q(x)\to Q(x-\pi)$ accompanying the inversion. The inversion splitting is considered to be proportional to

$$\int_0^{2\pi} (x)^*Q(x-\pi)dx\,,$$

and the constant of proportionality may be regarded as an empirical parameter.

One of the component levels of the inversion doublet is symmetric and the other is antisymmetric with respect to the exchange of the positions of two protons in the $NH_2$ group. The nuclear statistical weights of these levels are 1 and 3 respectively. Which of these levels is the lower or the higher can be found as follows. Let the positions of two protons be exchanged by ( i ) the turning over of the $NH_2$ group from one side to the opposite of the $CH_3$ group followed by (ii) a 180° rotation of the $NH_2$ group about the $CH_3$ figure axis. Operation (i) is represented by a transformation $V_a\to V_b$, where $V_a$ and $V_b$ denote the wave functions for the vibrational states of the $NH_2$ group in each side of the $CH_3$ group. (We assume as the first approximation that the molecule is a symmetric top and that its principal axes are not moved by operation (i)). Operation (ii) is represented by a simultaneous transformation of internal and overall rotational wave functions $Q(x)\to Q(x-\pi)$, $\Theta_{JKM}(\theta,\phi,\psi)\to\Theta_{JKM}(\theta,\phi,\psi+\pi)=(-1)^K\times\Theta_{JKM}(\theta,\phi,\psi)$, where $\Theta_{JKM}$ denotes the wave function of the symmetric rotor and $\theta,\phi,\psi$ are the Eulerian angles of the $NH_2$ group. The overall transformation, therefore, is

$$\begin{aligned} V_a\Theta_{JKM}(\theta,\phi,\psi)Q(x)\to&(-1)^K \\ \times& V_b\Theta_{JKM}(\theta,\phi,\psi)Q(x-\pi). \end{aligned} \qquad (30)$$

Now the symmetric and antisymmetric states correspond to the sum and difference of the two sides of (30), form which we know that the energy of inversion splitting measured from the singlet (symmetric) to the triplet (antisymmetric) level is given by

$$\varDelta=(-1)^K\varDelta_0\int_0^{2\pi}Q(x)Q(x-\pi)dx \tag{31}$$

inclusive of sign, where $\varDelta_0$ is a positive constant to be determined empirically.

We may now formally introduce the Hamiltonian of inversion $\mathbf{H}_i$ which is defined by its matrix elements

$$(\mathbf{H}_i)^{JK\mu n\pm}_{JK\mu n\pm}=\pm\tfrac{1}{2}(-1)^K\varDelta_0 \times\int_0^{2\pi}Q^{K\mu n}(x)^*Q^{K\mu n}(x-\pi)dx\,. \tag{32}$$

By adding $\mathbf{H}_i$ to the rotational Hamiltonian $\mathbf{H}_r$ of (13) we obtain the total Hamiltonian

$$\mathbf{H}=\mathbf{H}_r+\mathbf{H}_i\,. \tag{33}$$

The matrix elements of $\mathbf{H}$ can be obtained by adding (28) and (32). The calculations of the following sections will be based on this Hamiltonian $\mathbf{H}$.

By the way, it can be shown from the form of the internal rotational Hamiltonian (15) that the integral $\int_0^{2\pi}Q(x)^*Q(x-\pi)dx$ is a periodic function of $\gamma'=\frac{\pi}{3}(\lambda K+\mu)+\pi\mu$:

$$\int_0^{2\pi}Q(x)^*Q(x-\pi)dx=\sigma_n\cos\gamma'+\sigma_n{}'\cos3\gamma'+\cdots, \tag{34}$$

where $\sigma_n, \sigma_n{}', \cdots$ are constants for each torsional state $n$. It is to be noted that only odd multiples of $\gamma'$ appear in (34).

## § 5. Determination of Molecular Constants

Apparent rotational constants of methylamine were determined by Lide[2] from the three lines of 23341 Mc ($J_{K_{-1},\,K_{+1}}=5_{1,4}\to4_{2,2}$), 36452 Mc ($5_{1,5}\to4_{2,3}$) and 23450 Mc ($5_{2,3}\to6_{1,5}$), neglecting the effects of internal rotation and inversion. Later, however, the inversion partners of these lines have been found at 17476 Mc, 30566 Mc and 29312 Mc[2], and it is necessary to take the mean values of the two sets of frequencies to eliminate the effect of inversion doubling. The mean frequencies are expressed as

$$-13\frac{h}{16\pi^2}\left(\frac{1}{A}+\frac{B}{B^2+D^2}\right)+3\frac{h}{8\pi^2}\left(\frac{B+C}{BC-D^2}-\frac{B}{B^2+D^2}\right)-15\frac{h}{16\pi^2}\left(\frac{1}{A}-\frac{B}{B^2+D^2}\right)I^{-100}_{100} +\frac{E^{200}}{h}-\frac{E^{100}}{h}+\frac{\mathcal{E}_1}{h}=20408\text{ Mc}\,, \tag{35a}$$

$$-13\frac{h}{16\pi^2}\left(\frac{1}{A}+\frac{B}{B^2+D^2}\right)+3\frac{h}{8\pi^2}\left(\frac{B+C}{BC-D^2}-\frac{B}{B^2+D^2}\right)+15\frac{h}{16\pi^2}\left(\frac{1}{A}-\frac{B}{B^2+D^2}\right)I^{-100}_{100} +\frac{E^{200}}{h}-\frac{E^{100}}{h}+\frac{\mathcal{E}_2}{h}=33509\text{ Mc}\,, \tag{35b}$$

$$15\frac{h}{16\pi^2}\left(\frac{1}{A}+\frac{B}{B^2+D^2}\right)-3\frac{h}{8\pi^2}\left(\frac{B+C}{BC-D^2}-\frac{B}{B^2+D^2}\right)+21\frac{h}{16\pi^2}\left(\frac{1}{A}-\frac{B}{B^2+D^2}\right)I^{-100}_{100} -\frac{E^{200}}{h}+\frac{E^{100}}{h}+\frac{\mathcal{E}_s}{h}=26381\text{ Mc}\,, \tag{35c}$$

where the last terms in the left hand sides are the contributions from the off-diagonal elements of the Hamiltonian.

In addition to the above frequencies, the origins of the $p_1$ and $p_2$ series[1] may be used in the determination of the molecular constants. These series correspond to the transitions $J\to J$, $K=0\to1$, $\mu=1$, $n=1$, and the mean frequency of the origins of the $p_1$ and $p_2$ series is expressed as

$$-\frac{h}{16\pi^2}\left(\frac{1}{A}+\frac{B}{B^2+D^2}\right) +\frac{h}{8\pi^2}\left(\frac{B+C}{BC-D^2}-\frac{B}{B^2+D^2}\right) +\frac{E^{111}}{h}-\frac{E^{011}}{h}+\frac{\mathcal{E}_4}{h}=30187\text{ Mc}. \tag{36}$$

The frequencies of the lines of (35) and (36) are all quite insensitive to $D$. On the other hand, the Stark coefficients of the lines of the $p_1$ and $p_2$ series are sensitive to $D$, so that they are pertinent to be used in the determination of the value of D.

One more condition is necessary to fix all the molecular constants $A, B, C_1, C_2, C(=C_1+C_2), D$ and $H$ (barrier height). However, it is known that the value of $C_2$ is almost equal to the moment of inertia of methane in many molecules such as methylalcohol and methyl halides. Therefore, as a first step, we tentatively assume that the value of $C_2$ is equal to the moment of inertia of methane.

The determination of molecular constants is a problem of successive approximation, and after several cycles of calculations a fairly good set of trial values has been obtained. Using these trial values, the Stark coefficients of the lines of the $p_1$ series are expressed by the following equation:

$$\left[\frac{\mu_{\|}}{J^2+J}+\mu_{\pm}\frac{h}{4\pi^2c}\frac{D}{(B^2+D^2)}\left(\frac{0.116}{J^2+J}+0.439\right)\right]\frac{M}{\hbar}$$

The value of $\mu_{\|}$ and $\alpha_{\pm}$ have been obtained by Lide[2)] as $\mu_{\|}=0.304$ D and $\mu_{\pm}=1.232$ D from the Stark coefficients of the lines of (35) with a sufficient accuracy to be put into the above expression. The experimental value of Stark coefficients were measured on the third line ($J=3$) of $p_1$ series to be $0.0228\times10^{-24}$ $M/h$ $Mc$/sec[1)]. Thus we obtain

$$\frac{h}{4\pi^2c}\frac{D}{B^2+D^2}=-0.0045\ \text{cm}^{-1}\ . \qquad (37)$$

The pertubation terms in (35) and (36) have been calculated from the trial values of molecular constants as

$\varepsilon_1/h=149$ Mc, $\varepsilon_2/h=44$ Mc, $\varepsilon_3/h=-330$ Mc and $\varepsilon_4/h=0$, and these values have been put into (35) and (36). Then, from (35), (36) and (37) and by repeated cycles of calculations we have obtained the values of the molecular constants are listed in Table I. In Table I, the values of inversion splitting constant $\varDelta_0$ for the ground and first excited torsional states are also given. The value of $\varDelta_0$ for $n=0$ has been obtained from the frequency difference of the pair of lines of 23341 Mc and 17476 Mc, while the values of $\varDelta_0$ for $n=1$ has been obtained from the origins of the $p_1$ and $p_2$ series.

From the constants in Table I the moments and products of inertia of the molecule and the barrier height of internal rotation can be determined. The results are given in Table II.

Table I. Molecular Constants.

$$\frac{h}{16\pi^2}\left(\frac{1}{A}+\frac{B}{B^2+D^2}\right)=22164.6\ \text{Mc}$$

$$\frac{h}{8\pi^2}\left(\frac{B+C}{BC-D^2}-\frac{B}{B^2+D^2}\right)=103144.8\ \text{Mc}$$

$$\frac{h}{16\pi^2}\left(\frac{1}{A}-\frac{B}{B^2+D^2}\right)=461.46\ \text{Mc}$$

$$\frac{h}{4\pi^2}\frac{D}{B^2+D^2}=-135\ \text{Mc}$$

$$\frac{h}{8\pi^2}\frac{1}{U}\left(=\frac{h}{8\pi^2}\frac{1}{C_2}\frac{BC-D^2}{BC_1-D^2}\right)=456609\ \text{Mc}$$

$$\lambda\left(=\frac{C_2\sqrt{B^2+D^2}}{BC-D^2}\right)=0.655276$$

$$\alpha\left(=\frac{UH}{2\hbar^2}\right)=11.3444$$

$$\Delta_0=\begin{cases}28604\ \text{Mc (for } n=0)\\ 29358\ \text{Mc (for } n=1)\end{cases}$$

Table II. Inertial constants and barrier height.

$A = 37.085\times10^{-40}$ gcm²
$B = 38.662$ 〃
$C = 8.136$ 〃
$C_1 = 2.805$ 〃
$C_2 = 5.331$ 〃
$D = -0.120$ 〃
$H = 691.1$ cm⁻¹

The values in Tables I and II are dependent on the assumption on the value of $C_2$. However, calculations of the frequencies of the other lines have shown a good agreement with the experimental results[1),2)] within errors of an order of 100 to 200 Mc*, and additional adjustment of the molecular constants proved to give no appreciable improvement on the agreement between observed and calculated frequencies. Therefore, the values in Tables I and II may be accepted as final values within an uncertainty of a few tenth of a percent which correspond to the discrepancies of 100 to 200 Mc mentioned above. These discrepancies will be due to the neglect of various higher-order effects, and are of an allowable order of manitude. Further checks on our results have been obtained by the comparison of observed and calculated values for the Stark coefficients and hyperfine splittings of the assigned lines and the expansion coefficients of $p_1$ and $p_2$ series*.

The percentage error in the value of $D$, however, is expected to be rather large, since the Stark pattern of the line was contaminated by the quardrupole effect and since the Stark coefficients of the line of the $p_1$ series were used instead of the mean values of the coefficients of the lines of the $p_1$ and $p_2$ series. The maximum possible error in $D$ will be about $0.05\times10^{-40}$ g cm$^2$, which however, results only in an error of 10′ in the angle between the CN axis and the methyl axis.

---

* T. Nishikawa: to be published.

## § 6. Molecular Structure and Barrier Height

There are seven structural parameters of the molecule while only five inertial constants are available, so that it is necessary to make two assumptions to fix the molecular structure. The most acceptable assumption will be to set the CH distance equal to the methane value 1.093 A. This assumption is also equivalent to set the HCH angle equal to the tetrahedral angle 109°28′, on account of the assumption made in the preceding section on the value of $C_2$. The next assumption we make on the locations of the hydrogen atoms in the amino group, since hydrogen atoms are light and have minor effects on the inertial constants. Among the three structural parameters involving these hydrogen atoms ($d_{NH}$, $\angle$HNH and $\angle$CNH), we take $d_{NH}$ equal to that in ammonia, 1.014 A, since in general bond lengths are less affected by the surroundings than bond angles, i.e. bond stretching force constants are usually larger than bond bending force constants.

With the above assumptions the molecular structure of methylamine is determined as shown in Table III. The possible errors for these values are also indicated in Table III. These possible errors take account of the above assumptions and of the discrepancies between observed and calculated frequencies mentioned in the preceding section.

Table III. Structural Parameters.

| | |
|---|---|
| $d_{CH}$ = 1.093 A (assumed) | $\angle$HCH = 109°30′ ± 1° |
| $d_{NH}$ = 1.014 A (assumed) | $\angle$HNH = 105°50′ ± 1° |
| $d_{CN}$ = 1.474 A ± 0.005 A | $\angle$CNH = 112°10′ ± 1° |

The angle between CN and the methyl axis = 3°30′ ± 20′. (The methyl axis passes through the $NH_2$ triangle.)

The CN distance of 1.474 A is in good agreement with the electron diffraction value 1.47 A[7], while both are somewhat shorter than the sum of covalent radii 1.50 A. The HNH angle of 105°50′ is slightly smaller than that in ammonia 106°47′ but the difference is almost within the probable error. The CNH angle of 112°10′ is considerably larger than the HNH angle in ammonia. The CN direction is not on the symmetry axis of the methyl group, being deviated by an angle of 3°30′. These deviations are probably due to the repulsion between the amino group and the methyl group.

The height of potential barrier to internal rotation is obtained from $U^{-1}$ and $\alpha$ as 691.1 ±1.0 cm$^{-1}$. This value is about twice as large as that in methylalcohol[8] (374.8 cm$^{-1}$), apparently corresponding to the presence of two hydrogen atoms in the amino group as compared to one hydrogen atom in the hydroxyl group. However, this apparent relation may be merely an accidental one, since three are various types of complicated interactions between the two mutually rotating groups of these molecules to be taken into account.

The values of the inversion splitting constant $\Delta_0$, 28604 Mc for $n=0$ and 29358 Mc for $n=1$, are rather large as compared with the inversion splittings in ammonia (0.7935 cm$^{-1}$) and deuterated ammonias $NH_2D$ (0.406 cm$^{-1}$), $NHD_2$ (0.1705 cm$^{-1}$) and $ND_3$ (0.068 cm$^{-1}$)[9]. The large $\Delta_0$ of methylamine may be related to the large CNH angle, i.e. the small distance between the two minima of the potential to inversion, which facilitates the inversion motion. Except for this point, the potential curves for these molecules will be similar.

## § 7. Discussion

The internal motion of methylamine is a very complicated problem, so that a number of simplifying assumptions has been made in its treatment. The main assumptions made are as follows. (1) In treating internal and overall rotations it was assumed that the molecule is rigid except for the internal rotation. (2) The potential to internal rotation was approximated by a sinusoidal function. (3) The inversion doubling was treated semi-empirically. In spite of these assumptions, however, satisfactory agreement between theory and experiment has been obtained within allowable errors. The remaining discrepancies between observed and calculated frequencies are considered to be due to various higher-order effects. In particular, the rigorous treatment of the wave equation of the internal motion on a two dimensional potential surface will be necessary to obtain a complete agreement with experiment.

### § 8. Acknowledgement

The author wishes to express his hearty thanks to Prof. M. Kotani for his encouragement during the course of this investigation. He also wishes to express his appreciation to Prof. K. Shimoda for helpful advice, and to Dr. T. Nishikawa for valuable discussion and for the help in some of the numerical calculations. He is indebted to Dr. D. R. Lide, Jr. for the communication of his results.

# The Time Lag and other undesirable Phenomena observed in Vacuum Photo-tubes at Weak Illumination II

By Masao SUGAWARA

*Hitachi Central Research Lab. Kokubunji-machi, Kitatamagun, Tokyo*

(Received October 4, 1955)

Using the tubes with two photocathodes the abnormalities of photocurrents were studied. The abnormalities of the tubes were conspicuous when one of the cathodes was isolated. These abnormal effects could be well explained from the results obtained when the potential of the isolated cathode was varied and current characteristics of the tubes were measured at various wave length of light. The effects were considered to be due to the voltage changes of the isolated cathode resulting from its own photoemission and secondary emission caused by the incidence of light. Photoelectric materials of usual photo-tubes adhering to the undesired portion of the inner surfaces can be analogously considered to the isolated cathodes of the tubes.

### § 1. Introduction

In the previous paper¹⁾ the writer has described that the photoelectric materials adhered to the undesired portion of the inner surface of the photo-tube are main cause of the non-proportionality of the photocurrent to the illuminating flux and also of the time lag of photocurrent, Preston and McDermott²⁾ have carried out calculations in simple cases and explained the current-flux non-proportionality observed in their experiment. It seems, however, that the relations between these phenomena and the behavior of photoelectric materials on the tube wall have not yet been sufficiently clarified.

As it is very hard to study the behavior of the adhered photoelectric materials with ordinarily prepared photo-tubes, we have

made the tubes comprising two photo-cathods, and further experiments were carried out with them.

## § 2. Experimental Procedures

In Fig. 1, the tube used in this experiment is shown, where A is an anode, B an ordinary photo-cathode and C an additive photocathode which is semi-transparent and adhered on the inner surface of the window. Hereafter, B and C will be called the first and the second cathodes, respectively. Too cathodes are separated, so that one can apply different voltages on them individually. To the 2nd cathode, two leads are attached. The resistance between them was about $10^4\,\Omega$ and which is small compared with those between any two electrodes of the tube.

Silver-caesium oxide photo-surface and antimony-caesium photo-surface where used for cathodes and following four kinds of tubes were made.

(a) 1st cathode : silver-caesium oxide
  2nd cathode : antimony-caesium
(b) 1st cathode : antimony-caesium
  2nd cathode : silver-caesium oxide
(c) Both 1st and 2nd cathodes : silver-caesium oxide
(d) Both 1st and 2nd cathodes : antimony-caesium.

The monochrometer and the current amplifier were the same as described in the previous paper¹⁾. The tube was so placed that the monochromatic beam illuminated the 1st cathode, after shining on and passing through the 2nd cathode. At first, maintaining the 1st cathode at a constant voltage, the voltage of the 2nd cathode was varied and the photoelectric current and dark current, i.e. the current flowing in the un-illuminated case, to the anode and to the 1st and the 2nd cathodes were measured respectively. The circuit used for the measurement of the current to the 2nd cathode is shown in Fig. 2. Secondly, isolating the 2nd cathode and maintaining the 1st cathode at the same constant voltage as above the abnormal effects as well as the spectral sensitivity were measured. At last, the two cathodes were connected, and similar measurements were carried out. The method was the same as reported in the previous paper except that the current was measured on the anode side.

## § 3. Experimental Results

Experiments were carried out with four kinds of tubes above mentioned, the results obtained in every case were similar in many respects and were summarized as:

(a) In the case that the 1st and 2nd cathodes are connected, abnormal effects are hardly observable.
(b) In the case that the 2nd cathode is isolated, abnormal effects markedly appear.
(c) The wave length range, where the abnormal effects appear, depends on the photoelectric material of the 2nd

cathode, irrespective of that of the 1st.

(d) In some tubes of which the dark current to the 1st cathode is large, the dual characteristics are observed.

Therefore, in following paragraphs, only the results for Tube I and Tube II will be described. Both tubes have the silver ceasium-oxide as the 1st cathode and antimony-ceasium as the 2nd, and the dark current of Tube I is small, while that of Tube II is large.

in both cases. In Table III are given the abnormalities when the 1st cathode is isolated and the 2nd cathode is maintained at −30 V. In Fig. 4 are shown the spectral sensitivity curves of the tube.

(2) *Tube II*

The results in the case of Tube II illuminated with the light of 500 m$\mu$ are plotted in Fig. 5. As the photocurrent to the 1st cathode is very small, the curve corresponding to it is omitted. This small photocurrent seemed to be due to the absorption of illuminating light at the 2nd cathode. Photocurrent to the anode was almost equal to that to the 2nd cathode.

In Fig. 6, is shown the photocurrent variation due to the change of wave length of incident light at constant slit width, 0.05 mm, measured when the 2nd cathode is isolated. Curve *a* was obtained in which the wave length was increased from 400 m$\mu$ towards red side, while curve *b* was obtained when the wave length was decreased from 600 m$\mu$ to violet side without interrupting the light. When the light was interrupted, however, the measured values after the interruption come to curve *a*. No duality was observed in the range of wave length longer than 520 m$\mu$.

## § 4. Discussions

(1) *Tube I*

In Fig. 3, the photocurrent curves $p, q$ and $s$ are rather complicated, these are probably due to the fact that some photoelectrons emitted from the 1st cathode arrive at the 2nd cathode, and from there the secondary electrons may be emitted. The dark current to the anode is very small and omitted in this figure. This fact represent that the thermal emission of the cathodes is negligibly small in this tube and that the dark current is mainly due to the leakage between the two cathodes. Further the relations $P \doteqdot Q+S$ and $Q'+S'=0$ are obtained, where $P, Q, S, Q'$, and $S'$ are the values corresponding to the 2nd cathode voltage on the curves $p, q, s, q'$ and $s'$ respectively.

From Fig. 3, it is conceived that when the 2nd cathode is connected to the 1st, by the illumination of the light of 600 m$\mu$, the photocurrent readings in the anode, the 1st and the 2nd cathode leads would be $P_0$, $Q_0$ and $S_0$, but when the 2nd cathode is isolated, $P_1$, $Q_1$ and $S_1$ respectively. In the latter case, the voltage of the isolated 2nd cathode varies from $V_0$ to $V_1$, because at the lower voltages than $V_1$, the supply of electrons by the leakage current is not large enough to compensate the photoelectrons emitted from the 2nd cathode.

Owing to the capacitance between the 2nd cathode and the soroundings, some durations will be required before the potential of the 2nd cathode becomes to $V_1$, and therefore, the time lag of the anode photocurrent appears. In the case shown in Fig. 3, the anode photocurrent increases to a maximum from $P_0$ then decreases and becomes $P_1$. It is expected to be the *C*-type time lag as classified in the previous paper.

An ultimate current $S_1$ of the 2nd cathode depends rather on the resistance between cathodes and does not change in proportion to the illumination when a standard filter is inserted. This is perhaps the reason why the discordance appears and it would be larger in the light more sensitive to the isolated cathode as shown in Tables I and III.

The decrease of the sensitivity of the response curves *b* and *c* in Fig. 4 in the wave length range 620∼720 m$\mu$ and 380∼640 m$\mu$ respectively can be understood from the result in Fig. 3 that $P_1$ is smaller than $P_0$. As seen from Table II, when the 2nd cathode is connected to the 1st, little abnormalities are observed, since in this case there are no isolated parts.

As stated in the previous paper, one can keep off the abnormalities by providing the tube wall with a conductive film. This fact will be explained similarly.

Now, the ascertainment of the above considerations will be made more quantitatively. Let us consider the case, for ex., of isolating the 2nd cathode. The abnormalites when illuminated by the light of 600 m$\mu$ are summarized in Table IV including those shown in Table I. The transient abnormality or the time lag may be considered analogously to the transient phenomena at the charge of the condensers in the equivalent circuit as shown in Fig. 7, where $R_1$, $R_2$ are the resistances between the two cathodes, and between the 2nd cathode and the anode, $C_1$, $C_2$ and $C_3$ are the capacitances of het 2nd cathode with

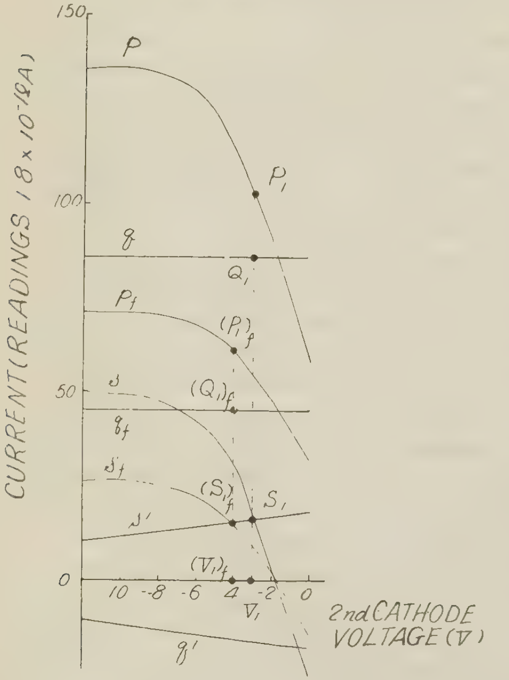

Fig. 8. Current—2nd Cathode Voltage Characteristics of Tube I.

$p$: anode photocurrent $q$: 1st cathode photocurrent $q$: 2nd cathode photocurrent $q'$: 1st cathode dark current $s'$: 2nd cathode dark current suffix $_f$: when filter was inserted.

respect to the 1st cathode, the anode and the container of the tube, respectively.

Following equations are obtained when the switch is off;

$$\begin{aligned} i_0 &= (1/R_1+pC_1)V_1=p(C_2+C_3)V_2\,, \\ i &= pC_2V_2\,, \qquad\qquad (1) \\ V_1+V_2 &= E\,, \end{aligned}$$

where $i$ is the current measurable in a meter, $i_0$ is the total current, $V_1$ and $V_2$ are the voltages of $C_1$ and $C_2$, respectively and $p$ is an operator representing $d/dt$. Considering the initial condition,

$$V_2=R_2E/(R_1+R_2) \quad \text{at} \quad t=0\,,$$

The current $i$ is given by

$$i=\frac{C_2E}{(R_1+R_2)(C_1+C_2+C_3)}\exp\left(-\frac{t}{R_1(C_1+C_2+C_3)}\right) \tag{2}$$

Similarly when the switch is on, the current $i$ is given by

$$i=\frac{E}{R_1+R_2}+\frac{E}{R_2}\left(\frac{R_1}{R_1+R_2}-\frac{C_2}{C_1+C_2+C_3}\right)\times\exp\left(-\frac{(R_1+R_2)t}{R_1R_2(C_1+C_2+C_3)}\right) \tag{3}$$

It can be seen from Eq. (2) that the A-type time lag appears when the light is cut off. On the other hand, from Eq. (3) A-type or C-type is expected at the beginning of the illumination.

The numerical values of $C_1$, $C_2$ and $C_3$ of the tube are measurable. Since the curve $s'$ is almost straight line, $R_1$ can be easily obtained from its inclination in Fig. 3. For $R_2$, as the first approximation, the value obtained from the inclination of the curve $s$ at the point $S_1$ will be used. The numerical values of these quantities are as follows;

$$R_1=1\times10^{12}\,\Omega\,,$$
$$R_2=4\times10^{10}\,\Omega\,,$$
$$C_1=C_2=1\ \mu\mu\text{F}\,,$$
$$C_3=10\ \mu\mu\text{F}\,.$$

Substituting above values and $E=30$ V into Eqs. 2 and 4, the equations lead to

Table V. Values concernning the Discordance calculated from Fig. 8.

| Condition of measurements | 2nd cathode voltage (V) | Anode Photo-current $(1.8\times10^{-12}A)$ | 1st cathode photocurrents $(1.8\times10^{-12}A)$ | 2nd cathode photocurrents $(1.8\times10^{-12}A)$ | $P'/P$ ×100 | $Q'/Q$ ×100 | $S'/S$ ×100 |
|---|---|---|---|---|---|---|---|
| no filter | $V_1=-3$ | $P_1=103$ | $Q_1=86.8$ | $S_1=16$ | 59.2 | 52.5 | 93.9 |
| inserting filter | $V_f=-4$ | $(P_1)_f=61$ | $(Q_1)_f=45$ | $(S_1)_f=15$ | | | |

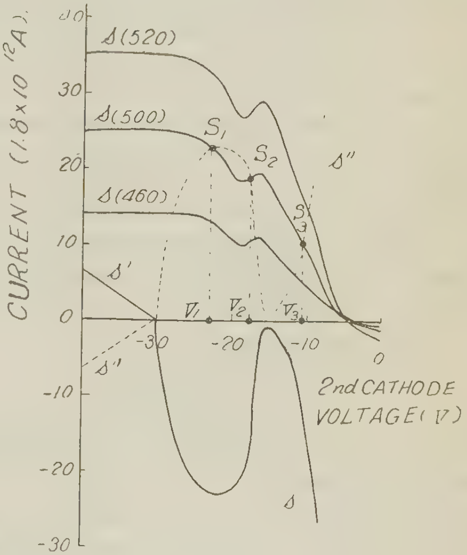

Fig. 9. Current—2nd Cathode Voltage Characteristics of Tube II.
1st cathode: $-30$ V.
$s$ (460): 2nd cathode photocurrent for 460 m$\mu$
$s$ (500): for 500 m$\mu$ $s$ (520): for 520 m$\mu$
$s'$: 2nd cathode dark current $s''$: symmetrical curve to $s'$.

$$i=2.4\times10^{-12}e^{-0.08t}\,, \qquad (2')$$

and

$$i=2.9\times10^{-11}+6.6\times10^{-10}e^{-2.2t}\,, \qquad (3')$$

respectively. Equation (3′) represents the time lag corresponding to the C-type, and above results well coincide with the experimental results shown in Table IV. If the time intervals needed before the current reaches to the ultimate value is assumed to be the time elapsed before the photocurrent comes as near as $1.8\times10^{-13}$ A to the ultimate one, the value 33 secs. and 4 secs. are obtained from Eqs. (2′) and (3′) respectively. The former coincides with the experimental value in Table IV, whereas the latter somewhat but tolerably differs from the experimental result, this may be due to the rough approximation for $R_2$.

To consider the discordance, the photocurrent readings when the filter is inserted are necessary in addition to the result shown in Fig. 3. The results are shown in Fig. 8, where the readings in the filter inserted case are designated with sufix $f$. To compare with the measured values shown in Table IV, expected values from Fig. 8 are summarizely described in Table V, in which $(P_1)_f/P_1\times100$ should be the value measured as the transmittance of the filter. The transmittance of the filter is 59,7% in Table IV and 59.2% in Table V, two values being in good agreement. The ratio for the 1st cathode photocurrent (52.5%) well coincides with the standard transmittance (52.9%), whereas that for the 2nd cathode (93.9%) quite disagrees. The discordance is apparently due to the fact that the 2nd cathode photocurrent is not proportional to the illumination.

### (2) *Tube II*

The curves corresponding to the dark currents in Fig. 5 are rather complicated. It is presumed that some thermally emitted electrons from the 1st cathode arrive at the 2nd cathode and, in a certain circumstances, emit secondary electrons. Accurate measurements were difficult in this case, as the thermal emission was very sensitive to temperature. However, the relation $P'\doteqdot Q'+S'$, also exists in this case.

The duality as shown in Fig. 6 can be similarly interpreted as in the case of Tube I. In Fig. 9, the curve $s''$ is the one drawn in symmetry to the dark current curve $s'$ with regards to the horizontal axis, Curves $s_{(460)}$, $s_{(500)}$, $s_{(520)}$ correspond to the cases of the incident light of 460 m$\mu$, 500 m$\mu$ and 520 m$\mu$, respectively. Curve $s''$ intersects the curve $s_{(500)}$ at three different point $S_1$, $S_2$ and $S_3$, and from these three potentials $V_1$, $V_2$ and $V_3$ are obtained, but the potential $V_2$ is unstable and may not be held. On the other hand, at longer wave length for which the photocurrent is larger, curve $s$ intersects curve $s''$ at only one point like as curve $s_{(520)}$ in Fig. 9. The anode current, of course, takes different values according to whether $V_1$ or $V_2$ is the potential of the 2nd cathode.

Then it is conceived that there are the cases where $S_1$ is adjacent to $S_2$. In these cases, the photocurrents may take the value $S_1$ at first, but it may change beyond $S_2$, due to any accidental causes such as temperature change, and terminates to $S_3$ instead of $S_1$. This is expected to be the B-type time lag, and would accompany with the duality as stated in the previous paper.

In this case numerical treatment is not so simple as in the case of Tube I, because the dark current varies with the 2nd cathode voltage.

Taking the variation of the dark current in calculation, the photocurrent reading in the anode by the light of 500 mμ, when the 2nd cathode is isolated is given by

$$\begin{aligned} i_p &= P_1-(P_0'-P_1') \\ &= 23-(313-304)=14 \text{ (scales)} \end{aligned}$$

from Fig. 5. In the same way, the anode current to be measured for another stable 2nd cathode potential $V_3$, is calculated to be 28 scales. For various wave lengths, these values are plotted in Fig. 10, which qualitatively agree with Fig. 6. The disagreements in absolute values seem to be attributed to the change in temperature. If the measurements are started from shorter wave length, the 2nd cathode would have a potential $V_1$ and the curve *a* in Fig. 6 or Fig. 10 would be obtained. When the wave length is longer than 500 mμ, the 2nd cathode can take the potential $V_3$ only and the duality should disappear. In the measurements started from longer wave length towards the violet side, the 2nd cathode would have a potential $V_3$, thereby curve *b* will be obtained. If the illumination is once cut off, the 2nd cathode potential would become −30 V and, therefore, the 2nd cathode would take a potential $V_1$ instead of $V_3$ when re-illuminated.

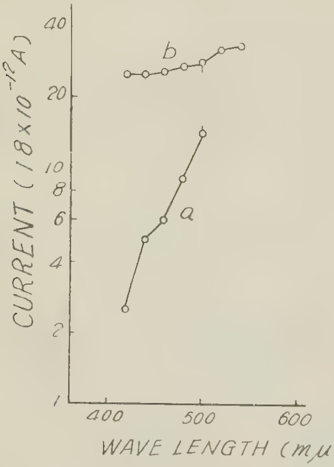

Fig. 10. Dual Character of Tube II obtained by calculation.
*a*: at lower voltage *b*: at higher voltage.

## § 5. Conclusion

The photo-tubes having two cathodes were prepared and the abnormal effects of them were measured in the case when one of the cathodes was isolated. It has been proved that the abnormalities are explained by considering the following factors; photoemission and secondary emission from the isolated cathode, the leakage resistances between the isolated cathode and other electrode, and the thermal emission from the ordinary cathode. It has been found that the abnormal effects can be explained quantitatively by presuming the isolated cathode potential and taking its capacitance into consideration. The abnormalities observed in usual photo-tubes are believed to be caused by the similar factors, that is the photoelectric materials adhering on the undesired portion of the inner surfaces of the tube.

## Acknowledgment

The writer wishes to express his gratitude to Dr. H. Hamada and Dr. B. Tadano for their kind guidance throughout this study and to Mr. S. Kobayashi, Mr. M. Matsuki, Miss A. Saito and Miss F. Kumasaka for their helpful assistance in the production of the experimental tubes. He also wishes to thank Mr. S. Takei and Mr. N. Morito for their valuable advises on preparing this paper.

# Diffraction of Elastic Waves by a Spherical Surface

By Masahumi NAGASE

*Department of Physics, Faculty of Liberal Arts,*
*University of Saga, Saga, Japan*

(Received February 8, 1955)

To clarify the effect of the curvature of a surface on the propagation of elastic waves generated at a point source, as alluded to by Lamb in the case of a plane surface, we investigate the properties of waves in an infinite elastic medium enclosing a spherical cavity. Waves of any kind are shown to be represented as linear combinations of $\Phi$, $A_\varphi$, $d_\varphi$, the scalar potential, the $\varphi$-component of the vector potential and the $\varphi$-component of the displacement, if the phenomena are independent of $\varphi$, the longitudinal angle in spherical polar coordinates with the polar axis joining the source and the center of the cavity. Taking as the initial waves $\Phi$, $A_\varphi$, $d_\varphi$ with monochromatic dipole character respectively, we obtain, in the ordinary way of mathematical physics, the solutions satisfying the boundary conditions in series forms, which are transformed into more rapidly convergent ones. In the first two cases we find the waves representing $\Phi$, $A_\varphi$ in three separated groups, correponding to three types in the case of a plane surface respectively, and in the third we find only group of solutions representing $d_\varphi$. The angular and distance dependence of their amplitudes and phases are investigated in detail.

## I. INTRODUCTION

**§1.** When the propagation of such elastic waves over a plane surface of a semiinfinite homogeneous isotropic elastic solid as are produced by a disturbance concentrated at a point on the surface was studied By H. Lamb[1], he pointed out that it remains to inquire how far the theory is to be modified by the situation of an internal source, by the heterogeneity of the earth and by the curvature of the surface. While the problem of an internal source has been discussed by H. Nakano[2], K. Sezawa[3], T. Sakai[4] and others, especially in details by Sakai, the one of a curved surface was treated by Y. Nomura[5] only with reference to the propagation of elastic waves in a spherical body. The aim of the present work is to discuss thoroughly the case of an internal source under a curved surface from another point of view having a closer relationship to the Lamb's.

As our main interest is in the effect of the curvature of the surface, we may take a spherical surface as the simplest curved one. Imagining a large spherical cavity of radius $r_0$ in an infinite elastic medium and a wave source at distance $r_s$ $(>r_0)$ from its center, we consider how the behavior of the incident simple harmonic waves of frequency $\omega$ emitted from this source will be modified by the presence of the spherical surface. The results, therefore, may be indeed less interesting from the practical point of view, except in its application to the propagation of seismic waves in seabeds or large valleys, but will show some features noteworthy from the standpoint of mathematical physics, especially in contrast with geometrical optics.

If we assume, for the sake of simplicity, the symmetry about the axis joining the center of the sphere and the source and introduce such a spherical polar coordinate system $(r, \theta, \varphi)$ as has this axis as the polar axis, the fundamental equantions of elastic vibrations are reduced to three separated wave equations, concerning the scalar potential $\Phi$ of the displacement field $\mathbf{d}$, the $\varphi$-component of the vector potential $\mathbf{A}$ and the $\varphi$-component of the displacement itself respectively.

Now, since all possible states of incident waves emitted by the source can be represented as the superposition of those derived from these three fundamental quantities, we may classify any incident waves into three characteristic types corresponding to these quantities, respectively, one being of dilatational and two of distortional character, and shall pick up for each type a wave of dipole-character as the representative one.

Then for each given incident wave we assume, as the secondary waves corresponding to the fundamental quantities, the series of which each term is such a particular solution, multiplied by an unknown coefficient, of the above-mentioned wave equations as has the character of outward radiations at a large distance from the center and we shall formally determine the coefficients so that the superposed waves satisfy the condition of a free surface for $r=r_0$. The series thus formally obtained will not be shown so useful, though convergent, to compute any physical quantities from them on account of their slow convergence.

In order to transform these series into more rapidly convergent ones, we shall employ such a method as was adopted by G. N. Watson[6] and others when treating the diffraction of electromagnetic waves by the earth. The essential point is that we can transform

$$\Sigma_{n=0}^{\infty}(2n+1)P_n(\cos\theta)f(n)/g(n)$$

into

$$\Sigma_i[2\nu\pi P_{\nu-1/2}(\cos(\pi-\theta))f(\nu-1/2) \times\{\cos\nu\pi\partial g(\nu-1/2)/\partial\nu\}^{-1}]_{\nu=\nu_i}$$

noticing that $-(2n+1)P_n(\cos\theta)f(n)/g(n)$ is the residue at $\nu=n+1/2$ of

$$2\nu\pi P_{\nu-1/2}(\cos(\pi-\theta))f(\nu-\tfrac{1}{2})/\{g(\nu-1/2)\cos\nu\pi\},$$

where $f(n)$, $g(n)$ denote any functions satisfying some conditions and $\nu_1, \nu_2, \cdots$ the zero of $g(\nu-1/2)$ qua function of $\nu$. In our problem the function corresponding to $g(\nu-\frac{1}{2})$ is shown to be such a complicated transcendental function that one cannot find out the zeros intuitively. On the location of these zeros, however, the present author has already discussed in detail[8]. By employing this result we shall find that the series thus derived converge very rapidly unless $\theta$ is very small, and are suited for our purpose. For small $\theta$, instead of summing up the terms of the series, we shall evaluate them directly from the integrals along the contours enclosing these zeros by utilizing the method of steepest descents.

Lastly, we discuss all the properties of the vibrations given by these series minutely in the respective cases, especially in contrast with the diffractions of electromagnetic waves.

## II. GENERAL FORMULATIONS

### § 2. Fundamental Equations and Particular Solutions

When **d** is expressed as $\mathbf{d}=\text{grad}\,\Phi+\text{curl}\,\mathbf{A}$ (div $\mathbf{A}=0$), then $\Phi$, $\mathbf{A}$ are the respective solutions of the wave equations with the velocities of propagation $v_l, v_t$, i.e. those of dilatational and distortional waves respectively. If we, introducing spherical polar coordinates, consider axially symmetrical cases only and take further only such harmonically oscillating waves as contain $\exp(i\omega t)$ as the time factor, the wave equations will be reduced to

$$\{\partial^2/\partial r^2+(2/r)\partial/\partial r+(1/r^2\sin\theta)\partial/\partial\theta(\sin\theta\partial/\partial\theta)\} \times(\Phi, A_\varphi^*, d_\varphi^*)+(h^2\Phi, k^2A_\varphi^*, k^2d_\varphi^*)=0, \quad (2.1)$$

where $A_\varphi=\partial A_\varphi^*/\partial\theta$, $d_\varphi=\partial d_\varphi^*/\partial\theta$, $h=\omega/v_l$, $k=\omega/v_t$.

Their particular solutions without any singularity at $\theta=0$ and $\pi$ are only those which take the forms $r^{-1/2}C_{n+1/2}(hr)P_n(\cos\theta)$, $r^{-1/2}C_{n+1/2}(kr)P_n(\cos\theta)$, respectively, where $C_{n+1/2}$ is a cylinder function of order $n+1/2$ and $P_n$ is Legendre function of order $n$, $n$ being a positive integer.

### § 3. Incident Waves

Whatever kinds of waves are emitted by the source, they are naturally represented as the superposition of those derived from $\Phi$, $A_\varphi^*$, $d_\varphi^*$, so it suffices for our purposes to consider the waves of such types respectively. Since among the waves that have infinities at the site of the source the simplest one is obviously that of dipole-character and the waves emitted by multipoles are obtained from it by differentiation with respect to the coordinates of the source and hence the corresponding results may be inferred from the dipole case, we take as the representative one the wave of dipolecharacter without losing the generality of our consideration, though in some actual cases, for example, that of earthquakes, waves of quadrupole character are thought to be prevalent. Let us consider their respective features more closely.

1. Dilatational incident wave. We assume as the dilatational incident wave such one as corresponds to

$$\Phi^p=\exp(-ihR)/R\,,\quad A_\varphi^{*p}=0\,,\quad d_\varphi^{*p}=0\,, \quad (3.1)$$

where $R=(r^2+r_s^2-2rr_s\cos\theta)^{1/2}$; this function obviously satisfies the wave equation and has the character of outward radiations in view of the time factor. Among the non-vanishing displacement components comming from it, $d_r$, $d_\theta$ tend to $-ih\exp(-ihR)/R+0(R^{-2})$ and $0(R^{-2})$ respectively as $r\to\infty$: it shows that the elementary portion at any field point at a large distance from the surface vibrates longitudinally.

2. Distortional incident wave of the first kind. We take such a wave as corresponding to

$$\Phi^p=0\ ,\quad A_\varphi{}^{*p}=\exp(-ikR)/R\ ,\quad d_\varphi{}^{*p}=0\ . \qquad (3.2)$$

This also satisfies the wave equation obviously and has the character of outward radiations. $d_r$, $d_\theta$, then, tend to

$$0(R^{-2})\ ,\quad k^2 r_s\sin\theta\exp(-ikR)/R+0(R^{-2})$$

respectively; it shows that at a large distance the vibration is transverse and in the incident plane.

3. Distortional incident wave of the second kind. We take such a wave as corresponds to

$$\Phi^p=0\ ,\quad A_\varphi{}^{*p}=0\ ,\quad d_\varphi{}^{*p}=\exp(-ikR)/R\ . \qquad (3.3)$$

Then $d_r$, $d_\theta$ vanish and

$$d_\varphi\to-ikr_s\sin\theta\exp(-ikR)/R+0(R^{-2})\ ,$$

as $R\to\infty$; it shows that the vibration is transverse and perpendicular to the incident plane: all the points of the spherical surface of radius $R$ oscillate together rotationally about the polar axis, as if the whole sphere were a rigid one.

## § 4. Boundary Conditions

Since secondary waves to be looked for must represent at a large distance from the surface some outward radiating waves, they comprise as cylinder functions $C_{n+1/2}$ only the second of the two Hankel functions, $H^{(2)}_{n+1/2}$, taking account of their asymptotic behavior for large $r$ together with the time factor.

Secondly they must, superposed on the primary one, satisfy the condition of a free surface at $r=r_0$ or any stress components must vanish there.

## III. DILATATIONAL SOURCE

## § 5. Primary and Secondary Waves

The dilatational primary wave $\exp(-ihR)/R$, defined in the last section, can be expanded by the addition theorem as follows:

$$\Phi^p=-(i/hrr_s)\Sigma_{n=0}^{\infty}(2n+1)[\zeta_n(hr_s)\psi_n(hr),\ \text{or}\ \psi_n(hr_s)\zeta_n(hr)]P_n(\cos\theta)\ , \qquad (5.1)$$

according as $r<r_s$ or $r>r_s$, where

$$\begin{aligned}\zeta_n(x)&=(\pi x/2)^{1/2}H^{(2)}_{n+1/2}(x)\ ,\\ \psi_n(x)&=(\pi x/2)^{1/2}J_{n+1/2}(x)\ .\end{aligned} \qquad (5.2)$$

In view of this expression we assume as the secondary waves the following ones:

$$\Phi^s=-(i/hrr_s)\Sigma_{n=0}^{\infty}(2n+1)a_n\zeta_n(hr)P_n(\cos\theta)\ , \qquad (5.3.1)$$

$$A_\varphi{}^s=-(i/krr_s)\Sigma_{n=0}^{\infty}(2n+1)b_n\zeta_n(kr)\times dP_n(\cos\theta)/d\theta\ , \qquad (5.3.2)$$

$$d_\varphi{}^s=0\ , \qquad (5.3.3)$$

where $a_n$, $b_n$ are unknown coefficients.

Assuming further the convergence of these series and the uniform convergence of those obtained by differentiating these series term by term, we can find out the values of $a_n$, $b_n$ from the boundary condition for $r=r_0$. Thus we have as the resultants

$$\Phi=-(i/hrr_s)\Sigma_{n=0}^{\infty}(2n+1)\{[\zeta_n(hr_s)\psi_n(hr)\ ,\ \text{or}\ \zeta_n(hr)\psi_n(hr_s)] -\zeta_n(hr_s)\zeta_n(hr)D_1(n)/D(n)\}P_n(\cos\theta)\ , \qquad (5.4.1)$$

$$A_\varphi=-(2/hrr_sma)\Sigma_{n=0}^{\infty}(2n+1)(a^2-2n(n+1)+4)\times\zeta_n(hr_s)\zeta_n(kr)dP_n(\cos\theta)/d\theta\cdot 1/D(n)\ , \qquad (5.4.2)$$

according as $r<r_s$ or $r>r_s$, where

$$\begin{aligned}D(n)=&4\{2-n(n+1)\}\zeta_n'(ma)\zeta_n'(a)\\ &+4a\zeta_n'(ma)\zeta_n(a)+(2/ma)\\ &\times\{a^2+2n(n+1)-4\}\zeta_n(ma)\zeta_n'(a)\\ &+(1/ma^2)\{(a^2-2n(n+1))^2-4a^2\\ &-8n(n+1)\}\zeta_n(ma)\zeta_n(a)\ ,\end{aligned}$$

and $D_1(n)$ is $D(n)$ with $\zeta_n(ma)$ replaced by $\psi_n(ma)$ and $a=kr$, $m=h/k$.

## § 6. Convergence of the Series

To ascertain whether the series obtained formally in the preceding section have their proper sense or not, we will investigate their convergence. Since the dominant term of $\zeta_n(a)$ for large $n$ is $(-1)^n i\pi^{1/2}(a/2)^{-n}/\Gamma(\frac{1}{2}-n)$, we find after some calculations that the $n$-th term of the series representing $\Phi$ is, for large $n$,

$$-(1/2r)(2n+1)[(r/r_s)^{n+1},\ \text{or}\ (r_s/r)^{n+1}]\times P_n(\cos\theta)\{1+0(1/n)\}$$

and so this series is convergent in virtue of $|P_n(\cos\theta)|\leqq 1$.

As to the series representing $A_\varphi$, since the $n$-th term of the series is, if $n$ is large, equal to $4n^2m/(1-m^2)1/r_0(r_0{}^2/r_sr)^{n+1}dP_n(\cos\theta)/d\theta$ within the error of $0(n^{-1})$, as we can show in the same way, we find that this series also converges, in view of $|P_n'(\cos\theta)|\leqq n^2$.

Since the series expected to represent $d_r$, $d_\vartheta$, which are obtained by differentiating the series representing $\varPhi$, $A_\varphi$ term by term with respect to $r$, $\theta$ and then by combining them linearly, are convergent uniformly for $r\leqq r_s-\delta$, $r\geqq r_s+\delta(\delta>0)$, $0\leqq\theta\leqq\pi$, as easily shown in an analogous way, these series also have their meaning as $d_r$, $d_\vartheta$.

Thus the series have been shown to be convergent indeed but their convergency is so slow that we cannot estimate them by using the first several terms only, unless $r\gg r_s$, $r\gg r_0$, and therefore we want to have other expressions, more convenient for computation.

## § 7. Transformation of the Series

If we notice that $-(2n+1)P_n(\cos\theta)f(n)$ is the residue at $\nu=n+\frac{1}{2}$ of

$$2\nu\pi P_{\nu-1/2}(-\cos\theta)f(\nu-\tfrac{1}{2})/\cos\nu\pi\ ,$$

we are led to the study of the integrals:

$$\frac{i}{hrr_s}\int\frac{\nu P_{\nu-1/2}(-\cos\theta)}{\cos\nu\pi}\times\left\{\begin{bmatrix}\zeta_{\nu-1/2}(hr_s)\psi_{\nu-1/2}(hr)\\ \text{or}\ \ \zeta_{\nu-1/2}(hr)\psi_{\nu-1/2}(hr_s)\end{bmatrix}-\zeta_{\nu-1/2}(hr_s)\times\zeta_{\nu-1/2}(hr)\frac{D_1(\nu-1/2)}{D(\nu-1/2)}\right\}d\nu\ ,$$

$$\frac{2}{krr_sma}\int\frac{\nu}{\cos\nu\pi}\frac{dP_{\nu-1/2}(-\cos\theta)}{d\theta}\times\frac{a^2-2(\nu^2-1/4)+4}{D(\nu-1/2)}\zeta_{\nu-1/2}(hr_s)\zeta_{\nu-1/2}(kr)d\nu\ ,$$

taken round a suitable contour.

Since

$$P_{\nu-1/2}(-\cos\theta)=F(\tfrac{1}{2}-\nu,\ \tfrac{1}{2}+\nu;\ 1;\ \tfrac{1}{2}+\tfrac{1}{2}\cos\theta),$$

it is obvious that $P_{\nu-1/2}(-\cos\theta)$ is an even integral function of $\nu$ when $\cos\theta$ has any assigned value such that $-1\leqq\cos\theta<1$. Thus, in view of the relations,

$$\left.\begin{aligned}H_{-\nu}^{(1)}(x)&=\exp(\nu\pi i)H_\nu^{(1)}(x)\ ,\\ H_{-\nu}^{(2)}(x)&=\exp(-\nu\pi i)H_\nu^{(2)}(x)\ ,\end{aligned}\right\}\qquad(7.1)$$

we find that the integrands of the above integrals are odd functions of $\nu$, whose only poles are at the zeros of the function

$$\cos\nu\pi D(\nu-\tfrac{1}{2})\ ,$$

since $H_\nu^{(2)}(x)$ is an integral function of $\nu$ when $\mathrm{Re}\,x$ is positive.

We assume for the moment that $D(\nu-\frac{1}{2})$, qua function of $\nu$, has no zeros on the positive half of the real axis or on the imaginary axis, and then we take the contour of integration to be formed by a semicircle of large radius $R$, whose center is at origin, which lies on the right of the imaginary axis, together with the part of the imaginary axis which joins the points $\pm Ri$. It will be supposed that $R\rightarrow\infty$ through such values that no poles of the integrands ever lie on the contour. Since the integrands are odd functions of $\nu$, the integrals along the part of the imaginary axis vanish.

Next consider the integrals along the semicircle; so long as $\theta\not\approx 0,\ \pi$, we may use Laplace's approximations,

$$P_{\nu-1/2}(-\cos\theta)\sim\cos\{\nu(\pi-\theta)-\pi/4\}\times\{(\pi/2)\nu\sin\theta\}^{-1/2}\ ,$$

which is valid when $|\nu|$ is large and $\mathrm{Re}(\nu-\frac{1}{2})\geqq 0$; also the dominant terms of $H_\nu^{(2)}(x)$ are

$$i(\sin\nu\pi)^{-1}\{(x/2)^{-\nu}/\Gamma(1-\nu)-\exp(\nu\pi i)(x/2)^\nu/\Gamma(1+\nu)\}\ ,$$

of which the latter part is negligible except near the ends of the semicircle; it follows that, since the path of integration avoids the infinities of the integrands, the values of the integrands, except the factors $P_{\nu-1/2}(-\cos\theta)$, $dP_{\nu-1/2}(-\cos\theta)/d\theta$, have their moduli on the coutour, comparable respectively with those of $(\nu/2r)[(r/r_s)^{\nu+1/2}$, or $(r_s/r)^{\nu+1/2}](\cos\nu\pi)^{-1}$, $(4/r_0)m/(1-m^2)\nu^2(r_0^2/rr_s)^{\nu+1/2}(\cos\nu\pi)^{-1}$ and so, by an application of Jordan's Lemma, the integrals round the semicircle tend to zero as the radius to infinity. Hence the sums of the residues of the respective integrands at their poles on the right of the imaginary axis are zero. If we assume the zeros of $D(\nu-\frac{1}{2})$ all simple and call them $\nu_1,\nu_2,\cdots$, then, transforming $\zeta$ into Hankel function, we have

$$\varPhi=\frac{4\pi}{a}\frac{1}{(rr_s)^{1/2}}\sum_j\left[\frac{\nu P_{\nu-1/2}(-\cos\theta)}{\cos\nu\pi}\times\frac{H_\nu^{(2)}(hr_s)H_\nu^{(2)}(hr)}{H_\nu^{(2)}(ma)}\left\{\frac{2}{a^2}\left(\nu^2-\frac{9}{4}\right)H_\nu^{(2)\prime}(a)+\frac{1}{a}\left(\frac{\nu^2-9/4}{a^2}-2\right)H_\nu^{(2)}(a)\right\}\Big/\frac{\partial\varDelta(\nu)}{\partial\nu}\right]_{\nu=\nu_j},\qquad(7.2.1)$$

$$A_\varphi=-\frac{4\pi}{a^2}\frac{1}{(rr_s)^{1/2}}\sum_j\left[\frac{\nu}{\cos\nu\pi}\frac{dP_{\nu-1/2}(-\cos\theta)}{d\theta}\times\left\{1-\frac{2(\nu^2-9/4)}{a^2}\right\}\times H_\nu^{(2)}(hr_s)H_\nu^{(2)}(kr)\Big/\frac{\partial\varDelta(\nu)}{\partial\nu}\right]_{\nu=\nu_j},\qquad(7.2.2)$$

where

$$\Delta(\nu)=-4m\frac{\nu^2-9/4}{a^2}H_\nu^{(2)\prime}(a)H_\nu^{(2)\prime}(ma)$$
$$+\frac{2}{a}\left(1+\frac{\nu^2-9/4}{a^2}\right)H_\nu^{(2)\prime}(a)H_\nu^{(2)}(ma)$$
$$+\frac{2m}{a}\left(2-\frac{\nu^2-9/4}{a^2}\right)H_\nu^{(2)}(a)H_\nu^{(2)\prime}(ma)$$
$$+\left\{1-\frac{4\nu^2}{a^2}+\frac{4\nu^2}{a^4}\left(\nu^2-\frac{9}{4}\right)\right\}$$
$$\times H_\nu^{(2)}(a)H_\nu^{(2)}(ma)\,. \tag{7.3}$$

It is to be noted that the distinction between the cases $r>r_s$, $r<r_s$, treated hitherto separately, and therefore the singularity at $r=r_s$ have disappeared.

## § 8. Zeros of $\Delta(\nu)$

In order to evaluate the newly-obtained series, it is necessary to know the zeros of $\Delta(\nu)$. Here we recapitulate the result of 8) briefly.

There exist such three groups of zeros of the first order, as enumerated below, in the fourth quadrant of the $\nu$-plane and no zeros lie on the real and imaginary axes; the zeros in the second quadrant are irrelevant to our problem. To avoid the analytical difficulties we assume henceforth $a$ to be fairly large, which does not limit the applicability of our result, since we are always interested in the waves whose wave-length is far shorter than the radius of curvature of the surface.

1. There is a zero $\nu_0$ near the real axis, whose real part is given asymptotically by the following formula:

$$\mathrm{Re}\,\nu_0\sim a\zeta^{1/2}-p_1(\zeta-1)^{1/2}$$
$$+(1/2p_1{}^2\zeta^{1/2}-p_2(\zeta-1)^{1/2})a^{-1}+\cdots, \tag{8.1}$$

where $\zeta$ is the unique real root of the cubic equation,

$$(1-m^2)\zeta^3-(3/2-m^2)\zeta^2+1/2\zeta-1/6=0\,,$$

and as to $p_1$, $p_2$ 8) is to be refered to. We are informed from the well-known discussion on Rayleigh wave that $\zeta$ is greater than unity. Really, from the definition

$$m=h/k=\{1/2(1-2\sigma)/(1-\sigma)\}^{1/2}\,,$$

where $\sigma$ denotes Poisson's ratio, we know $m<1/\sqrt{2}$, in view of $0<\sigma<\frac{1}{2}$ and, therefore, if we assign $\frac{1}{2}$ the commonest value to $m$, or 1/3 to $\sigma$, then we have $\zeta=1.149947966\cdots$, and further

$$\mathrm{Re}\,\nu_0\sim a(1.072\cdots+11.32\cdots a^{-1}$$
$$+263.2\cdots a^{-2}+\cdots\cdot)\,. \tag{8.2}$$

Its imaginary part is given by

$$\mathrm{Im}\,\nu_0\sim -a\zeta^{-1/2}[\exp\{-2a(\zeta^{1/2}\cosh^{-1}\zeta^{1/2}$$
$$-(\zeta-1)^{1/2})\}+\exp\{-2a$$
$$\times(\zeta^{1/2}\cosh^{-1}(\zeta^{1/2}/m)-(\zeta-m^2)^{1/2})\}]\,, \tag{8.3}$$

which becomes, for $m=\frac{1}{2}$,

$$-0.277\cdot\cdot a(\exp(-0.037\cdot\cdot a)+\exp(-1.10\cdot\cdot a)\}.$$

If we put $a=100$, 200, 500 to show its smallness, $\mathrm{Im}\,\nu_0$ takes $-0.69\cdot\cdot$, $-0.03\cdot\cdot$, $-0.000001\cdots$, respectively.

2. The second group of zeros $\nu_{1j}$ $(j=1, 2, \cdots)$ are placed nearly along the curve

$$\mathrm{Re}\,(\gamma\cosh\gamma-\sinh\gamma)=0 \quad (\nu=a\cosh\gamma),$$

which starts from $\nu=a$ making an angle $-\pi/3$ with the positive axis and passes off to $-\infty i$. The first several zeros, the most interesting ones, are given by

$$\nu_{1j}\sim a[1+1/2q_j{}^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j{}^3+1/120q_j{}^4$$
$$-\{-17/6+1/2(1-m^2)^{-1}+16/3(1-m^2)\}$$
$$\times(4i/3\rho_j)(1-m^2)^{1/2}q_j{}^5+\cdots]\,,$$
$$j=1, 2, 3, \cdots, \tag{8.4}$$

where $q_j=(3\rho_j/a)^{1/3}\exp(5/6\cdot\pi i)$, $\rho_j$ being one of the roots of $H^{(2)}_{-1/3}(\rho e^{\pi i})=0$, i.e. $2.383466\cdots$, $5.5101956\cdots$, $8.6473577\cdots$, $11.7868429\cdots$, $14.9272068\cdots$, $\cdots$.

3. The third group lies nearly along the curve

$$\mathrm{Re}\,(\gamma^*\cosh\gamma^*-\sinh\gamma^*)=0 \quad (\nu=ma\cosh\gamma^*).$$

This curve starts from the point $\nu=ma$, making an angle $-\pi/3$ with the positive real axis, and goes off to $-\infty i$. The first several zeros are given by

$$\nu_{2j}\sim ma[1+1/2q_j{}^{*2}-(4m^3/3\rho_j)(1-m^2)^{1/2}$$
$$\times(2m^2-1)^{-2}q_j{}^{*3}+1/120q_j{}^{*4}$$
$$-\{1/6-(2m^2+1)/(2m^2-1)$$
$$-1/2m^2/(1-m^2)-16/3m^6(1-m^2)$$
$$\times(2m^2-1)^{-4}\}(4m^3/3\rho_j)(1-m^2)^{1/2}$$
$$\times(2m^2-1)^{-2}q_j{}^{*5}+\cdots]\,,$$
$$j=1, 2, 3, \cdots\,, \tag{8.5}$$

where $q_j{}^*=(3\rho_j/ma)^{1/3}e^{5/6\pi i}$.

The zeros of large moduli are approximately given by $-(n+\frac{1}{2})\pi i/\log(1/m)$, where $n$ denotes a large positive integer. Though these zeros seem to lie on the imaginary axis, it is due to the imperfection of the approximations. They never cross the axis, as shown in 8) § 3.2.

## § 9. Convergence of the New Series

In order to investigate the convergence of the series newly obtained we estimate the order of magnitude of the higher terms of the series, corresponding to the zeros of large moduli.

For such zeros we find that $\partial\Delta(\nu)/\partial\nu$ becomes $32/\pi\cdot(-1)^n \log m\nu^{-1}\cosh^4\gamma\{1+0(a^{-1})\}$, and so a higher term of the series representing $\Phi$ is

$$4(rr_s)^{-1/2}(2/\sin\theta)^{1/2}(\log(1/m))^{-1/2}(n+\tfrac{1}{2})^{-1/2}$$
$$\times\exp[-\{(n+\tfrac{1}{2})\pi/\log(1/m)\}\theta]O(1).$$

Thus it is obvious that the series representing $\Phi$ is convergent, rapidly especially for not small $\theta$.

Secondly a higher term of the series representing $A_\varphi$ is shown to be

$$2(rr_s)^{-1/2}(2/\sin\theta)^{1/2}(\log(1/m))^{-1/2}(n+\tfrac{1}{2})^{-1/2}$$
$$\times\exp[-\{(n+\tfrac{1}{2})/\log(1/m)\}\theta)O(1).$$

Thus the convergence of this series also has been shown.

It is easily seen that their convergence is uniform with respect to $r_s$, $r$ when $r_s\geqq r_0$, $r\geqq r_0$; and so, by Abel's theorem, we may write $r_0$ for $r_s$, $r$ in the series when we wish to find the effect due to an oscillator placed on the surface and the state on the surface respectively. And the series obtained by differentiating term by term the above-mentioned series with respect to $r$ and $\theta$ are uniformly convergent, as easily shown in an analogous way, so it is permissible to obtain the displacement components from these series in such a way.

Since the above-mentioned series are rapidly convergent except when $\theta$ is quite small, we can estimate them correctly by taking up the first several terms in such a case. We shall discuss them in detail and investigate of vibration in the following sections.

## § 10. Terms Corresponding to $\nu_0$

We are to evaluate the first terms, corresponding to $\nu_0$, of the series representing $\Phi$ and $A_\varphi$, respectively.

Let us evaluate $\Phi_0$, the term of the right-handed side of (7.2.1) corresponding to $\nu_0$. Among the factors of this expression

$$\nu P_{\nu-1/2}(\cos(\pi-\theta))/\cos\nu\pi$$

is equal to

$$-i(2\nu/\pi\sin\theta)^{1/2}[\exp\{\nu(\pi-\theta)i+\pi/4i\}$$
$$-\exp\{-\nu(\pi-\theta)i-\pi/4i\}]$$
$$\times\{\exp(\nu\pi i)+\exp(-\nu\pi i)\}^{-1}\{1+O(\nu^{-1})\}$$

in view of Laplace's approximation formula; if we expand the denominator in series considering that $\mathrm{Im}\,\nu_0<0$, we have

$$\nu P_{\nu-1/2}(\cos(\pi-\theta))/\cos\nu\pi$$
$$=(2\nu/\pi\sin\theta)^{1/2}[\Sigma_{s=0}^{\infty}(-1)^s$$
$$\times\exp\{-\nu(\theta+2s\pi)i-\pi/4i\}+\Sigma_{s=0}^{\infty}(-1)^s$$
$$\times\exp\{-\nu(2(s+1)\pi-\theta)i+\pi/4i\}]$$
$$\times\{1+O(\nu^{-1})\}\,. \tag{10.1}$$

In this expression the first sum means the superposition of waves each of which propagates on the surface in the direction of positive $\theta$ after having passed $s$ times $2\pi$ and the second the one of waves propagating backward, as it is obvious when we consider the time factor and the fact, $\nu_0\sim\zeta^{1/2}kr_0$. Though $\mathrm{Im}\,\nu_0$ is so small in this case that the damping factors depending on $\theta$, $\exp\{-\mathrm{Im}\,\nu_0(\theta+2s\pi)\}$, $\exp\{-\mathrm{Im}\,\nu_0(2s\pi+2\pi-\theta)\}$ is not so effective and the second and further terms are not negligible compared with the first, it suffices for our purpose to consider only the first term, i.e. that with the factor $\exp(-\nu\theta i-(1/4\pi i)$, since the other terms behave in quite the same way.

By employing the asymptotic expansions of Hankel functions for such values of $\nu$ (9) §8.6); we have

$$\Phi_0=8k\zeta(\zeta-1)^{1/2}[8(\zeta-1)^{1/2}(\zeta-m^2)^{1/2}-8(2\zeta-1)$$
$$+2\zeta\{(\zeta-m^2)^{1/2}(\zeta-1)^{-1/2}$$
$$+(\zeta-1)^{1/2}(\zeta-m^2)^{-1/2}\}+1/2(2\zeta-1)^2$$
$$\times\{(\zeta-m^2)^{-1}+(\zeta-1)^{-1}\}]^{-1}$$
$$\times(2\pi/\zeta^{1/2}kr_0\sin\theta)^{1/2}\exp[-(\zeta-m^2)^{1/2}$$
$$\times k(r_s-r_0+r-r_0)-i\zeta^{1/2}kr_0\theta\{1-p_1(\zeta-1)^{1/2}$$
$$\times\zeta^{-1/2}(kr_0)^{-1}\}-\pi/4i]\{1+O(1/kr_0)\}$$
$$\times\{1+O((r_s-r_0)/r_0)\}\{1+O((r-r_0)/r_0)\}\,. \tag{10.2}$$

We enumerate its properties as follows:

1. $\Phi_0$ is of finite amplitude, only if the source is near the surface, i.e. $r_s-r_0\ll r_0$.
2. $\Phi_0$ is of finite magnitude only in the vicinity of the surface, i.e. $r-r_0\ll r_0$; in other words it is of character of a surface wave.
3. $\Phi_0$ is inversely proportional to $(r_0\sin\theta)^{1/2}$, i.e. to the square root of the length of the perpendicular from the field point to the polar axis, as it must be so if we consider the energy flow concentrated in the neighborhood of the surface.

4. Its phase, combined with the time factor, is given by $\exp[i\omega\{t - v_R^{-1}(1 - p(\zeta-1)^{1/2}\zeta^{-1/2} \times (kr_0)^{-1} + \cdots)s\}]$, where $v_R = \zeta^{-1/2}v_t$, the velocity of Rayleigh wave, and $s = r_0\,\theta$ the circumferential distance between the source and the field point concerned. It shows that the wave propagates on the surface with the velocity $v_R\{1 + p_1(\zeta-1)^{1/2}(v_R/\omega r_0) + \cdots\}$, which is, for $m=1/2$, $0.9325\cdots v_t\{1 - 10.56\cdots(v_t/\omega r_0) + \cdots\}$. Since the velocity of propagation depends on the frequency $\omega$, this wave is of dispersive chracter, the group velocity of which is $v_R\{1 + O((kr_0)^{-2})\}$, or is equal to the well-known propagation velocity of Rayleigh wave.

5. Since $\mathrm{Im}\,\nu_0$ is small, the damping with $\theta$ is negligible and the wave propagating in both directions and reappearing after several round trips are to be considered at the same time.

6. The displacement components derived from it are

$$d_r \sim -k(\zeta - m^2)^{1/2}\Phi_0\,, \quad d_\theta \sim -ik\zeta^{1/2}\Phi_0\,.$$

thus

$$d_r/d_\theta \sim \exp(-\pi/2i)(\zeta - m^2)^{1/2}\zeta^{-1/2}\,,$$

and it shows that there is a phase difference $\frac{1}{2}\pi$ between the two components. The point moves along an elliptic orbit whose major and minor axes are in the directions of $d_\theta$ and $d_r$ respectively and the sense of motion is from the direction of positive $d_\theta$ to that of positive $d_r$. The ratio of two principal axes is, for $m=\frac{1}{2}$, $1:0.885\cdots$.

We will then evaluate $A_{\varphi 0}$, the term of the right-handed side of (7.2.2) corresponding to $\nu_0$. The procedure is quite the same as in the preceding case. The result of the calculation is

$$\begin{aligned} A_{\varphi 0} = 4k\zeta^{1/2}&(2\zeta-1)[8(\zeta-m^2)^{1/2}(\zeta-1)^{1/2} \\ &-8(2\zeta-1) + 2\zeta\{(\zeta-m^2)^{1/2}(\zeta-1)^{-1/2} \\ &+(\zeta-1)^{1/2}(\zeta-m^2)^{-1/2}\} + 1/2(2\zeta-1)^2 \\ &\times\{(\zeta-m^2)^{-1} + (\zeta-1)^{-1}\}]^{-1} \\ &\times(2\pi/\zeta^{1/2}kr_0 \sin\theta)^{1/2} \\ &\times\exp[-(\zeta-m^2)^{1/2}k(r_s-r_0) - (\zeta-1)^{1/2} \\ &\times k(r-r_0) - i\zeta^{1/2}kr_0\theta\{1-(\zeta-1)^{1/2} \\ &\times\zeta^{-1/2}p_1(kr_0)^{-1}\} + \pi/4i]\{1+O(a^{-1})\} \\ &\times\{1+O((r_s-r_0)/r_0)\}\{1+O(r-r_0)/r_0)\}\,. \end{aligned} \tag{10·3}$$

Its properties are as follows:

1. $A_{\varphi 0}$ is of finite magnitude only in the vicinity of the surface, though its rate of damping with $r$ is smaller than that of $\Phi_0$ as shown by the factor $\exp\{-(\zeta-1)^{1/2}k(r-r_0)\}$, compared with $\exp\{-(\zeta-m^2)^{1/2}k(r-r_0)\}$, $\zeta$ being fairly close to unity.

2. It has the same properties as 1, 3, 4, 5 shown by $\Phi_0$.

3. The displacement components are

$$d_r \sim -ik\zeta^{1/2}A_{\varphi 0}\,, \quad d_\theta \sim k(\zeta-1)^{1/2}A_{\varphi 0}\,,$$

then

$$d_r/d_\theta \sim \exp(-\pi/2i)\zeta^{1/2}(\zeta-1)^{-1/2}\,.$$

It shows an elliptically polarized oscillation with the major and minor axes coinciding with the directions of $d_r$ and $d_\theta$ respectively, $d_\theta$ being $\frac{1}{2}\pi$ in advance to $d_r$. Their ratio for $m=1/2$ is $2.77\cdots:1$.

Though $\Phi_0$ and $A_{\varphi 0}$ behave differently for arbitrary $r$, they behave in a similar way for $r=r_0$ and can be superposed to one state; the displacement components coming from the superposed one are, in view of the equation for $\zeta$ to satisfy,

$$\begin{aligned} d_r = 2k^2(2\zeta-1)&[8(\zeta-1)^{1/2}(\zeta-m^2)^{1/2} - 8(2\zeta-1) \\ &+2\zeta\{(\zeta-m^2)^{1/2}(\zeta-1)^{-1/2} \\ &+(\zeta-1)^{1/2}(\zeta-m^2)^{-1/2}\} + 1/2(2\zeta-1)^2 \\ &\times\{(\zeta-m^2)^{-1} + (\zeta-1)^{-1}\}]^{-1} \\ &\times(2\pi/\zeta^{1/2}kr_0\sin\theta)^{1/2}\exp[-(\zeta-m^2)^{1/2} \\ &\times k(r_s-r_0) - i\zeta^{1/2}kr_0\theta\{1-p_1(\zeta-1)^{1/2} \\ &\times\zeta^{-1/2}(kr_0)^{-1}\} - \pi/4i]\{1+O(1/kr_0)\} \\ &\{1+O((r_s-r_0)/r_0)\}\,, \end{aligned} \tag{10.4.1}$$

$$\begin{aligned} d_\theta = -4ik^2\zeta^{1/2}&(\zeta-1)^{1/2}[8(\zeta-1)^{1/2}(\zeta-m^2)^{1/2} \\ &-8(2\zeta-1) + \cdots\,, \end{aligned} \tag{10.4.2}$$

where the dots mean the same expression as in the first equation. Then

$$d_r/d_\theta \sim (\zeta - 1/2)\zeta^{-1/2}(\zeta-1)^{-1/2}i\,.$$

The point oscillates along the elliptic orbit, whose major and minor axes are in the direction of $d_r$ and $d_\theta$, in the sense from the direction of positive $d_r$ to that of positive $d_\theta$. The ratio of the axes is

$$(v_t^2 - 1/2v_R^2)v_t^{-1}(v_t^2 - v_R^2)^{-1/2}\,,$$

whose numerical value for $m=1/2$ is $1.565\cdots$. These results are entirely compatible with those of Sakai's study on the propagation of Rayleigh wave on a plane surface (4) § 16).

At the end of the section we notice that the expansion representing this zero is useful so far as $a$ is several scores as shown in (8.2). Now the method of separating this zero from the second group of zeros $\nu_{1j}$ is valid only when $a^{-1/3} \ll \cosh^{-1}(\nu_0/a)$, since $\cosh^{-1}(\nu_{1j}/a) = O(a^{-1/3})$ (see (8.4)) and so $\nu_0$ can be separated so far as $a \gg 1000/64 \sim 1000/27$, as we see from § 8, $\cosh^{-1}(\nu_0/a)$ being 0.3∼0.4; hence $a$ must be larger than several scores. Thus we know that $r_0$ must be larger than several scores times of the wave-length in order that such a surface wave propagates with negligible damping.

## § 11. Terms Corresponding to $\nu_{1j}$

Let us investigate such terms of the series representing $\Phi$ and $A_\varphi$ as corresponding to $\nu_{1j}$, given by (8.4). At first we evaluate $\Phi_{1j}$, the term in the right-handed side of (7.2.1) corresponding to $\nu_{1j}$.

As to the factor $\nu P_{\nu-1/2}(\cos(\pi-\theta))/\cos\nu\pi$, we scrutinize the formula (10.1), corresponding to $\nu_{1j}$; since now

$$\mathrm{Im}\,\nu_{1j}=-(3\rho_j)^{2/3}\sqrt{3}/4a^{1/3}\{1+O(a^{-2/3})\}\ ,$$

the second and further terms are negligible to the first and we have

$$\begin{aligned}\nu P_{\nu-1/2}(\cos(\pi-\theta))/\cos\nu\pi=&(2a/\pi\sin\theta)^{1/2}(1+1/4q_j^2)\\&\times\exp[-ia\theta\{1+1/2q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3+1/120q_j^4-(-17/6+1/2(1-m^2)^{-1}\\&+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}]\{1+O(a^{-1})\}\ .\end{aligned}\tag{11.1}$$

Then we have, employing for $H_\nu^{(2)}(ma)$ the ordinary asymptotic expansion of large order and for $H_\nu^{(2)}(a)$ the asymptotic formula in the transitional region 10),

$$\begin{aligned}\Phi_{1j}=&-(8/r_0)\{1+(-31/12+16(1-m^2))q_j^2\}(2\pi/kr_0\sin\theta)^{1/2}\\&\times\exp[-(1-m^2)^{1/2}k(r_s-r_0+r-r_0)-ikr_0\theta\{1+\tfrac{1}{2}q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3\\&+1/120q_j^4-(-17/6+1/2(1-m^2)^{-1}+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}-\pi/4i]\\&\times\{1+O(1/kr_0)\}\{1+O((r_s-r_0)/r_0)\}\{1+O((r-r_0)/r_0)\}\ .\end{aligned}\tag{11.2}$$

Its properties are as follows;

1. $\Phi_{1j}$ is of finite magnitude only if $r_s-r_0\ll r_0$.
2. $\Phi_{1j}$ is of finite magnitude only in the vicinity of the surface on account of the factor $\exp[-(1-m^2)^{1/2}k(r-r_0)]$, or it has a character of a surface wave and has such a factor as $(r_0\sin\theta)^{1/2}$ as it must be so.
3. It propagates on the surface with the propagation velocity $v_t\{1-1/4(3\rho_i v_t/\omega r_0)^{2/3}\}\{1+O(v_t/\omega r_0)\}$, fairly close to $v_t$; the waves corresponding to different values of $\rho_i$ thus propagate with different velocities and the wave corresponding to the lowest $\rho_i$ is the fastest. They have also their own character of dispersion.
4. It attenuates with $\theta$, the rate of which is given by $\exp[-\sqrt{3}/4(3\rho_j)^{2/3}(\omega r_0/v_t)^{1/3}\theta]$, if we retain the first term only to estimate its order of magnitude. Its values for $a(=\omega r_0/v_t)=100$ are tabulated, for several values of $\rho$ and $\theta$, as follows:

| | $\theta=0.1$ | 0.2 | 0.5 | 1 |
|---|---|---|---|---|
| $\rho_1$ | 0.4743.. | 0.2249.. | 0.02399.. | 0.00058.. |
| $\rho_2$ | 0.2714.. | 0.0736.. | 0.00134.. | 0.000002.. |
| $\rho_3$ | 0.1718.. | 0.0295.. | 0.00015.. | |
| $\rho_4$ | 0.1152.. | 0.0132.. | | |
| $\rho_5$ | 0.079.. | 0.006.. | | |
| $\rho_6$ | 0.056.. | 0.003.. | | |
| $\rho_7$ | 0.041.. | | | |

It becomes obvious that in order to estimate within the error of 1 per cent we must take 6 $\rho$'s for $\theta=0.2$, 2 $\rho$'s for $\theta=0.5$ and for $\theta=1$ have only to take the first one. For $\theta\sim0.1$ this method is not effective obviously.

5. The displacement components derived from it are

$$d_r\sim-(1-m^2)^{1/2}k\Phi_{1j}\ ,\qquad d_\theta\sim-i\Phi_{1j}\ ;$$

thus

$$d_r/d_\theta\sim e^{-\pi/2i}(1-m^2)^{1/2}\ .$$

The point oscillates along an elliptic orbit, whose major and minor axes are in the direction of $d_\theta$ and that of $d_r$ respectively. Its sense is from the direction of positive $d_\theta$ to that of positive $d_r$. The ratio of two axes is $1:(1-m^2)^{1/2}$, or $2:\sqrt{3}$, for $m=1/2$ on the surface.

We further evaluate $A_{\varphi ij}$, the term of the right-handed side of (7.2.2) corresponding to $\nu_{1j}$, After the consideration analogous to the previous one, we reach the following result for $r$ not close to $r_0$:

$$\begin{aligned} A_{\varphi 1j}=&(12ik/q_j^2)(J_{2/3}(\rho_j)-J_{-2/3}(\rho_j))^{-1}(1/kr_0kR_{AP})(\sin\theta_1/\sin\theta)^{1/2}\{1+(-23/20+8(1-m^2)\\ &+1/4\cot^2\theta_1)q_j^2\}\exp[-(1-m^2)^{1/2}k(r_s-r_0)-ikr_0(\theta-\theta_1)\{1+1/2q_j^2\\ &-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3+1/120q_j^4-(-17/6+1/2(1-m^2)^{-1}\\ &+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}-ikR_{AP}-ikr_0\cot\theta_1(1/8q_j^4\\ &-(2i/3\rho_j)(1-m^2)^{1/2}q_j^5)]\{1+0(1/kr_0)\}\{1+0((r_s-r_0)/r_0)\}\,, \end{aligned} \tag{11.3}$$

if we denote by $\theta_1$, $R_{AP}$ the angle $AOP$ and the distance from $A$ to $P$, the field point, where $A$ is the contact point of the tangent line through $P$ to the meridian in the meridian plane through $P$ (see Fig. 1); the values of $J_{2/3}(\rho_j)-J_{-2/3}(\rho_j)$ for the above-mentioned values of $\rho_j$ are computed to be 0.899715, −0.589375, 0.470172, −0.402633, 0.357749,⋯⋯

For such $r$ that $kr-kr_0=0(a^{1/3})$ we obtain

$$\begin{aligned} A_{\varphi 1j}=&(4k/q_j^2)3^{1/2}e^{-\pi/4i}(J_{2/3}(\rho_j)-J_{-2/3}(\rho_j))^{-1}(1/kr_0)(2\pi/kr_0\sin\theta)^{1/2}(q_j^2\\ &-\tan^2\theta_1)^{1/2}[H_{-1/3}^{(2)}(ia/3(q_j^2-\tan^2\theta_1)^{3/2})-4i(1-m^2)^{1/2}(q_j^2\\ &-\tan^2\theta_1)^{1/2}H_{2/3}^{(2)}(ia/3(q_j^2-\tan^2\theta_1)^{3/2})+\{-7/20\tan^2\theta_1-73/60q_j^2+16(1\\ &-m^2)q_j^2-(16/9\rho_j^2)(1-m^2)q_j^6(q_j^2-\tan^2\theta_1)^{-2})-8(1-m^2)\tan^2\theta_1\}H_{-1/3}^{(2)}(ia/3(q_j^2\\ &-\tan^2\theta_1)^{3/2})+ia/3(q_j^2-\tan^2\theta_1)^{3/2}\{-(16/3\rho_j^2)(1-m^2)q_j^6(q_j^2-\tan^2\theta_1)^{-2}\\ &+1/5\tan^2\theta_1(q_j^2-3\tan^2\theta_1)(q_j^2-\tan^2\theta_1)^{-1}\}H_{2/3}^{(2)}(ia/3(q_j^2-\tan^2\theta_1)^{3/2})]\\ &\times\exp[-(1-m^2)^{1/2}k(r_s-r_0)-ikr_0\theta\{1+1/2q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3\\ &+1/120q_j^4-(-17/6+1/2(1-m^2)^{-1}+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}]\{1\\ &+0(1/kr_0)\}\{1+0((r_s-r_0)/r_0)\}\,, \end{aligned} \tag{11.4}$$

and for $r$ close to $r_0$,

$$\begin{aligned} A_{\varphi 1j}=&16(1-m^2)^{1/2}e^{\pi/4i}/r_0(2\pi/kr_0\sin\theta)^{1/2}\{1+(-49/12+1/2(1-m^2)^{-1}\\ &+16(1-m^2))q_j^2\}\{1-1/4(1-m^2)^{-1/2}(1+(3-1/2(1-m^2)^{-1})q_j^2)k(r-r_0)\}\\ &\times\exp[-(1-m^2)^{1/2}k(r_s-r_0)-ikr_0\theta\{1+1/2q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3\\ &+(1/120)q_j^4-(-17/6+1/2(1-m^2)^{-1}+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}]\{1\\ &+0(1/kr_0)\}\{1+0(k^2(r-r_0)^2/(kr_0)^{2/3})\}\{1+0((r_s-r_0)/r_0)\}\,. \end{aligned} \tag{11.5}$$

It has the following properties:

1. $A_{\varphi 1j}$ is of finite order as far as the source is near the surface on account of the factor $\exp\{-(1-m^2)^{1/2}k(r_s-r_0)\}$.

2. Its amplitude is proportional to $(1/kR_{AP})$ $(\sin\theta_1/\sin\theta)^{1/2}$ unless the field point is close to the surface.

3. When $\theta>\theta_1$, as we see from its phase, it behaves as if, starting from $Q_1$, the projection of the source on the surface, it propagated to $A$ on the surface with a velocity of propagation fairly close to $v_t$ and depending on $\rho$ and $\omega$, then traveled on a straight line to $P$ with the velocity $v_t$. Its behavior when propagating on the surface is quite analogus to that of $\Phi_{1j}$. When $\theta<\theta_1$, though the geometrical interpretation is not so simple, the phase is given in the first approximation by $-ik\{R_{AP}-r_0(\theta_1-\theta)\}$, which closes to $-ikR_{Q_1P}$ for $R_{AP}\gg r_0(\theta_1-\theta)$. This difference comes from the fact that, while in the latter case the field point is exposed to the direct radiation, in the former case the state of affairs there is determined in the main by the wavelet at $A$ in Huygens' meaning.

4. It attenuates on its way on the surface, if $\theta>\theta_1$, or $P$ is in the shade; its rate is given by $\exp\{-\sqrt{3}/4(3\rho_j)^{2/3}(\omega r_0/v_t)^{1/3}(\theta-\theta_1)\}$, if we retain its first terms only; its numerical values

corresponding to various values of $\rho$ are the same as those of $\Phi_{1j}$ with $\theta$ replaced by $\theta-\theta_1$. If $\theta<\theta_1$, it means on the contrary, the increase of the amplitude, corresponding to the case $P$ being exposed to the direct radiation. In this case its numerical value increases with increasing $\rho$, though it does not mean the divergence of the series since such a form holds in the first several terms only, and, therefore, this procedure is not suited here for quantative treatment, but useful for qualitative discussion only.

5. The displacement components at a field point not near the surface are

$$d_r \sim -ik(r_0/r)A_{\varphi 1j}\,, \qquad d_\theta \sim ik\{1-(r_0/r)^2\}^{1/2}A_{\varphi 1j}\,,$$

and so

$$d_r/d_\theta \sim -r_0/(r^2-r_0^2)^{1/2} \doteqdot -\cot\theta_1;$$

the particle thus oscillates on a line perpendicular to $AP$, or transversely, while on the surfac elliptically polarized ones with $d_r$ as the major axis prevail since $d_r/d_\theta \sim -4i(1-m^2)^{1/2}$.

6. It is noticeable that $A_{\varphi 1j}$ radiates out into the exterior medium, while $\Phi_{1j}$ is finite only in the vicinity of the surface.

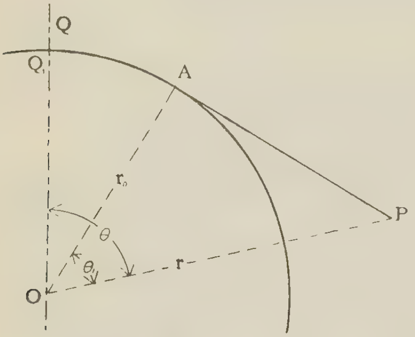

Fig. 1.

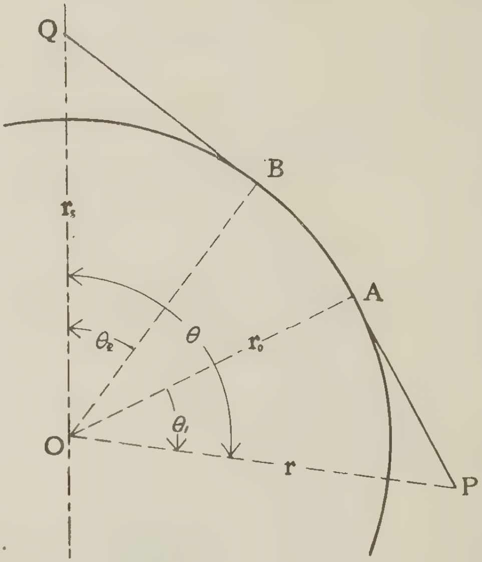

Fig. 2.

## § 12. Terms Corresponding to $\nu_{2j}$

Let us investigate such terms of the series representing $\Phi$ and $A_\varphi$ as correspond to $\nu_{2j}$, given by (8.5).

For such values of $\nu$ we obtain

$$\begin{aligned}\Phi_{2j} = {} & (9h/q_j^{*4})^i e^{\pi/4i}(J_{2/3}(\rho_j)-J_{-2/3}(\rho_j))^{-2}(hR_{QB}hR_{AP})^{-1}(2/\pi hr_0)^{1/2}(\sin\theta_1 \sin\theta_2/\sin\theta)^{1/2}\{1 \\ & +(17/60+1/4\cot^2\theta_1+1/4\cot^2\theta_2+32m^6(1-m^2)(2m^2-1)^{-4})q_j^{*2}\} \\ & \times\exp[-ihr_0(\theta-\theta_1-\theta_2)\{1+1/2q_i^{*2}-(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*3} \\ & +1/120q_j^{*4}-(1/6-(2m^2+1)/(2m^2-1)-16/3m^6(1-m^2)(2m^2-1)^{-4})(4m^3/3\rho_j) \\ & \times(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}-ihR_{QB}-ihR_{AP}+ihr_0(\cot\theta_1+\cot\theta_2)(-1/8q_j^{*4} \\ & +(2m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5})]\{1+0(1/hr_0)\}\,,\end{aligned}$$

for $r$, $r_s$ not close to $r_0$, if we denote, beside the notations employed in § 11, by $\theta_2$ and $R_{QB}$ the angle $QOB$ and the distance from $Q$ to $B$, $B$ being the contact point of the tangent line through $Q$ on the meridian in the meridian plane throuth $P$ (see Fig. 2); for $r$, $r_s$ close to $r_0$, or $hr_s-h_0<0(a^{1/3})$, $hr-hr_0<0(a^{1/3})$, we have further

$$\begin{aligned}\Phi_{2j} = {} & -16he^{-\pi/4i}m^6(1-m^2)(2m^2-1)^{-4}(1/hr_0)(2\pi/hr_0\sin\theta)^{1/2}\{1+(5/12-2(2m^2 \\ & +1)/(2m^2-1)-m^2/(1-m^2)+16m^6(1-m^2)(2m^2-1)^{-4})q_j^{*2}\}[1-i/4(2m^2-1)^2m^{-3}\end{aligned}$$

$$\times(1-m^2)^{-1/2}\{1+((2m^2+1)/(2m^2-1)+1/2m^2/(1-m^2))q_j^{*2}\}h(r-r_0+r_s-r_0)]$$
$$\times\exp[-ihr_0\theta\{1+1/2q_j^{*2}-(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*3}$$
$$+1/120q_j^{*4}-(1/6-(2m^2+1)/(2m^2-1)-1/2m^2/(1-m^2)-16/3m^6(1-m^2)$$
$$\times(2m^2-1)^{-4})(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}]\{1+0(1/hr_0)\}\{1$$
$$+0((hr-hr_0)^2/(hr_0)^{2/3})\}\{1+0((hr_s-hr_0)^2/(hr_0)^{2/3})\}\,. \tag{12.2}$$

Though for such value of $r$, $r_s$ that $hr-hr_0=0\ ((hr_0)^{1/3})$, $hr_s-hr_0=0\ ((hr_0)^{1/3})$ we have found an expression somewhat analogous to (11.4), we refrain from reproducing it here on account of its complexness and sterility.

Its properties are as follows:

1. Its magnitude is proportional to $R_{QB}^{-1}R_{AP}^{-1}$ $(\sin\theta_1\sin\theta_2/\sin\theta)^{1/2}$, unless the source and the field point are very close to the surface.

2. If $\theta>\theta_1+\theta_2$, we find from the exponential function that the dilatational wave propagates straight from $Q$ to $B$ with the velocity $v_l$, and then decomposes into many waves, each of them travels on the spherical surface to the point $A$ with a velocity near to $v_l$ and from here again straight to $P$ with the propagation velocity $v_l$. If $\theta<\theta_1+\theta_2$, the phase is approximately equal to $-ih(R_{QB}-\text{arc}\,AB+R_{AP})$ or $-ih(R_{QB}-\text{arc}\,Q_1B+R_{AP}-\text{arc}\,Q_1A)$ according as $\theta>\theta_1$ or $\theta<\theta_1$, as shown in Fig. 3; these become $-ih(R_{QA}+R_{AP})$ and $-ih(R_{QQ_1}+R_{Q_1P})$ respectively, as $R_{QB}$, $R_{AP\to\infty}$.

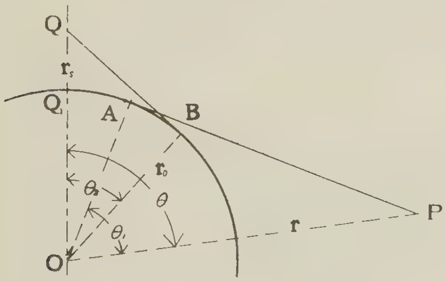

Fig. 3. (a) $\theta>\theta_1$.

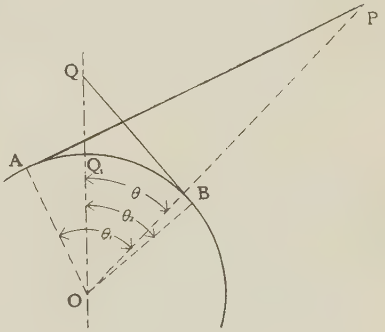

Fig. 3. (b) $\theta<\theta_1$.

3. The propagation velocity on the surface is $v_l\{1-1/4(3\rho_jv_l/\omega r_0)^{2/3}\}$; the waves are dispersive and the one corresponding to the lowest $\rho$ is the fastest.

4. While propagating on the surface it attenuates so far as $\theta>\theta_1+\theta_2$; the rate of damping is given by $\exp\{-\sqrt{3}/4(3\rho_j)^{2/3}(\omega r_0/v_l)^{1/3}(\theta-\theta_1-\theta_2)\}$, if we retain the first term only; it means that the field point $P$ is in the shade. Its values for $a=100$, $m=1/2$ are tabulated, for several values of $\rho_j$ and $\theta-\theta_1-\theta_2$ as follows:

| | $\theta-\theta_1-\theta_2=0.2$ | 0.5 | 1 |
|---|---|---|---|
| $\rho_1$ | 0.3060 | 0.0518 | 0.0027 |
| $\rho_2$ | 0.1249 | 0.0057 | 0.00004 |
| $\rho_3$ | 0.0611 | 0.0009 | |
| $\rho_4$ | 0.0322 | 0.0001 | |
| $\rho_5$ | 0.0179 | | |
| $\rho_6$ | 0.0104 | | |
| $\rho_7$ | 0.0029 | | |

If $\theta<\theta_1+\theta_2$, it increases its intensity with the rate given by

$$\exp\{\sqrt{3}/4(3\rho_j)^{2/3}(\omega r_0/v_l)^{1/3}(\theta_1+\theta_2-\theta)\}\,,$$

which corresponds to the case of the direct exposure to the radiation. In this case such a discussion as that stated in § 11 still holds.

5. The displacement components at a field point not near the surface are given by

$$d_r \sim -ih(r^2-r_0^2)^{1/2}/r_0\Phi_{2j}\,, \qquad d_\theta \sim -ihr_0/r\Phi_{2j}\,.$$

Thus

$$d_r/d_\theta \sim (r^2-r_0^2)^{1/2}/r_0 = \tan\theta_1\,.$$

The particle oscillates in the line $AP$, or longitudinally, while on the surface such linearly polarized oscillations prevail that $d_r/d_\theta \sim 1/4(2m^2-1)m^{-3}(1-m^2)^{-1/2}$, which is $1/\sqrt{3}$ for $m=0.5$.

Secondly we evaluate $A_{\varphi 2j}$. This leads to

$$\begin{aligned} A_{\varphi 2j} = & -12imh(2m^2-1)^{-1}q_j^{*-2}(J_{2/3}(\rho_j)-J_{-2/3}(\rho_j))^{-1}(hR_{QB}kR_{A^*P})^{-1} \\ & \times(\sin\theta_1^*\sin\theta_2\sin\theta_3/\sin\theta)^{1/2}\{1+(17/20-1/4(\cot^2\theta_3-\cot^2\theta_1^*-\cot^2\theta_2) \\ & +24\mathrm{m}^6(1-m^2)(2m^2-1)^{-4}-2m^2/(2m^2-1))q_j^{*2}\}\exp[-ihR_{QB}-ihr_0(\theta-\theta_1^* \\ & -\theta_2+\theta_3)\{1+1/2q_j^{*2}-(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*3}+1/120q_j^{*4} \\ & -(1/6-(2m^2+1)/(2m^2-1)-1/2m^2/(1-m^2)-16/3m^6(1-m^2)(2m^2-1)^{-4}) \\ & \times(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}-ikR_{DP}+ihr_0(\cot\theta_1^*+\cot\theta_2 \\ & -\cot\theta_3)(-1/8q_j^{*4}+(2m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5})]\{1+0(1/kr_0)\}\,, \end{aligned} \tag{12.3}$$

for $r_s$ not close to $r_0$, if we denote by $A^*$ the contact point of the tangent line through $P$ on the circle which is formed by the intersection of the meridian plane through $P$ and the sphere of radius $mr_0$, by $D$ the point of intersection of $PA^*$ and the original sphere by $\theta_1^*$, $\theta_3$ the angle $POA^*$, $DOA^*$ (see Fig. 4), and by $R_{DP}$ the distances between $D$ and $P$.

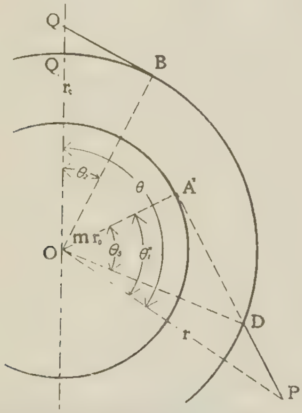

Fig. 4.

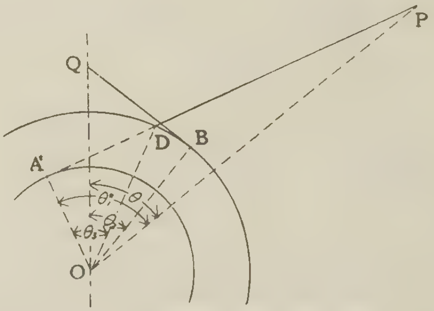

Fig. 5.

For $r_s$ close to $r_0$, or $hr_s-hr_0<0(a^{1/3})$,

$$\begin{aligned} A_{\varphi 2j} = & -16he^{-\pi/4i}m^4(1-m^2)^{1/2}(2m^2-1)^{-3}(1/kR_{A^*P})(2\pi\sin\theta_1^*\sin\theta_3/hr_0\sin\theta)^{1/2}\{1 \\ & +(-13/12-3/(2m^2-1)+16m^6(1-m^2)(2m^2-1)^{-4}-3/4\cot^2\theta_3 \\ & +1/4\cot^2\theta_1^*)q_j^{*2}\}\{1-i/4(2m^2-1)^2m^{-3}(1-m^2)^{-1/2}(1+(2m^2+1)/(2m^2-1) \\ & +1/2m^2(1-m^2)^{-1})q_j^{*2})h(r_s-r_0)\}\exp[-ihr_0(\theta-\theta_1^*+\theta_3)\{1+1/2q_j^{*2} \\ & -(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*3}+1/120q_j^{*4}-(1/6-(2m^2+1)/(2m^2-1) \\ & -1/2m^2(1-m^2)^{-1}-16/3m^6(1-m^2)(2m^2-1))^{-4})(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2 \\ & -1)^{-2}q_j^{*5}\}-ikR_{DP}+ihr_0(\cot\theta_1^*-\cot\theta_3)(-1/8q_j^{*4}+(2m^3/3\rho_j)(1 \\ & -m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5})]\{1+0(1/kr_0)\}\{1+0((hr_s-hr_0)^2/(hr_0)^{2/3})\,. \end{aligned} \tag{12.4}$$

The formula corresponding to the case that $h(r-r_0)=0\ ((hr_0)^{1/3})$, $h(r_s-r_0)=0\ ((hr_0)^{1/3})$ is omitted here because we do not need it so much.

Its properties are as follows;

1. The magnitude is proportional to $(R_{A^*P}R_{QB})^{-1}(\sin\theta)^{-1/2}(\sin\theta_1^*\sin\theta_2\sin\theta_3)^{1/2}$; the last factor is to be interpreted to be $(\sin\theta_3)^{-1/2}\sin\theta_3$, whose latter factor appears to represent the

component in the direction of the line $DP$ of the vector, tangential to the surface at the point $D$, as it should be so if we consider the transversality and the longitudinality of the wave to be discussed below.

2. From its phase it appears that, if $\theta > \theta_1^* + \theta_2 - \theta_3$, the initial wave travels out straight from $Q$ to $B$ with the velocity $v_l$ and then many waves corresponding to various $\rho_j$ propagate on the surface with velocities close to $v_l$, respectively, attaining $D$ and from here they straight to $P$ with the velocity $v_t$. If $\theta < \theta_1^* + \theta_2 - \theta_3$ the phase is approximately equal to $-ih(R_{QB} - \text{arc}\, DB) - ikR_{DP}$ as shown in Fig. 5, which closes to $-ihR_{QD} - lk_{DP}$ with increasing $R_{QB}$, $R_{DP}$; this shows the path in the sense of geometrical optics.

3. The propagation velocity on the surface is $v_l\{1 - 1/4(3\rho_j v_l/\omega r_0)^{2/2}\}$; the waves are dispersive and the one corresponding to the smallest $\rho$ is the fastest.

4. If $\theta > \theta_1^* + \theta_2 - \theta_3$, it attenuates in the propagation on the sphere, whose rate of damping is given by $\exp\{-\sqrt{3}/4(3\rho_j)^{2/3}(\omega r_0/v_l)^{1/3}(\theta - \theta_1^* - \theta_2 + \theta_3)\}$ in the first approximation, the state corresponding to the shade in geometrical optics, while, for $\theta < \theta_1^* + \theta_2 - \theta_3$, it increases its intensity, as given by the same formula; this represents the case where the source is visible from the field point.

5. The displacement components resulting from it are

$$d_r \sim -ih(r_0/r)A_{\varphi 2j}\,, \qquad d_\theta \sim ik/r(r^2 - m^2 r_0^2)^{1/2} A_{\varphi 2j}\,,$$

and so

$$d_r/d_\theta \sim -mr_0/(r^2 - m^2 r_0^2)^{1/2} = -\cot\theta_1^*\,.$$

The elementary portion at $P$ oscillates in the line perpendicular to $A^*P$, or transversely; this state still holds, when $P$ is on the surface.

## § 13. Case of Small $\theta$

It was shown in § 9 that, while the series representing $\Phi$ and $A_\varphi$ are so rapidly convergent for not small $\theta$ that it suffices for our purpose to sum up, beside the one corresponding to Rayleigh wave, first several terms corresponding to the residues at the two rows of zeros near the real axis, this method fails for small $\theta$ and we need some other procedures. We can now attain our end by evaluating $\Phi$ and $A_\varphi$ in their original integral forms along the contours $C_1$, $C_2$ enclosing these two rows of zeros respectively. The case of small $\theta$, however, does not arouse any more interest but its importance lies only in the point that it shows behaviors transitional to the case of reflection by a plane surface, treated by Sakai. To compare with his result, we limit ourselves to treat the components of the displacement on the surface without treating $\Phi$, $A_\varphi$ in their general forms throughly, and further assume $r - r_0 \ll r_0$, $r_s - r_0 \ll r_0$.

Let us evaluate following integrals derived from the discussion in § 7:

$$\begin{aligned} d_r = -\frac{i}{r_0(r_0 r_r)^{1/2}} \int_{C_1+C_2} &\frac{\nu P_{\nu-1/2}(\cos(\pi-\theta))}{\cos\nu\pi} \frac{H_\nu^{(2)}(hr_s)}{H_\nu^{(2)}(ma)} \left[\frac{2}{a}F(\nu, a) + 1 - \frac{2\nu^2}{a^2}\left(1 - \frac{3}{4\nu^2}\right)\right] \\ &\times \left[1 - \frac{4\nu^2}{a^2} + \frac{4\nu^2}{a^4}\left(\nu^2 - \frac{9}{4}\right) + \frac{2}{a}\left(1 + \frac{\nu^2 - 9/4}{a^2}\right)F(\nu, a) + \frac{2m}{a}\left(2 - \frac{\nu^2 - 9/4}{a^2}\right)F(\nu, ma) \right. \\ &\left. - 4m\frac{\nu^2 - 9/4}{a^2}F(\nu, ma)F(\nu, a)\right]^{-1} d\nu\,, \end{aligned} \tag{13.1.1}$$

$$\begin{aligned} d_\theta = -\frac{2i}{ar_0(r_0 r_s)^{1/2}} \int_{C_1+C_2} &\nu \frac{dP_{\nu-1/2}(\cos(\pi-\theta))}{d\theta} \frac{1}{\cos\nu\pi} \frac{H_\nu^{(2)}(hr_s)}{H_\nu^{(2)}(ma)} \left(F(\nu, a) - \frac{3}{2a}\right) \\ &\left[1 - \frac{4\nu^2}{a^2} + \frac{4\nu^2}{a^4}\left(\nu^2 - \frac{9}{4}\right) + \frac{2}{a}\left(1 + \frac{\nu^2 - 9/4}{a^2}\right)F(\nu, a) + \frac{2m}{a}\left(2 - \frac{\nu^2 - 9/4}{a^2}\right)F(\nu, ma) \right. \\ &\left. - 4m\frac{\nu^2 - 9/4}{a^2}F(\nu, a)F(\nu, ma)\right]^{-1} d\nu\,, \end{aligned} \tag{13.1.2}$$

where

$$F(\nu, a) = H_\nu^{(2)\prime}(a)/H_\nu^{(2)}(a)\,, \qquad F(\nu, ma) = H_\nu^{(2)\prime}(ma)/H_\nu^{(2)}(ma)\,, \tag{13.2}$$

the contours $C_1$, $C_2$ being such as shown in Fig. 6.

By investigating the analytical behavious of the constituents of the integrands on the contours in detail, we can reduce these integrals to

$$\begin{aligned} d_r = & -(ik/r_0)(2a/\pi \sin\theta)^{1/2} e^{-\pi/4i} \int_{C_1'} \exp\{-a\theta\, i \cosh w - (\cosh^2 w - m^2)^{1/2} k(r_s \\ & - r_0)\} \cosh^{1/2} w (1 - 2\cosh^2 w - 2/a \sinh w\{(1 - 2\cosh^2 w)^2 - 4\cosh^2 w \\ & \times \sinh w (\cosh^2 w - m^2)^{1/2}\}^{-1} \sinh w dw\{1 + 0((a\theta)^{-1})\} \\ & - ih/r_0 (2ma/\pi \sin\theta)^{1/2} e^{-\pi/4i} \int_{C_2'} \exp\{-ma\theta i \cosh w - \sinh w h(r_s - r_0)\} \\ & \times \cosh^{1/2} w\{1 - 2m^2 \cosh^2 w - 2/a(m^2 \cosh^2 w - 1)^{1/2}\}\{1 - 2m^2 \cosh^2 w)^2 \\ & - 4m^3 \cosh^2 w (m^2 \cosh^2 w - 1)^{1/2} \sinh w\}^{-1} \sinh w dw\{1 + 0((ma\theta)^{-1})\}\,, \end{aligned} \tag{13.3.1}$$

$$\begin{aligned} d_\theta = & -(2i/r_0^2)(2a^3/\pi \sin\theta)^{1/2} e^{\pi/4i} \int_{C_1'} \exp\{-a\theta i \cosh w - (\cosh^2 w - m^2)^{1/2} k(r_s \\ & - r_0)\} \cosh^{3/2} w\{\sinh w + (3/2a)\}\{(1 - 2\cosh^2 w)^2 - 4\cosh^2 w \sinh w \\ & \times (\cosh^2 w - m^2)^{1/2}\}^{-1} \sinh w dw\{1 + 0((a\theta)^{-1})\} \\ & - 2ihm/r_0 (2ma/\pi \sin\theta)^{1/2} e^{\pi/4i} \int_{C_2'} \exp\{-ma\theta i \cosh w - \sinh w h(r_s - r_0)\} \\ & \times \cosh^{3/2} w\{(m^2 \cosh^2 w - 1)^{1/2} + 3/(2a)\}\{(1 - 2m^2 \cosh^2 w)^2 \\ & - 4m^3 \cosh^2 w (m^2 \cosh^2 w - 1)^{1/2} \sinh w\}^{-1} \sinh w dw\{1 + 0((ma\theta)^{-1})\}\,, \end{aligned} \tag{13.3.2}$$

where $C_1'$, $C_2'$ are such as shown in Figs. 7, 8.

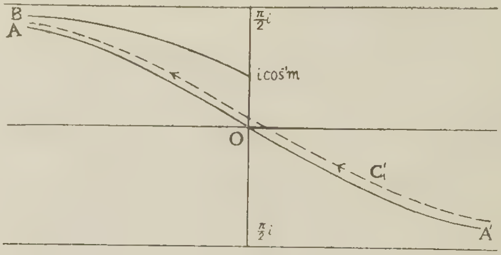

Fig. 7.

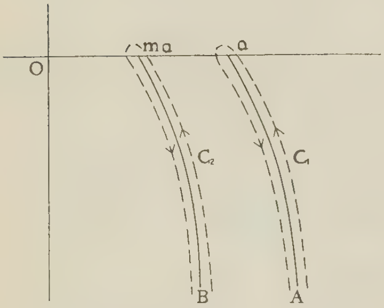

Fig. 6.

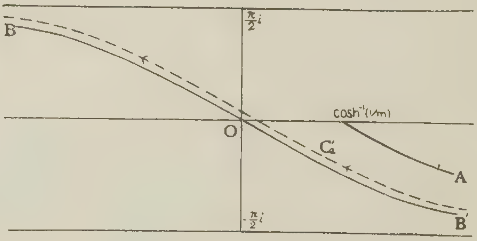

Fig. 8.

By integration along the contours of steepest descents through $w=0$, $i(\pi/2-\psi)$ they become

$$\begin{aligned} d_r = & [-8e^{\pi/4i}(1-m^2)^{5/4}(\sin\psi)^{-1/2}\{(1-m^2)^{1/2} i \sin\psi + \cos\psi\}^{-3/2} R^{-2} \exp\{-ikR \sin\psi \\ & - (1-m^2)^{1/2} kR \cos\psi\} + 2ih(1 - 2m^2 \sin^2\psi) \cos\psi\{(1 - 2m^2 \sin^2\psi)^2 \\ & + 4m^3 \sin^2\psi (1 - m^2 \sin^2\psi)^{1/2} \cos\psi\}^{-1} \exp(-ihR)/R]\{1 + 0(1/kR)\}\,, \end{aligned} \tag{13.4.1}$$

$$\begin{aligned} d_\theta = & [4e^{-\pi/4i}(1-m^2)^{3/4}(\sin\psi)^{-1/2}\{(1-m^2)^{1/2} i \sin\psi + \cos\psi\}^{-3/2} R^{-2} \exp\{-ikR \sin\psi \\ & - (1-m^2)^{1/2} kR \cos\psi\} - 4\, ihm \sin\psi \cos\psi (1 - m^2 \sin^2\psi)^{1/2}\{(1 - 2m^2 \sin^2\psi)^2 \\ & + 4m^3 \sin^2\psi (1 - m^2 \sin^2\psi)^{1/2} \cos\psi\}^{-1} \exp(-ihR)/R]\{1 + 0(1/kR)\}\,, \end{aligned} \tag{13.4.2}$$

where $\psi$ denotes the incident angle. These results are completely equivalent to those of

Sakai's research on the behavior of distortional and dilatational waves on a plane surface (4) p. 35) and so we refrain from proceeding further.

## IV. DISTORTIONAL SOURCE OF THE FIRST KIND

### § 14. General Form of the Solutions

The treatment of the case of a distortional source follows much the same course as in the preceding case, so that we shall not enter into particulars except some new points.

The distortional primary wave, expressed by (3.3), can be expanded as follows:

$$A_\varphi{}^p=-(i/krr_s)\sum_{n=0}^{\infty}(2n+1)[\zeta_n(kr_s)\psi_n(kr),\ \text{or}\ \psi_n(kr_s)\zeta_n(kr)]dP_n(\cos\theta)/d\theta\ , \tag{14.1}$$

according as $r<r_s$ or $r>r_s$.

Assuming, in view of this expression, as the secondary waves the expression (5.3), we determine the coefficients from the boundary condition. After the same transformation as in § 7, we have as the resultants

$$\varPhi=-\frac{4\pi}{(rr_s)^{1/2}}\sum_j\left[\nu\frac{P_{\nu-1/2}(-\cos\theta)}{\cos\nu\pi}\frac{\nu^2-1/4}{a^2}\left\{1-2\frac{(\nu^2-9/4)}{a^2}\right\}\frac{H_\nu{}^{(2)}(kr_s)H_\nu{}^{(2)}(hr)}{\partial\varDelta(\nu)/\partial\nu}\right]_{\nu=\nu_j}, \tag{14.2.1}$$

$$A_\varphi=\frac{2\pi}{(rr_s)^{1/2}a}\sum_j\left[\nu\frac{dP_{\nu-1/2}(-\cos\theta)}{d\theta}\frac{1}{\cos\nu\pi}\frac{H_\nu{}^{(2)}(kr_s)H_\nu{}^{(2)}(kr)}{H_\nu{}^{(2)}(a)\partial\varDelta(\nu)/\partial\nu}\left\{4m\frac{\nu^2-9/4}{a^2}H_\nu{}^{(2)\prime}(ma)\right.\right.$$
$$\left.\left.-\frac{2}{a}\left(1+\frac{\nu^2-9/4}{a^2}\right)H_\nu{}^{(2)}(ma)\right\}\right]_{\nu=\nu_j}. \tag{14.2.2}$$

for all values of $r$.

### § 15. Terms Corresponding to $\nu_0$

The result of the calculation is

$$\varPhi_0=-4k^2r_0\zeta(2\zeta-1)[8(\zeta-1)^{1/2}(\zeta-m^2)^{1/2}-8(2\zeta-1)+2\zeta\{(\zeta-m^2)^{1/2}(\zeta-1)^{-1/2}$$
$$+(\zeta-1)^{1/2}(\zeta-m^2)^{-1/2}\}+(1-2\zeta)^2\tfrac{1}{2}\{1/(\zeta-m^2)+1/(\zeta-1)\}]^{-1}e^{-\pi/4i}(2\pi/\zeta^{1/2}kr_0\sin\theta)^{1/2}$$
$$\times\exp[-(\zeta-m)^{1/2}k(r-r_0)-(\zeta-1)^{1/2}k(r_s-r_0)-i\zeta^{1/2}kr_0\theta\{1-\zeta^{-1/2}(\zeta-1)^{1/2}$$
$$\times(p_1/kr_0)\}]\{1+0(1/kr_0)\}\{1+0((r_s-r_0)/r_0)\}\{1+0((r-r_0)/r_0)\}\ .$$

Its behaviors are quite the same as those of $\varPhi_0$ in § 10, except for its rate of damping with respect to $r$.

Then we have

$$A_{\varphi0}=-8k^2r_0\zeta^{3/2}(\zeta-m^2)^{1/2}[8(\zeta-1)^{1/2}(\zeta-m^2)^{1/2}-8(2\zeta-1)+2\zeta\{(\zeta-m^2)^{1/2}(\zeta-1)^{-1/2}$$
$$+(\zeta-1)^{1/2}(\zeta-m^2)^{-1/2}\}+(1-2\zeta)^2\tfrac{1}{2}\{1/(\zeta-m^2)+1/(\zeta-1)\}]^{-1}e^{\pi/4i}(2\pi/\zeta^{1/2}kr_0\sin\theta)^{1/2}$$
$$\times\exp[-(\zeta-1)^{1/2}k(r_s-r_0+r-r_0)-i\zeta^{1/2}kr_0\theta\{1--(\zeta-1)^{1/2}\zeta^{-1/2}(p_1/kr_0)\}]\{1$$
$$+0(1/kr_0)\}\{1+0((r_s-r_0)/r_0)\}\{1+0((r-r_0)/r_0)\}\ . \tag{15.2}$$

Its behaviors are quite the same as those of $A_{\varphi0}$ in § 10, except for its rate of damping with respect to $r$.

The components of the resultant displacement on the surface are

$$d_r=-4e^{-\pi/4i}\zeta(\zeta-m^2)^{1/2}k^3r_0(2\pi/\zeta^{1/2}kr_0\sin\theta)^{1/2}[8(\zeta-1)^{1/2}(\zeta-m^2)^{1/2}-8(2\zeta-1)$$
$$+2\zeta\{(\zeta-m^2)^{1/2}(\zeta--1)^{-1/2}+(\zeta-1)^{1/2}(\zeta-m^2)^{-1/2}\}+(1-2\zeta)^2\tfrac{1}{2}\{1/(\zeta-m^2)$$
$$+1/(\zeta-1)\}]^{-1}\exp[-(\zeta-1)^{1/2}k(r_s-r_0)-i\zeta^{1/2}kr_0\theta\{1-(\zeta-1)^{1/2}\zeta^{-1/2}(p_1/kr_0)\}]$$
$$\times\{1+0(1/kr_0)\}\{1+0((r_s-r_0)/r_0)\}\{1+0((r-r_0)/r_0)\}\ , \tag{15.3.1}$$

$$d_\theta=2e^{\pi/4i}k^3r_0\zeta^{1/2}(2\zeta-1)(2\pi/\zeta^{1/2}kr_0\sin\theta)^{1/2}[8(\zeta-1)^{1/2}(\zeta-m^2)^{1/2}-\cdots\cdots\ , \tag{15.3.2}$$

therefore

$$d_r/d_\theta\sim\zeta^{1/2}(\zeta-m^2)^{1/2}/(\zeta-\tfrac{1}{2})i\ ;$$

It shows that the volume element on the surface oscillates in an elliptic orbit, whose major and minor axes are in the directions of $d_r$, $d_\theta$ respectively, in the sense from the positive direction of $d_r$ to that of $d_\theta$. The ratio of the axes is $v_t^2/(v_t^2-\frac{1}{2}v_R^2)(v_t^2-v_R^2)^{1/2}/v_t$, and its numerical values for $m=\frac{1}{2}$ is 1.56520…. This result is compatible with that of Sakai's study on the propagation of Rayleigh wave on a plane surface 4) p. 58).

### 16. Terms Corresponding to $\nu_{1j}$

We obtain

$$\begin{aligned}\Phi_{1j}=&12q_j^{-2}(J_{2/3}(\rho_j)-J_{-2/3}(\rho_j))^{-1}(1/kR_{QB})(\sin\theta_2/\sin\theta)^{1/2}\{1+(1/4\cos^2\theta_2\\&-13/20+8(1-m^2))q_j^2\}\exp[-(1-m^2)^{1/2}k(r-r_0)-ikR_{QB}-ikr_0(\theta-\theta_2)\\&\times\{1+1/2q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3+1/120q_j^4-(-17/6+1/2(1-m^2)^{-1}\\&+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}-ikr_0\cot\theta_2\{1/8q_j^4-(2i/3\rho_j)\\&\times(1-m^2)^{1/2}q_j^5\}]\{1+0(1/kr_0)\}\{1+0((r_s-r_0)/r_0)\}\{1+0((r-r_0)/r_0\},\end{aligned}\tag{16.1}$$

for $k(r_s-r_0)>0((kr_0)^{1/3})$.

For $k(r_s-r_0)<0((kr_0)^{1/3})$, we have

$$\begin{aligned}\Phi_{1j}=&16ke^{-\pi/4i}(1-m^2)^{1/2}\{1+(-43/12+1/2(1-m^2)^{-1}+16(1-m^2))q_j^2\}(2\pi/kr_0\\&\times\sin\theta)^{1/2}[1-1/4(1-m^2)^{1/2}\{1+(3-1/2(1-m^2)^{-1})q_j^2\}k(r_s-r_0)]\exp[-(1\\&-m^2)^{1/2}k(r-r_0)-ikr_0\theta\{1+1/2q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3+1/120q_j^4\\&-(-17/6+1/2(1-m^2)^{-1}+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^4\}[\\&\times\{1+0(1/kr_0)\}\{1+0((r-r_0)/r_0)\}\{1+0((kr_s-kr_0)^2/(kr_0)^{2/3})\}.\end{aligned}\tag{16.2}$$

Its properties are as follows:

1. $\Phi_{1j}$ is of finite magnitude only if $r-r_0\ll r_0$, or has the character of a surface wave.
2. $\Phi_{1j}$ is proportional to $1/(kR_{QB})(\sin\theta_2/\sin\theta)^{1/2}$.
3. From the phase it seems that, if $\theta>\theta_2$, a distortional wave travels from the source to $B$ and then many waves corresponding to various values of $\rho_j$ propagate on the surface to the field point with propagation velocities fairly close to $v_t$, whose values are given approximately by $v_t\{1-1/4(3\rho_j v_t/\omega r_0)^{2/3}\}$; the wave corresponding to the lowest $\rho$ is the fastest. They are all dispersive. Although we have not such a conspicuous geometrical interpretation for $\theta<\theta_2$, the phase approximately given by $-ik((R_{QB}-r_0(\theta_2-\theta))$ is close to $-ikR_{QP}$ so far as $\theta$ is not small; this means the wave propagates from $Q$ to $P$ directly with $v_t$.
4. If $\theta>\theta_2$, it attenuates with $\theta-\theta_2$, the rate of which is given by $\exp\{-\sqrt{/}3/4(3\rho_j)^{2/3}(\omega r_0/v_t)^{1/3}(\theta-\theta_2)\}$ if we retain only the first term in the exponent; this is the same as in § 11, if we replace $\theta$ by $\theta-\theta_2$, so we need not consider further. If $\theta<\theta_2$, it increases with $\theta_2-\theta$ exponentially, which means that the field point is exposed to the direct radiation. It was already discussed in the last part of § 11 that this procedure is not so suited to the computation in the latter case.
5. The displacement components resulting from it are as follows:

$$d_r\sim-(1-m^2)^{1/2}k\Phi_{1j},\qquad d_\theta\sim-ik\Phi_{1j}.$$

Then

$$dr/d_\theta\sim-i(1-m^2)^{1/2},$$

which means that the elementary portion at the field point oscillates along an elliptic orbit whose major and minor axes are in the directions of $d_\theta$, $d_r$, respectively; the sense is from the positive direction of $d_\theta$ to that of $d_r$. The numerical value of the ratio of these axes is, for $m=(1/2)$, 1: 0.866.

Next we consider $A_{\varphi 1j}$. As the result of the calculation we obtain for $k(r--r_0)>0\ ((kr_0)^{1/3})$, $k(r_s-r_0)>0((kr_0)^{1/3})$

$$\begin{aligned}A_{\varphi 1j}=&9ke^{3/4\pi i}q_j^{-4}(J_{2/3}(\rho_i)-J_{-2/3}(\rho_j))^{-2}(1/kR_{QB}kR_{AP})(2kr_0\sin\theta_1\sin\theta_2/\pi\sin\theta)^{1/2}\\&\times\{1+(47/60-1/2\cot^2\theta_1-1/2\cot^2\theta_2)q_j^2\}\exp[-ikR_{QB}-ikR_{AP}\\&-ikr_0(\theta-\theta_1-\theta_2)\{1+1/2q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3+1/120q_j^4-(-17/6\end{aligned}$$

$$\begin{aligned}&+1/2(1-m^2)^{-1}+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}-ikr_0(\cot\theta_1+\cot\theta_2)\\&\{1/8q_j^4-(2i/3\rho_j)(1-m^2)^{1/2}q_j^5\}]\{1+0(a^{-1})\}\ ,\end{aligned}\tag{16.3}$$

if we use such notations as in § 12, and for the case corresponding to $r, r_s$ close to $r_0$

$$\begin{aligned}A_{\varphi 1j}=&(32/r_0)e^{\pi/4i}(\pi/kr_0\sin\theta)^{1/2}(1-m^2)\{1+(-61/12+(1-m^2)^{-1}+16(1-m^2))q_j^2\}\\&\times[1-1/4(1-m^2)^{1/2}\{1+(3-1/2(1-m^2)^{-1})q_j^2\}k(r-r_0+r_s-r_0)]\exp[-ikr_0\theta\\&\times\{1+1/2q_j^2-(4i/3\rho_j)(1-m^2)^{1/2}q_j^3+1/120q_j^4-(-17/6+1/2(1-m^2)^{-1}\\&+16/3(1-m^2))(4i/3\rho_j)(1-m^2)^{1/2}q_j^5\}]\{1+0(1/kr_0)\}\{1+0((kr-kr_0)^2/\\&(kr_0)^{2/3})\}\{1+0((kr_s-kr_0)^2/(kr_0)^{2/3})\}\ .\end{aligned}\tag{16.4}$$

Its properties are as follows:

1. $A_{\varphi 1j}$ is proportional to $1/(kR_{QB}kR_{AP})(\sin\theta_1\sin\theta_2/\sin\theta)^{1/2}$ unless $\theta_1$, $\theta_2$ are quite small.
2. From the phase it seems that if $\theta>\theta_1+\theta_2$ the distortional wave travels from $Q$ to $B$, then many waves, corresponding to various values of $\rho$ respectively, propagate on the surface with the same velocities as those of $\Phi_{1j}$ and then from $A$ to $P$ in a straight line with $v_t$. If $\theta<\theta_1+\theta_2$, on the contrary, the geometrical interpretation is not so simple; the phase $-ikR_{QB}+ikr_0(\theta_1+\theta_2-\theta)-ikR_{AP}$ is approximately equal to $-ikR_{QA}-ikR_{AP}$ or $-ikR_{QQ_1}-ikR_{Q_1P}$, according as $\theta>\theta_1$, or $\theta<\theta_1$, if $P, Q$ are far from the surface. These phases correspond to the case where the field is out of the geometrical shade.
3. As to the damping with $\theta$, the same discussion as in the case of $\Phi_{1j}$ is possible, if we replace $\theta-\theta_2$ by $\theta-\theta_1-\theta_2$.
4. The displacement components are

$$d_r\sim -ik\cos\theta_1A_{\varphi 1j}\ ,\qquad d_\theta\sim ik\sin\theta_1A_{\varphi 1j}\ ,$$

and we find

$$d_r/d_\theta\sim -\cot\theta_1;$$

that is, the elementary portion at $P$ vibrates in the line perpendicular to $AP$ in the meridian plane through $P$, as it should be if we consider the waves at $P$ transverse.

## § 17. Terms Corresponding to $\nu_{2j}$

We have

$$\begin{aligned}\Phi_{2j}=&12\pi kr_0m^3k(2m^2-1)^{-1}(J_{2/3}(\rho_j)-J_{-2/3}(\rho_j))^{-2}q_j^{*-2}(1/hR_{AP}kR_{QB}^*)\\&\times(\sin\theta_3\sin\theta_1\sin\theta_2^*/\sin\theta)^{1/2}[1+\{27/20+1/4(\cot^2\theta_2^*-\cot^2\theta_3+\cot^2\theta_1)-2m^2\\&\times(2m^2-1)^{-1}+24m^6(1-m^2)(2m^2-1)^{-2}\}q_j^{*2}]\exp[-ikR_{QB}-ihR_{AP}-ihr_0\\&\times(\theta-\theta_1-\theta_2^*+\theta_3)\{1+1/2q_j^{*2}-(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*3}+1/120q_j^{*4}\\&-(1/6-(2m^2+1)/(2m^2-1)-1/2m^2(1-m^2)^{-1}-(16m^6/3)(1-m^2)(2m^2-1)^{-4})\\&\times(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}-ihr_0(\cot\theta_1-\cot\theta_3+\cot\theta_2^*)\{1/8q_j^{*4}\\&-(2m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}]\{1+0(1/kr_0)\}\ ,\end{aligned}\tag{17.1}$$

for $h(r-r_0)>0((hr_0)^{1/3})$ if we employ such notations as shown in Fig. 9, and for $h(r-r_0)<0((hr_0)^{1/3})$ we have

$$\begin{aligned}\Phi_{2j}=&-16hr_0m^5k(1-m^2)^{1/2}(2m^2-1)^{-3}e^{\pi/4i}(2\pi\sin\theta_3\sin\theta_2^*/hr_0\sin\theta)^{1/2}(1/kR_{QB}^*)\\&\times[1+\{-7/12-3/4\cot^2\theta_3+1/4\cot^2\theta_2^*-3/(2m^2-1)+16m^6(1-m^2)\\&\times(2m^2-1)^{-4}\}q_j^{*2}]\exp[-ikR_{QB}-ihr_0(\theta-\theta_2^*+\theta_3)\{1+1/2q_j^{*2}-(4m^3/3\rho_j)(1-m^2)^{1/2}\\&\times(2m^2-1)^{-2}q_j^{*3}+1/120q_j^{*4}-(1/6-(2m^2+1)/(2m^2-1)-1/2\,m^2(1-m^2)^{-1}-(16m^6/3)\\&\times(1-m^2)(2m^2-1)^{-4}((4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}-ihr_0(\cot\theta_2^*-\cot\theta_3)\\&\times\{1/8\,q_j^{*4}-(2m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}]\{1+0(1/kr_0)\}\\&\times\{1+0((hr-hr_0)^2/(hr_0)^{2/3})\}\ .\end{aligned}\tag{17.2}$$

We omit here the case $h(r-r_0)=0((hr_0)^{1/3})$ for the same reason as before.

The properties are as follows:

1. It is proportional to $1/(kR_{QB*}hR_{AP})(\sin\theta_1 \sin\theta_3 \sin\theta_2^*/\sin\theta)^{1/2}$ unless $r$ is close $r_0$, or if we consider the component tangential to the circle at $E$ of the vector perpendicular to $QE$, it may be more reasonable to write $(\sin\theta_3/kR_{QB*}hR_{AP})(\sin\theta_1 \sin\theta_2^*/\sin\theta \sin\theta_3)^{1/2}$.

2. If $\theta-\theta_1-\theta_2^*+\theta_3>0$. it seems from the phase that the distortional wave propagates from $Q$ to $E$ straight and then many waves of the dilatational character corresponding to various values of $\rho$ travel on the surface to $A$ with the velocities $v_l\{1-1/4(3\rho_j v_l/\omega r_0)^{2/3}\}$, propagating lastly to $P$ straight with $v_l$. If $\theta-\theta_1-\theta_2^*+\theta_3<0$, though the geometrical interpretation is not so obvious, the phase is approximately given by $-ikR_{QE}-ihR_{EP}$, showing that the distortional wave resumed by the dilatational wave at $E$.

3. If $\theta-\theta_1-\theta_2^*+\theta_3>0$, they attenuate with increasing $\theta$, the rate of damping being given by $\exp\{-\sqrt{3}/4(3\rho_j)^{2/3}(\omega r_0/v_l)^{1/3})(\theta-\theta_1-\theta_2^*+\theta_3)\}$, where only the first term in the exponent is retained. Refer to § 12. For $\theta-\theta_1-\theta_2^*+\theta_3<0$, the amplitude increases exponentially and as to the accompanying trouble we have already discussed.

4. The displacements are

$$d_r \sim -ih \sin\theta_1 \Phi_{2j} \qquad d_\theta \sim -ih \cos\theta_1 \Phi_{2j};$$

then

$$d_r/d_\theta \sim \tan\theta_1 ,$$

which shows that the element at $P$ vibrates in parallel with $AP$ and in the meridian through $P$, or longitudinally.

Next we obtain

$$\begin{aligned}A_{\varphi 2j}=&8m^5ka^2e^{\pi/4i}(2\pi/hr_0 \sin\theta)^{1/2} \sin^2\theta_3(1/kR_{QB}{}^*kR_{A^*P})(\sin\theta_1^*/\sin\theta_3)^{1/2}\\ &(\sin\theta_2^*/\sin\theta_3)^{1/2}[1+\{1/4\cot^2\theta_2^*+1/4\cot^2\theta_1^*-1/2\cot^2\theta_3\\ &+23/12-4m^2(2m^2-1)^{-1}+16m^6(1-m^2)(2m^2-1)^{-4}\}q_j^{*2}]\exp[-ik(R_{QE}\\ &+R_{DP})-ih(\theta-\theta_1^*-\theta_2^*-2\theta_3)\{1+1/2q_j^{*2}-(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*3}\\ &+1/120q_j^{*4}-(1/6-(2m^2+1)/(2m^2-1)-1/2m^2(1-m^2)^{-1}-16/3m^6(1-m^2)\\ &\times(2m^2-1)^{-4})(4m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5}\}-ihr_0(\cot\theta_1^*+\cot\theta_2^*-2\cot\theta_3)\\ &\times(1/8q_j^{*4}-(2m^3/3\rho_j)(1-m^2)^{1/2}(2m^2-1)^{-2}q_j^{*5})]\{1+0(1/kr_0)\} ,\end{aligned}$$

the notations being illustrated in Fig. 10.

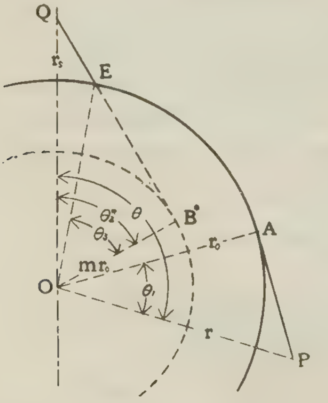

Fig. 9.

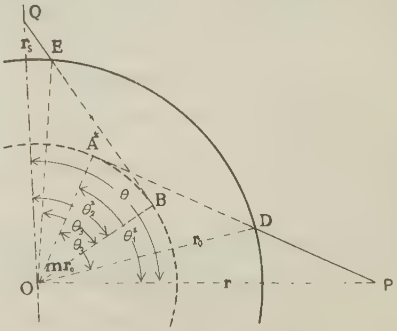

Fig. 10.

Its properties are as follows:

1. It is proportional to $(\sin^2\theta_3/kR_{QB}{}^*kR_{A^*P})(\sin\theta_1^* \sin\theta_2^*/\sin\theta_3 \sin\theta_3)^{1/2}$; the factor $\sin^2\theta_3$ means that we take the component, tangential at $E$, of the vector perpendicular to $QE$ and the component, perpendicular to $DP$, of the vector tangential at $D$.

2. If $\theta-\theta_1^*-\theta_2^*-2\theta_3>0$, it represents that the distortional wave propagates straight to $E$, then splits up into many dilatational waves, corresponding to various values of $\rho_j$ and travelling on the surface to $D$ and there each of them becomes distortional wave propagating straight to $P$. Their behavior on the surface is the same as that of $\Phi_{2j}$.

3. As to the damping with the angle $\theta-\theta_1^*-\theta_2^*-2\theta_3$, it is quite the same as in the case of $\Phi_{2j}$, if we replace $\theta-\theta_1-\theta_2^*+\theta_3$ by $\theta-\theta_1^*-\theta_2^*+2\theta_3$.

4. The displacement components are

$$d_r\sim-ih(r_0/r)A_{\varphi 2j} \qquad d_\theta\sim-ik(r^2-m^2r_0^2)^{1/2}/rA_{\varphi 2j};$$

then

$$d_r/d_\theta\sim-\cot\theta_1^*\,,$$

which means the vibration at $P$ is transverse in the meridian plane through $P$.

## § 18. Case of Small $\theta$

For the same reason as in § 13, we obtain for the series representing $d_r$, $d_\theta$ on the surface, except for the terms corresponding to $\nu_0$,

$$d_r=\frac{2ih}{(r_0r_s)^{1/2}}\int_{c_1+c_2}\frac{\nu P_{\nu-1/2}(-\cos\theta)}{\cos\nu\pi}\,\frac{H_\nu^{(2)}(kr_s)}{H_\nu^{(2)}(a)}\,\frac{\nu^2-1/4}{a^2}\left(F(\nu,ma)-\frac{3}{2ma}\right)\left[\left(1-\frac{2\nu^2}{a^2}\right)^2\right.$$
$$-\frac{9\nu^2}{a^2}+\frac{2}{a}\left(1+\frac{\nu^2-9/4}{a^2}\right)F(\nu,a)+\frac{2m}{a}\left(2-\frac{\nu^2-9/4}{a^2}\right)F(\nu,ma)-4m\frac{\nu^2-9/4}{a^2}F(\nu,ma)$$
$$\left.\times F(\nu,a)\right]^{-1}d\nu\,, \tag{18.1.1}$$

$$d_\theta=\frac{i}{(r_0r_s)^{1/2}r_0}\int_{c_1+c_2}\frac{\nu dP_{\nu-1/2}(-\cos\theta)/d\theta}{\cos\nu\pi}\,\frac{H_\nu^{(2)}(kr_s)}{H_\nu^{(2)}(a)}\left\{1-\frac{2(\nu^2+3/4)}{a^2}+\frac{4m}{a}F(\nu,ma)\right\}$$
$$\left[\left(1-\frac{2\nu^2}{a^2}\right)^2-\cdots\right]^{-1}d\nu\,, \tag{18.1.2}$$

where the integral contours $C_1$, $C_2$ are shown in Fig. 6.

The integrals along $C_1$ can be evaluated by the method employed in § 13 and we have

$$d_r=-4k^3r_0\sin^2\psi(m^2-\sin^2\psi)^{1/2}\cos\psi\{(1-2\sin^2\psi)^2+4\sin^2\psi\cos\psi(m^2-\sin^2\psi)^{1/2}\}^{-1}$$
$$\times(kR)^{-1}\exp(-ikR)\{1+0(1/kR)\}\,, \tag{18.2.1}$$

$$d_\theta=-2k^3r_0\sin\psi\cos\psi(1-2\sin^2\psi)\{(1-2\sin^2\psi)^2+4\sin^2\psi\cos\psi(m^2-\sin^2\psi)^{1/2}\}^{-1}$$
$$\times(kR)^{-1}\exp(-ikR)\{1+0(1/kR)\}\,, \tag{18.2.2}$$

by calculating the integrals along $C_1'$ through $i(\pi/2-\psi)$.

Next we investigate the integral along $C_2$; we put here

$$\nu=ma\cosh w$$

and investigate the contour $C_2'$ in $w$-plane. By studing the curve of steepests descents we find that for $\sin\psi<m$ these integrals are reduced to the previous ones and only for $\sin\psi>m$ we have new ones; they are shown to be

$$d_r=-4ikm^3a(1-2m^2)^{-2}\sin^{-1/2}\psi\cos^{3/2}\psi\sin^{-3/2}(\psi-\psi_1)(kR)^{-2}\exp\{-ikR\cos(\psi-\psi_1)\}$$
$$\{1+0(1/kR)\}\,, \tag{18.3.1}$$

$$d_\theta=8ik^2m^4a(1-2m^2)^{-3}\cos^{5/2}\psi\sin^{-1/2}\psi\sin^{-3/2}(\psi-\psi_1)(kR)^{-2}\exp\{-ikR\cos(\psi-\psi_1)\}$$
$$\{1+0(1/kR)\}\,, \tag{18.3.2}$$

where $\psi_1$ denotes the critical angle.

The displacement represented by (18.2.1), (18.2.2) is of the distortional wave and the one by (18.3.1), (18.3.2) is of the dilatational wave. These results are completely equivalent to those of Sakai's research (4) § 27~28).

## V. DISTORTIONAL SOURCE OF THE SECOND KIND

### § 19. General Form of the Solution

Since in this case the primary wave is given by (3.3), we assume as the secondary wave

$$d_\varphi{}^s=-(i/krr_s)\sum_{n=0}^{\infty}(2n+1)c_n\zeta_n(kr)dP_n(\cos\theta)/d\theta\ , \tag{19.1.1}$$

$$\Phi^s=A_\varphi{}^s=0\ , \tag{19.1.2}$$

where $c_n$ is an undetermined coefficient. Then the resultant is

$$\begin{aligned} d_\varphi=-(ikrr_s)\sum_{n=0}^{\infty}(2n+1)\{c_n\zeta_n(kr)+[\zeta_n(kr_s)\psi_n(kr),\ \text{or}\ \psi_n(kr_s)\zeta_n(kr)]\}& \\ \times dP_n(\cos\theta)/d\theta\ ,& \end{aligned} \tag{19.2}$$

according as $r<r_s$ or $r>r_s$.

After the same procedure as before we have

$$d_\varphi=-\frac{2\pi}{(rr_s)^{1/2}a}\sum_j\left[\nu\frac{dP_{\nu-1/2}(-\cos\theta)}{d\theta}\frac{1}{\cos\nu\pi}\frac{H_\nu{}^{(2)}(kr_s)H_\nu{}^{(2)}(kr)}{H_\nu{}^{(2)}(a)\partial\{H_\nu{}^{(2)\prime}(a)-(3/2a)H_\nu{}^{(2)}(a)\}/\partial\nu}\right]_{\nu=\nu_j}\ , \tag{19.3}$$

where $\nu_j$ means a zero of $H_\nu{}^{(2)\prime}(a)-(3/2a)H_\nu{}^{(2)}(a)$ qua function of $\nu$. According to 7) the zeros lie near the curve in the $\nu$-plane, which starts from $\nu=a$, making an angle $-\pi/3$ with the positive real axis, and goes off to $-\infty i$; the ones close to the real axis are given by

$$\nu_j\sim a\{1+(1/2)p_j{}^2+(1/120+(17/90\sigma_j{}^2))p_j{}^4+\cdots\}\qquad j=1,2,3,\cdots \tag{19.4}$$

where $p_j=(3\sigma_j/a)^{1/3}e^{5/6\pi i}$ and $\sigma$'s denote the roots of

$$H_{2/3}{}^{(2)}(\sigma e^{\pi i})=0\ ,$$

the first several ones being $0.6853843\cdots$, $3.9027676\cdots$, $7.0549300\cdots$, $10.2006884\cdots$, $13.3445027\cdots$; the zeros of extremely large moduli are of order of $-(m+1/4)\pi i/\log m$ with a large positive integer $m$.

To ascertain the convergence of this series, we estimate the order of magnitude of the terms corresponding to the large zeros, and find such terms are comparable with

$$-\nu^{3/2}e^{-i\nu\theta}a/\{\log\nu(\nu^2-a^2)^{1/2}\}$$

except when $\theta$ is small, and, therefore, the convergence is secured. Considering its rapid convergence for not small $\theta$, we evaluate the first several terms to estimate $d_\varphi$ in this case.

### § 20. Evaluation of the First Several Terms

Let us evaluate the term of the right-handed side of (19.3) corresponding to $\nu_j$, given by (19.4). As the result of calculation we find

$$\begin{aligned} d_{\varphi j}=-9kp_j{}^{-4}e^{-\pi/4i}&(J_{1/3}(\sigma_j)-J_{-1/3}(\sigma_j))^{-2}(1/kR_{QB}kR_{AP})(2kr_0\sin\theta_1\sin\theta_2/\pi \\ &\times\sin\theta)^{1/2}[1+\{59/60+1/4\cot^2\theta+1/4\cot^2\theta_2-(2/45\sigma_j{}^2)\}p_j{}^2] \\ &\times\exp[-ikR_{QB}-ikR_{AP}-ikr_0(\theta-\theta_1+\theta_2)\{1+1/2p_j{}^2+(1/120+17/90\sigma_j{}^{-2})p_j{}^4\} \\ &-i/8kr_0(\cot\theta_1+\cot\theta_2)p_j{}^4]\{1+0(1/kr_0)\} \end{aligned} \tag{19.5}$$

for $k(r-r_0)>0((kr_0)^{1/3})$, $k(r_s-r_0)>0((kr_0)^{1/3})$, if we use such notations as in Fig. 2, and

$$\begin{aligned} d_{\varphi j}=2kp_j{}^{-2}e^{-\pi/4i}&(2\pi/kr_0\sin\theta)^{1/2}[1+\{51/60-(2/45\sigma_j{}^2)-1/2k^2(r-r_0)^2-1/2k^2 \\ &\times(r_s-r_0)^2\}p_j{}^2]\exp[-ikr_0\theta\{1+1/2p_j{}^2+(1/120+17/90\sigma_j{}^{-2})p_j{}^4\}] \\ &\times\{1+0(1/kr_0)\}\{1+0((r-r_0)^3/r_0{}^3)\}\{1+0((r_s-r_0)^3/r_0{}^3)\} \end{aligned} \tag{19.6}$$

for $k(r-r_0)<0((kr_0)^{1/3})$, $k(r_s-r_0)<0((kr_0)^{1/3})$; the numerical values of $J_{1/3}(\sigma_j)-J_{-1/3}(\sigma_j)$ are $1.592206\cdots$, $-0.697477\cdots$, $0.519806\cdots$, $-0.432500\cdots$, $-0.378209\cdots$, $\cdots$ .

The properties are as follows:

1. The magnitude is proportional to $(kR_{QB}kR_{AP})^{-1}(\sin\theta_1\sin\theta_2/\sin\theta)^{1/2}$.

2. From the phase it is found that, if $\theta-\theta_1-\theta_2>0$, the distortional wave travels straight to $B$, then many waves corresponding to various $\sigma_j$ propagate on the surface to $A$ with the respective propagation velocity fairly close to $v_t$, that is, $v_t\{1-1/4(3\sigma_j v_t/\omega r_0)^{2/3}\}$, and then straight to $P$ with $v_t$. If $\theta-\theta_1-\theta_2<0$, the phase, approximately equal to $-ik\{R_{QB}-r_0|\theta-\theta_1-\theta_2|+R_{AP}\}$, means that the wave is reflected directly by the part of the surface between $A$ and $B$, as in the case of $\Phi_{2j}$ in § 12.

3. If $\theta-\theta_1-\theta_2>0$, it attenuates with increasing $\theta$, the rate being approximately given by $\exp\{-\sqrt{3}/4(3\sigma_j)^{2/3}(\omega r_0/v_t)^{1/3}(\theta-\theta_1-\theta_2)\}$. We tabulate below the numerical values of the rate corresponding to various values of $\sigma_j, \theta$ to give some idea about the order of each term, where $a$ is taken to be 100:

| | $\theta-\theta_1-\theta_2=0.1$ | 0.2 | 0.5 | 1.0 |
|---|---|---|---|---|
| $\sigma_1$ | 0.7225 | 0.5220 | 0.2725 | 0.03877 |
| $\sigma_2$ | 0.3548 | 0.1258 | 0.0158 | 0.00003 |
| $\sigma_3$ | 0.2149 | 0.0461 | 0.0021 | |
| $\sigma_4$ | 0.1400 | 0.0196 | | |
| $\sigma_5$ | 0.0952 | 0.0091 | | |

We see from it that for $\theta-\theta_1-\theta_2=0.2$ it suffices for us to take five terms to keep the error under one per cent, if we take only this point into consideration. For $\theta-\theta_1-\theta_2<0$ it increases exponentially with $\theta-\theta_1-\theta_2$, but this is to be interpreted as representing the qualitative behavior of the partial wave and we must sum up fairly many terms to estimate $d_\varphi$, since the terms increase their magnitude at first with increasing $\sigma_j$ and then begin to decrease when the relation $\nu_j-a=0(a^{1/3})$ becomes invalid.

4. The vibration at $P$ is apparently transverse and perpendicular to the meridian plane through $P$.

## § 21. Case of Small $\theta$

When $\theta\ll 1$, we can express $d_\varphi$ on the surface as

$$d_\varphi=\frac{i}{(r_0r_s)^{1/2}a}\int_{C_1}\frac{\nu dP_{\nu-1/2}(-\cos\theta)}{d\theta}\,\frac{1}{\cos\nu\pi}\,\frac{H_\nu^{(2)}(kr_s)}{H_\nu^{(2)\prime}(a)-(3/2a)H_\nu^{(2)}(a)}\,d\nu \tag{21.1}$$

referring to § 13. This becomes

$$d_\varphi=ika^{1/2}e^{\pi/4i}(2/\pi\sin\theta)^{1/2}\int_{C_1'}\cosh^{3/2}w\sinh w\exp\{-kR\sin\psi\cosh wi-kR\cos\psi\sinh w\}\{\sinh w+(3/2a)\}^{-1}dw\{1+0(1/kR)\}\,. \tag{21.2}$$

By integrating it along the curve of steepest descents through $i(\pi/2-\psi)$ we obtain

$$d_\varphi=-i2ka\sin\psi\exp(-ikR/(kR)\{1+0(1/kR)\}\,, \tag{21.3}$$

which is compatible with Sakai's result in the case of a plane surface 4) § 38).

## VI. CONCLUSION

### § 22.

By summarising the above results we have come to the following conclusion.

1. When a monochromatic elastic wave of dilatational character or distortional character of the first kind generated at the source reaches the surface, many secondary waves are produced, which, combined with the initial one, will be separated into three groups corresponding to three types of elastic waves on a plane surface, i.e. to the dilatational, distortional and Rayleigh waves. While the third group, $\Phi_0$, $A_{\varphi 0}$, consists of waves having such phase differences as correspond to the path differences of integral multiples of the whole circumference among themselves, the first two, $\Phi_1$ $A_{\varphi 1}$, $\Phi_2$, $A_{\varphi 2}$ are the groups of an infinite number of waves, corresponding to the two rows of the zeros of the function represented by the right side of (7.3) in the $\nu$-plane. When a distortional wave of the second kind has reached the surface, only the group of the same kind consisting of an infinite number of components occurs, corresponding to the zeros of the function $d/da\log H_\nu^{(2)}(a)-(3/2a)$.

2. If the field point is in such a position as exposed to the direct radiation from the source, the situation is not different essentially from that in the case of the reflection by a plane surface, already dealt with by, say, Sakai and our method is shown not to be so effective but to give us only some qualitative informations. The range we stated here to be exposed to the direct radiation does not always mean the region of points, which we can join with the source by a straight line without being intercepted by the surface as in geometrical optics, but the extent where the angle $\theta-\theta_1, \theta-\theta_1-\theta_2$, etc. are negative respectivly. This range, consequently, varies according as which wave are we concerned with and sometimes, as in the case of $A_\varphi$ in § 17, the field point fairly closed to the source may be still out of this range with respect to a certain kind of waves.

Out of this range, that is, in the shade, our method has shown its effectiveness and we have obtained the results that exhibit some significant features we shall state below.

3. In the shade, except for $\Phi_0, A_0$ in § 10, § 15, corresponding to Rayleigh wave in the case of a plance surface, the amplitudes of the waves attenuate exponentially with $\theta, \theta-\theta_1$, etc., the angles measuring their respective shades, which shows the continual dissipation on the surface on account of the continual change of the direction of propagation. The damping of $\Phi_0$. $A_{\varphi 0}$ in this respect is negligible so far as the radius of curvature of the surface is considerably large compared with their wave-length.

When travelling on the surface, all kinds of waves are of dispersive character, their propagation velocities depending on the frequency, although they are close to some of $v_l, v_t, v_R$, the veloctíes of dilatational, distortional and Rayleigh waves. Among the waves of the same kind the first-numbered, corresponding to the smallest $|\mathrm{Im}\nu|$ is the fast.

4. The case of a dilatational source. If the source is placed fairly far from the surface, only two sorts of waves belonging to the first group, $\Phi_2, A_{\varphi 2}$, are observable at any distance from the surface. These two sorts of waves propagate on the surface with the propagation velocities, though different for each member, considerably close to $v_l$ and then travel straight to the field point with $v_l$ and $v_t$ respectively, their respective vibrations being longitudinal and transverse in the meridian plane through the field point. While the so-called path of the former is tangential to the surface, that of the latter is oblique. Their amplitude is, except for the angluar dependence, inversely proportionaly to $R_{QB}R_{AP}$ and $R_{QB}R_{BA^*P}$, which are the product of the length of the straight path starting from the source and that of the straight path terminating at the field point and the product of the similar ones, respectively; this is essentially compatible with Huygens' principle. The extent of the shade is considerably larger for the latter than for the former, the shade of the former coinciding with that of geometrical optics.

When the source approaches to the surface, another kind of waves $A_{\varphi 1}$ becomes observable at any distance from the surface; the waves of this kind propagate round on the surface with the velocities close to $v_t$ and then travel to the field point along the straight path, tangential to the surface, with the velocity $v_t$, the vibration being transverse in the meridian plane. Their extent of the shade coincides with that in geometrical optics. The amplitude is, except for angular dependence, inversely proportional to $R_{AP}$. Still more, in the vicinity of the surface, waves of other three kinds $\Phi_0, A_{\varphi 0}, \Phi_1$ are observable. The first two propagate on the surface with the velocity, of which the group velocity is equal to $v_R$, and the last with the velocities equal to those of $A_{\varphi 1}$. The oscillations resulting from them are elliptically polarized ones with their own peculiarities.

5. The case of a distortional source of the first kind. If the source is considerably far from the surface, three sorts of waves, $\Phi_2$, $A_{\varphi 2}, A_{\varphi 1}$, belonging to the first and the second groups, are observable at any distance from the surface. The waves of the first two sorts propagate on the surface with the velocity, though differents from one another, close to $v_l$ and then straight to the field point with $v_l$, $v_t$, respectively. The path to the field point is tangential to the surface for $\Phi_2$, while for $A_{\varphi 2}$ it is oblique. The waves $A_{\varphi 1}$ travel on the surface with the velocity close to $v_t$ and propagate to the field point with $v_t$ along the path tangential to the surface. The extent of their shade increases in the order of $A_{\varphi 1}, \Phi_2$,

$A_{\varphi 2}$, the shade of $A_{\varphi 1}$ being coincident with that in geometric optics. Their amplitudes, omitting their angle-dependence, are inversely proportional to $R_{AP}R_{QB}$, $R_{QB^*}R_{AP}$, $R_{QB^*}R_{A^*P}$ respectively, the product of the lengths of the two straight paths or that of the analogous ones. The vibrations are transverse or longitudinal according as it results from $A_{\varphi}$ or $\Phi$. In the vicinity of the surface, waves of another short $\Phi_1$ also observable, which propagate with velocities close to $v_t$ and whose amplitudes are proportional to $R_{QB}$, the length of the straight path from the source. Their shade is coincident with that in geometrical optics. The vibrations resulting from them are elliptically polarized ones.

When the source approches the surface we can observe in the vicinity of the surface the surface waves $\Phi_0$, $A_{\varphi 0}$ which are quite analogout to those in the preceding case.

6. The case of a distortional source of the second kind. The waves of $d_{\varphi}$, corresponding to numerous zeros, propagate on the surface with velocities close to $v_t$ and travel straight to the field point with $v_t$. The extent of the shade is equal to that in geometrical optics. They, of cource, represent transverse vibration perpendicular to the meridian plane.

## Acknowledgment

I which to acknowledge my indebtness to to several persons for their help of my work. My gratitude is first due to late Professor Takuzo Sakai who indicated this problem and kindly guided me to establish the general plan. To Professor Isao Imai, I am indebted as well for much valuable advice during the work as for much encouragement during my depressive years due to my personal condition. I also wish to thank Professor Tosio Kato for many useful suggestions in informal talks. Further I wish to express my thanks to Dr. Hisamitu Nisi, President of University of Saga, for his kindness to administer to my convenience for research. I also wish to thank Dr. Tatudiro Sasaki, Chief of the Numerical Computation Bureau, Tokyo, for his generous permission to use the facilities of the institute and all the staffs of the Bureau, above all Mr. Masanori Masiko, for their sincere collaboration.

# Experimental Investigation of the Wakes behind Cylinders and Plates at Low Reynolds Numbers

By Sadatoshi TANEDA

*The Kobe University of Mercantile Marine*

(Received October 27, 1955)

Wakes behind cylinders and plates were photographically investigated at Reynolds numbers from 0.1 to 2,000. Main results are as follows.

In the case of a circular cylinder, the rear twin-vortices begin to form at $R=5$ ($R$ is $Ud/\nu$), then become more and more enlarged as $R$ increases, and finally become asymmetrical at about $R=45$. The laminar wake, on the other hand, begins to oscillate sinusoidally some distance downstream at $R=30$.

In the case of a flat plate parallel to the flow, the wake begins to oscillate sinusoidally some distance downstream at about $R=700$ ($R$ is $Ul/\nu$, where $l$ is the length of the plate).

Lastly, some detailed knowledges about the structure and the nature of the Kármán vortex street are obtained by a new method.

## § 1. Purpose and Outline of the Experiments

As for the flow of a fluid at low Reynolds numbers, some experimental and theoretical investigations have been made up to the present, but not a few problems are left still unsolved. It is well known that the calculations are successfully made with the approximations of Stokes or Oseen for very small Reynolds numbers, but as Reynolds number is increased, Oseen's as well as Stokes's approximations become more and more remote from the exact solution of the Navier-Stokes equations. On the other hand, the experiments which serve as a verification or guidance of the theories seem to be in great lack. The present author planned to investigate minutely the wakes behind circular cylinders and flat plates at Reynolds numbers from 0.1 to 2,000.

First, it was tried to determine the critical Reynolds number at which twin-vortices make their appearance in the rear of a circular cylinder. Concerning this problem there are several theoretical calculations[1][2][3]. It is from this aspect that the author is interested in the subject. Though some photographs of the flow around cylinders at low Reynolds numbers have already been taken by several experimenters[4][5], they are not fit for searching the critical Reynolds number, because the stream-lines in the immediate neighborhood of the rear stagnation point are not clear. Theauthor has succeeded in getting the clear stream-lines by giving long duration of the exposure.

Secondly, the experiments were made concerning the oscillation of the wake behind a circular cylinder. It is extremely difficult to detect the oscillation which appear in the wake for the first time, as it is very faint. In the present experiment, however, the ocillation was sensibly detected by utilizing the reflection of light from the aluminium dust suspended in the water. And it was found that the wake begins to oscillate at about $R=30$ and that the twin-vortices are independent, at least directly, of the oscillation of the wake.

Thirdly, the experiments were made using a model coated with condensed milk. This method enables us to see clearly the positions of separation point and the structure of twin-vortices. This series of experiments showed that the solutions of Navier-Stokes equations are in good agreement with the experimental data even in the case of $R=40$.

Fourthly, the wake behind a flat plates parallel to the direction of motion was investigated. In the case of a flat plate the separation does not occur, in other words twin-vortices do not appear, for this reason it is very interesting to investigate the relationship between the wake of a circular cylinder and that of a flat plate.

Lastly, the experiments by a new method clarifying the structure and the nature of the Kármán vortex street were carried out and some detailed knowledges concerned were obtained.

## § 2. Apparatus and Experimental Method

The experiments were carried out in the glass water tank of 100 cm in length, 20 cm in breadth and 30 cm in depth. The carriage, to which the model was attached, was moved on straight rails above the tank by means of a nut engaging on the lead screw which was turned by a 200 watt a.c. motor through a great box. The velocity of the carriage was varied in 10 steps by exchanging the gears. According to circumstances, d.c. motor could also be used. To obtain a uniform velocity, every part of the apparatus was carefully adjusted for a long period. Fig. 1 shows the general arrangement of the apparatus.

Table I.

| Circular Cylinder | | |
|---|---|---|
| $d$(mm) | $L$(mm) | $d/D$ |
| 6.00 | 300 | 1/33 |
| 3.93 | 250 | 1/51 |
| 2.95 | 250 | 1/68 |
| 1.99 | 200 | 1/100 |
| 1.54 | 200 | 1/130 |
| 1.02 | 180 | 1/196 |
| **Flat Plate** | | |
| $l$(mm) | $b$(mm) | $L$(mm) |
| 37.00 | 0.24 | 280 |
| 20.05 | 0.24 | 250 |

$d$: Diameter of the cylinder
$L$: Span of the model
$D$: Tank width
$l$: Length of the flat plate
$b$: Thickness of the flat plate

In order to visualize the motion of water below the free surface, aluminium dust was suspended uniformly in the water. And illuminating it by a sheet of intense light through a narrow slit, we could clearly observe the motion of water in the illuminated layer from the direction normal to the light. A 500 watt incandescent lamp with a line filament was used as the source of light.

The camera used was a Nikon F 1.4, and when necessary a Mirax (an enlarging equipment) was put on.

The sizes of the models are given in the Table I.

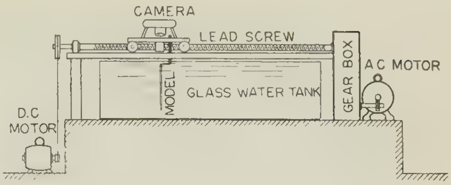

Fig. 1. Schematic diagram of the apparatus.

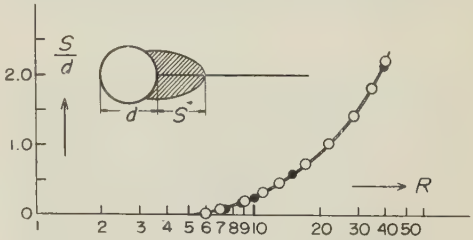

Fig. 2. Plot of $s/d$ against $R$.

## § 3. The Reynolds Number at which Twin-Vortices begin to Form in the Rear of a Cylinder

Concerning the critical Reynolds number at which twin-vortices begin to form in the rear of a circular cylinder, there has been no investigation except that by H. Nisi and A. Porter$^{6)}$, and little is known of the accurate value of the critical Reynolds number. This seems to be chiefly due to the extreme difficulties of the experimental technique.

In the present experiments the method of moving a model through still water was adopted. For such a low Reynolds number, even a very small residual motion of water cannot be neglected, therefore great care was taken to allow the water to come to rest before beginning an experiment.

A careful photographic technique was also required to get a sufficiently clear and sharp picture. A Mirax enlarging equipment was put on and the duration of the exposure was made sufficiently long.

It can be noticed from the photographs obtained that the twin-vortices are seen at $R=7$, though they are very small, but they are not seen at $R=6$. ($R$ is $Ud/\nu$, where $d$ is the diameter of the cylinder, $U$ is the model speed and $\nu$ is kinematic viscosity.) In the neighborhood of the critical Reynolds number, it is very difficult to detect the twin-vortices accurately for two reasons (i) the dimension of twin-vortices is still very small, (ii) the position they appear is situated in the immediate neighborhood of the rear stagnation

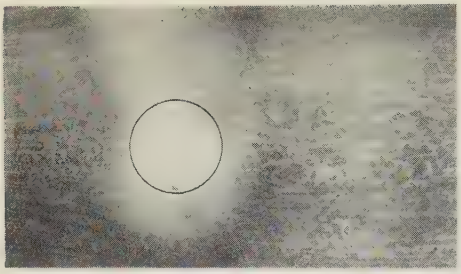

Photo 1. (a) $R=57.7$.

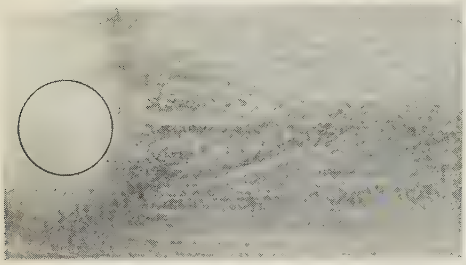

Photo 1. (b) $R=42.0$.

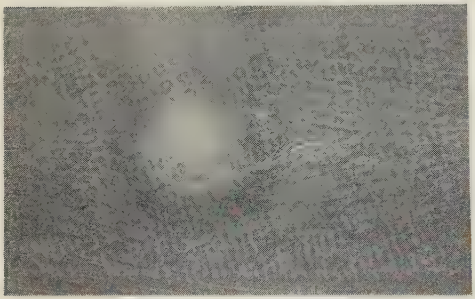

Photo 1. (c) $R=13.05$.

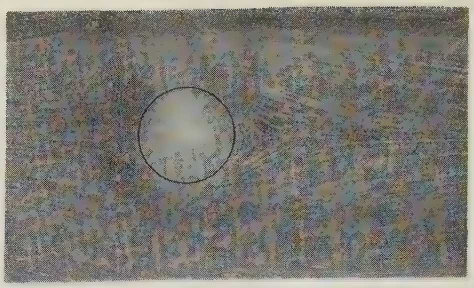

Photo 1. (d) $R=9.10$.

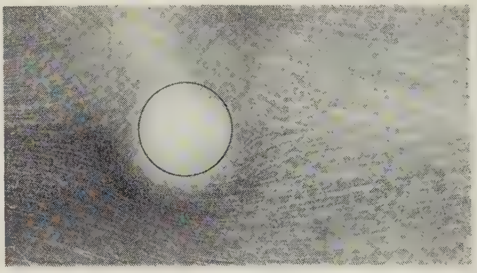

Photo 1. (e) $R=6.10$.

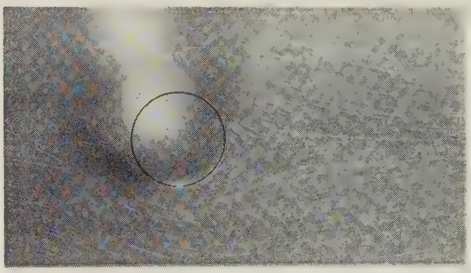

Photo 1. (f) $R=3.64$.

point where the velocity of the flow is extremely small. The size of twin-vortices, however, can be accurately measured at Reynolds numbers exceeding 7.

In Fig. 2 the size of twin-vortices is plotted against the Reynolds numbers, and from this curve the critical Reynolds number can be deduced. It may be concluded that the critical Reynolds number at which the twin-vortices begin to form in the rear of circular cylinder is 5.

Plate 1 shows the examples of the photographs obtained.

Further, the experiments indicate that the wall effect of the tank can be neglected when $d/D<1/50$ (where $d$ is the diameter of the cylinder and $D$ is the tank width).

## § 4. Twin-Vortices

The twin-vortices appear in the rear of a cylinder at $R=5$, and as the Reynolds number is increased these two eddies grow and become more and more elongated in the flow direction. But they adhere stably on the cylinder until the Reynolds number is reached of about 45.

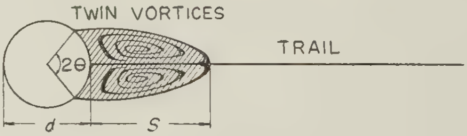

Fig. 3.

Thus, the wake behind a circular cylinder consists of two parts, twin-vortices and trail, at Reynolds numbers between 5 and 45. (see Fig. 3).

When a cylinder coated with condensed milk is set in motion in water, the milk melts in the wake little by little and draws clearly the boundary-line of the twin-vortices. Plate 2 are the examples of the photographs obtained by this method.

At $R>35$ a remarkable phenomenon is

observed. Tiny irregular gathers appear in the boundary of the twin-vortices, move downstream along the boundary-line till they reach the rear end of the twin-vortices, tremble for a short time and are died away. This small irregular motion, however, does not produce any effect on the flow behind the twin-vortices untill the Reynòlds number is reached of about 45.

The trail, on the other hand, begins to oscillate sinusoidally some distance downstream at $R=30$, and its amplitude becomes larger as the Reynolds number is increased. When the Reynolds number is reached of 45, the oscillation of the trail begins to exert an influence upon the twin-vortices. At Reynolds numbers above 45, the gathers of the twin-vortices are elongated along the trail, shed alternately from each of the twin-vortices and pass downstream, where they arrange themselves in a configuration corresponding to that of a Kármán vortex street. But a large portion of the twin-vortices is still stably attached on the cylinder. The size of the gather which travel downstream increases with the Reynolds number, and for Reynolds numbers above 150 a large portion of the twin-vortices are shed.

In 1953 Kawaguchi[7) carried out calculations about the flow arround a circular cylinder for the case $R=40$, integrating numerically the exact Navier-Stockes equations. Comparison between the calculations and the experimental data is shown in Table II. It may be concluded from Table II that the solutions of Navier-Stokes equations are in good agreement with the experimental data in the neighborhood of a circular cylinder even for $R=40$.

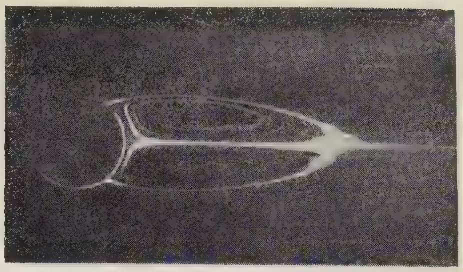

Photo 2. (a) $R=41.0$.

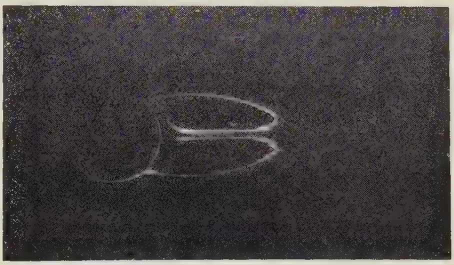

Photo 2. (b) $R=28.4$.

Table II.

| | | Calculated | Measured |
|---|---|---|---|
| Position of separation | $\theta$ | 52.2° | 53° |
| Size of twin-vortices | $s/d$ | 1.9 | 2.1 |

## § 5. Oscillation of the Wake behind a Circular Cylinder

The experiments about the oscillation of the wake behind a circular cylinder were carried out in the past by Thom (1933)[8) and Kovasznay (1949)[9), but comparatively little is known about the process of its development. The author planned to investigate this problem minutely.

As the oscillation which appears for the first time in the trail is very faint, its detection is extremely difficult. In the present study, however, the oscillation was sharply detected by means of the aluminium dust method. When the light comes into the water with suspended aluminium dust, we see innumerable tiny particles continually twinkling in the illuminated layer, and of course the brightness distributes homogeneously over the illuminated section so far as no motion of water exists. However, as soon as the wake begins to oscillate, there appears periodically striped pattern of brightness. As was clarified in the previous paper[10), this pattern relates to the direction of the local flow. Thus the wave-length of the wake was determined by examining the photographs. The relation between the wave-length $\lambda$ and the frequency $N$ is given by

$$\frac{d}{\lambda}=\frac{Nd}{U}\,\frac{U}{U-v}$$

where $U$ is the velocity of the cylinder and $v$ the velocity of the vortex filament. The wave length shows a tendency to increase downstream, so all the measurements were made at 20 diameters downstream from the cylinder.

The results are illustrated graphically in Fig. 4, and an example of the photographs is shown in Plate 3. The present experiment

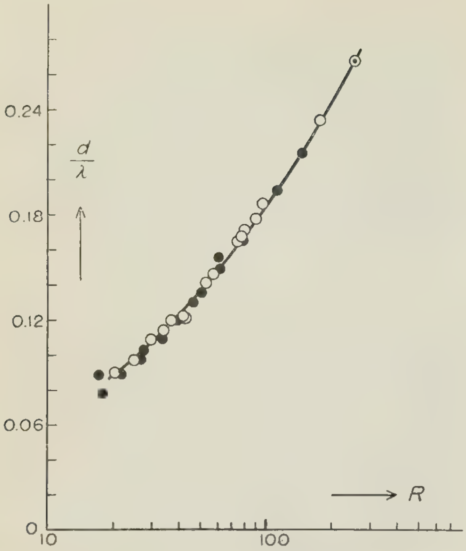

Fig. 4. Plot of $d/\lambda$ against $R$.

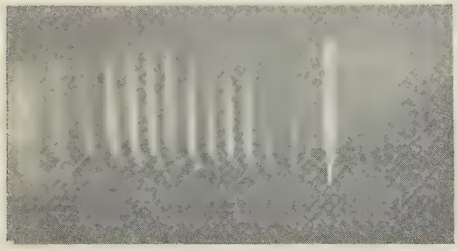

$R=42.0$.

Photo 3. Oscillation of the wake behind a circular cylinder.

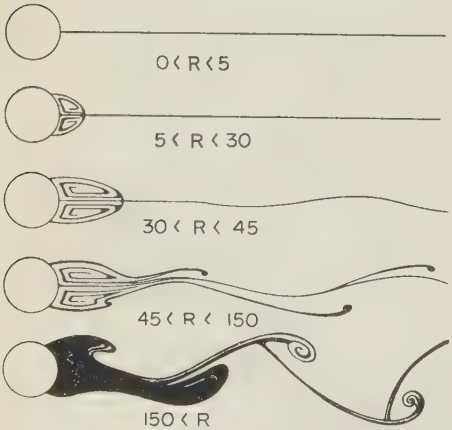

Fig. 5. Process of the development of the wake behind a circular cylinder.

indicates that the critical Reynolds number at which the wake begins to oscillate is 30.

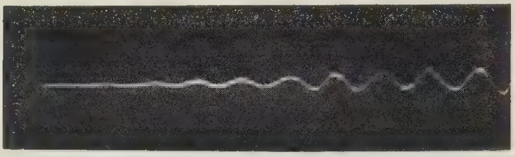
Of course if the cylinder is given a slight shock, the oscillation of the wake appears even at Reynolds numbers below 30. It should be noticed that the $d/\lambda-R$ curve is continuous at Reynolds numbers above 20, and does not show any sign of discontinuity at $R=30$ and at $R=45$.

As oscillation of the wake is affected strongly by the wall of the water tank, the present experiment was carried out at $d/D < 1/100$.

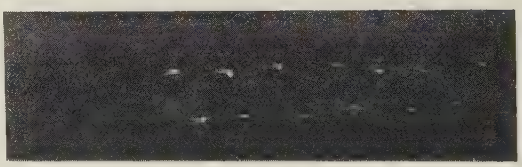
The process of the development of the wake behind a circular cylinder is summarized in Fig. 5.

## § 6. Oscillation of the Wake behind a Flat Plate

In the case of the cylinder the phenomenon is complicated as the wake is constituted from two parts, the twin-vortices and the trail. On the other hand, in the case of the flat plate parallel to the direction of motion, the phenomenon is simple because it consists of only one part, i.e. the trail.



(a) Neighborhood of plate. ($R=1815$)



(b) Downstream development of oscillation. ($R=1815$)

Photo 4. Oscillation of the wake behind a flat plate.

The plates used were made of steel and carefully tapered smoothly to sharp edges. The dimensions are shown in Table 1.

The results of the experiment indicated that the wake begins to oscillate at about $R=700$ ($R$ is $Ul/\nu$, where $l$ is the length of the plate) some distance downstream from the plate.

Some examples of the photographs obtained are shown in Plate 4.

As is seen from the photographs, the wake is laminar for a short distance behind a flat plate whilst further downstream it becomes sinusoidal and vortices appear in its loops. The appearance of the Karman vortex street is similar to the case of a circular cylinder. However, there is a little difference between the two cases of a plate and a cylinder; in the case of a flat plate the vortex filaments are produced from the general flow, while in the case of a circular cylinder they are shed from the twin-vortices. For this reason the shape of the wake behind the flat plate is a little different from that of the wake behind the circular cylinder.

## § 7. Structure of the Kármán Vortex Street

In order to observe the fine structure of the Kármán vortex street, experiments were carried out by two methods at the same time; one the aluminium dust method and the other, the condensed milk method. The aluminium dust enables us to see the velocity field, and the milk clearly shows the boundary between the flow which passed the right hand side of the cylinder and that passed the left.

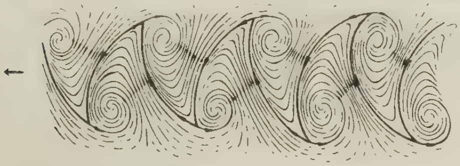


Fig. 6. Sketch of the Kármán vortex street. This is the picture seen from the view point which rests relatively to the vortex street.

Thus, when two methods are applied at the same time, we can acquire the detailed knowledges about the structure and the nature of the vortex street. The sketch of the Kármán vortex street is shown in Fig. 6.

The Kármán vortex street is deformed as time goes on and finally it is destroyed into pieces. But after an interval these scattered vortices are united and there appears again a new Kármán vortex street, the dimension of which is much larger than that of the primary one. This does, however, not always take place. It was often observed that the primary Kármán vortex street became directly turbulent flow.

In conclusion, the author wishes to express his thanks to Professor Hikoji Yamada of Research Institute for Applied Mechanics, for suggesting this investigation as well as for constant guidance in the course of this work.

# Apparatus for the Study of Spectral Response of Photoelectric Surface

By Hiroji MITSUHASHI and Tadahisa NAKAYAMA

*Technical Research Laboratory, Japan Broadcasting Corporation*
*Kinuta-machi, Setagaya-ku, Tokyo, Japan*

(Received September 19, 1955)

An optical instrument was designed which measures the photoelectricity for the visible wavelength region rapidly and accurately. *The output from a monochromator is kept constant for a long time.* The monochromatic beam emerging from it is split into two beams, one of which is brought to focus on a thermocouple alternately with the other white beams coming from a reference light source of well-stabilized brightness. Difference in intensity between these monochromatic and white beams generates ac signal which drives the optical attenuator in front of the entrance slit of the monochromator until their intensities are brought into balance. The other monochromatic beam is fallen upon a photoelectric surface, spectral response of which is recorded automatically.

## § 1. Introduction

It has become necessary to know the spectral response of the photoelectric surface, not only for study of their properties but also for their applications to spectrophotometry and television. If $E_\lambda$ is the intensity of the incident monochromatic beam and $I_\lambda$ the photocurrent from the surface then the spectral response $S_\lambda$ is given by

$$S_\lambda = k\frac{I_\lambda}{E_\lambda}\,. \tag{1}$$

It is clear from (1) that if we can keep $E_\lambda$ constant irrespective of wavelength by some means, then $I_\lambda$ is directly proportional to the spectral response. This is the principle of the instrument described here. Although there are many other ways of measurement of the photoelectric response,[1)2)3)4)] the authors believe that this is one of the most reliable methods.

To keep $E_\lambda$ constant, the intensity of the beam is controlled by the double beam principle: that is the radiation from the monochromator and reference white light are fed alternately to a thermocouple to induce the alternating thermoelectric voltage, which after being amplified operates a comb attenuator in front of the entrance slit of the monochromator so as to compensate the difference in intensity between them. Thus the intensity of monochromatic beam becomes automatically constant.

## § 2. General Arrangements of the Instrument

The arrangements of the instrument are shown schematically in Fig. 1. $S$ is a tungsten lamp and its color temperature is about 2800°K, whose intensity distribution is corrected by a blue filter. The monochromator consists of a single Littrow prism $P$ and collimating mirror $M_1$, operating about 7° off axis. Width of the entrance and exit slits $SL_1$ and $SL_2$ is fixed at 0.3 mm for all wavelengths. The intensity of the monochromator is stronger at 7000 Å than at 4000 Å by a factor of about 400. (ca $10^{-6}$ watt at 4000 Å.) W is an optical attenuator of comb form. The attenuation factor of about 3 percent of the maximum transmission is attainable.

The beam from the monochromator is brought to focus on the surface of a rotating semi-circular mirror $M_6$, which splits the beam into two. The reflected beam is introduced to the photosurface under investigation. The other beam is focused on a thermocouple connected with a servo-system to control the intensity of the beam. $S_0$ is a small standard lamp, whose wattage is very small (less than 1 watt), so the brightness is kept exactly constant for a long time. L is a lens, $M_9$ a plane mirror, and B a semi-annular shutter which rotates coaxially with $M_6$. The shutter is open while the beam from the monochromator is reflected toward the photosurface, and *vice versa*. The thermocouple generates an ac signal, as long as the intensities of the monochromatic and white beams are unbalanced. The phase of the signal is dependent on which of the beams is the stronger. This signal after amplification and subsequent phase-sensitive demodulation drives the balancing motor $MO_3$. The comb attenuator W is driven by this motor.

## § 3. Radiation Detector and Amplifiers

In order to keep the neutrality of pulsating monochromatic beam well, the radiation detector must have a rapid and non-selective response. Thermocouple of Bi–Sb and Bi–Cd alloy with gold-black receiver is best fitted for the purpose. The one here used has the following characteristics:

Radiation receiving area $=0.3\,\text{mm}\times2.3\,\text{mm}$
Electrical resistance $=5$ ohms
Sensitivity to stationary radiation $=1\,\mu\text{V}/1\,\mu\text{W}$
Time constant $=0.03$ second

If we assume the exponential build-up and decay of the thermocouple temperature in response to the pulsating radiation, the following relation for the ratio of the fundamental frequency component $E_\nu$ of the resulting thermoelectric voltage to that caused by stationary radiation $E_0$ is obtained;

$$E_\nu/E_0=2/(\pi\sqrt{1+4\pi^2\nu^2\tau^2})\ , \qquad (2)$$

where $\tau$ is the time constant of the thermocouple and $\nu$ is the frequency of the incident radiation. It is found advisable from (2) that $\nu\tau$ is not larger than 0.2. We chose $\nu=5$ c.p.s., as it cannot be made so small due to frequency susceptible of amplification. As the incident energy to the thermocouple by the violet radiation generates a signal of about $10^{-6}$ volt, the least effective radiation in putting the comb in motion corresponds to the signal as low as $10^{-8}$ volt. If the band width of amplification is made less than 0.5 c.p.s., Johnson noise of our thermocouple becomes $2\times10^{-10}$ volt. Although there are many literatures of the amplifier for very feeble signal,[5)6)] the one we constructed is of four stages, sharply tuned to 5 c.p.s. (Fig. 2.) The signal of the thermocouple is fed to a input transformer. The electron tube used for preamplification is a pentode 6SJ7 whose input noise level is about $5\times10^{-8}$ volt, partition noise being decreased by adopting triode connection. It is necessary for the noise transformed at the secondary winding to surpass that of the preamplifier tube. Therefore, the least turn ratio required for the transformer is 250, whereas it is 280 in our case. A twin-T filter is used to reduce the band width of the amplifier, with the result that $\Delta\nu=0.6$ c.p.s. The amplified 5 c.p.s. signal is fed to rotating phase-sensitive detector. The overall voltage gain of the ac amplifier preceding the servo amounts to about 145 db. By photographing the noise pattern using oscilloscope, it was made clear that Johnson noise of the thermocouple limits the minimum perceptible signal.

The photocurrent is amplified through another feed-back amplifier reported by Sturtevant.[7)] Two such amplifier units are connected in tandem to give overall voltage

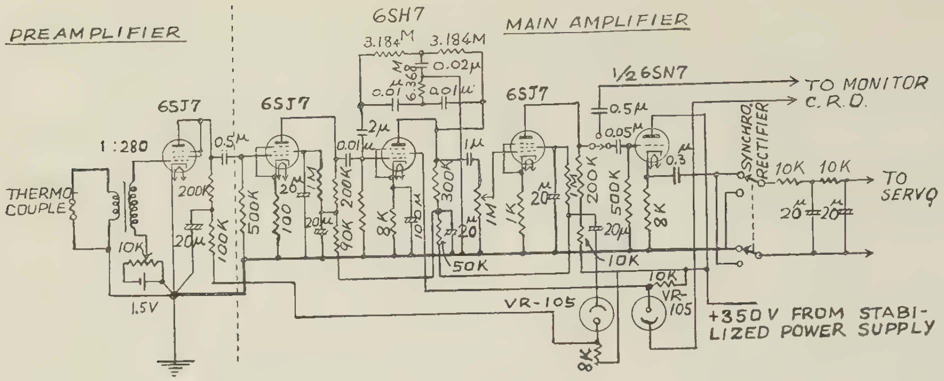

Fig. 2. Electrical circuit of the thermocouple amplifier.

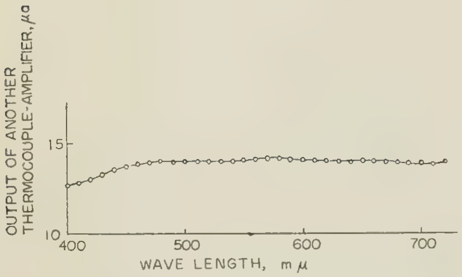

Fig. 3. Effectiveness of the controlling thermocouple.

amplification of 90 db. Ordinarily the band width of 0.3 c.p.s. is admitted. Excellent linearity as well as stability was obtained by heavy application of negative feed-back.

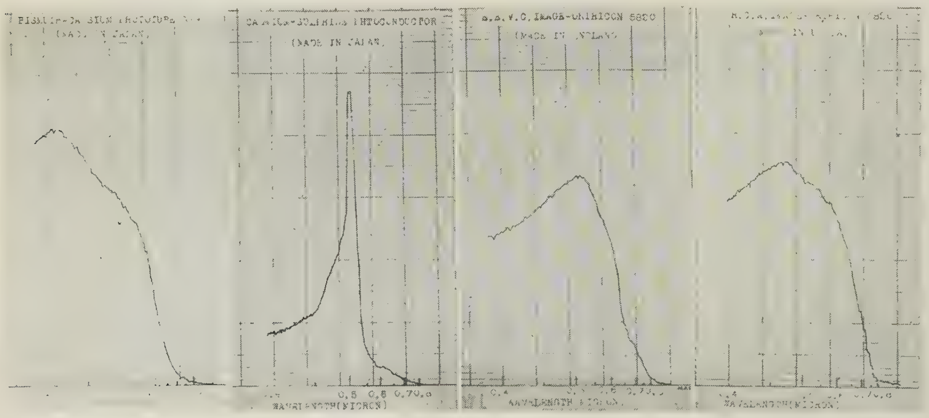
## § 4. Accuracy and Results of Measurements

The accuracy of our instrument mainly depends on the following characteristics.

i) Neutrality of the thermocouple receiver.
ii) Constancy of the beam energy from the monochromator.
iii) Spectral purity of the output radiation from the monochromator.

To test the neutrality of the thermocouple, diffuse spectral reflectance and transmittance of gold-black evaporated on a glass substratum were measured with a spectrophotometer of Beckman type. Deviation from perfect neutrality is less than ±2 percent.[8] The constancy of the output from the monochromator was studied with another thermocouple $T_2$, placed at the position optically symmetrical to the controlling thermocouple $T_1$. The signal from the controlled beam at $T_2$ is amplified through another amplifier, the microammeter record of which after demodulation is shown in Fig. 3. The control is satisfactory within ±1 percent. As to the spectral purity, resolving power of the monochromator is about 20 Å at 4000 Å and about 160 Å at 7000 Å.

Time required for the measurement of the spectral response of one surface is about 20 minutes. The final error can be reduced to



(a) (b) (c) (d)

Fig. 4. Measured spectral responses of some photosurfaces.

about one percent if we calibrate the errors arising from thermocouple with black body. Various experimental data are shown in Fig. 4.

## § 5. Conclusion

The instrument here described has been used in our laboratory for more than one year giving good results.

In conclusion, the authors are greatly indebted to Mr. T. Matsunami of Tokyo Optical Company for the efforts he made in mounting the double-beam arrangements, and to Mr. M. Nakamura and Mr. K. Kudo of Tokyo University of Education, for the preparation of gold-black and thermocouples. In addition, the authors wish to express their appreciation to the members of the Technical Research Laboratory, Japan Broadcasting Corporation, particularly to Dr. A. Yamashita, Mr. H. Kobayashi, Dr. K. Matsuyama and Mr. M. Yamada for their encouragements they have given throughout the work.

# New Determination of the Temperature of Gold and Silver Points on the Thermodynamic Temperature Scale

By Jiro OISHI, Mitsuru AWANO and Takeshi MOCHIZUKI*

*Physics Department, Tokyo Institute of Technology,*
*Oh-Okayama, Meguro-ku, Tokyo*

(Received September 29, 1955)

The freezing points of gold and silver are determined by a constant volume nitrogen gas-thermometer with a gas bulb made of silica glass.

The temperature of the gold point which is adopted as 1063.0°C on the International Temperature Scale is determined as

$$T_{\mathrm{Au}}=1336.84\pm0.05$$

on the Kelvin Scale and

$$t_{\mathrm{Au}}=1063.69\pm0.05$$

on the Celsius Scale.

The temperature of the silver point which is 960.8°C on the International Temperature Scale is

$$T_{\mathrm{Ag}}=1234.43\pm0.05 \quad \text{and} \quad t_{\mathrm{Ag}}=961.28\pm0.05$$

on the Kelvin and Celsius Scales respectively.

## § 1. Introduction

The freezing point of gold is the only fundamental fixed point in radiation region of the International Temperature Scale. The temperature on the Kelvin Scale is to be determined by gas-thermometric measurement with the triple point of water or the ice point as reference point which is 273.16 or 273.15°K respectively. From the measurements by Holborn and Day[1] in 1901 and Day and Sosman[2] in 1910, the "gold point" was estimated as 1063°C which was subsequently adopted on the International Temperature Scale. Based on this temperature of the gold point, a number of pyrometric measurement had been made on the radiation constant $C_2$ in the past and 1.432 cm·deg was obtained as the mean value which was also adopted for the International Temperature Scale in 1927.

---

* Now at the Central Inspection Institute of Weights and Measures, Ginza-Higashi, Chuo-ku, Tokyo.

On the other hand, recently revised values of the atomic constants, from which the most reliable value of $C_2$ was obtained, necessitated a change in the value to 1.43868 cm·deg[3)] and 1.438 cm·deg was adopted for the International Temperature Scale in 1948. As it is presumed that this discrepancy in the value of $C_2$ might have been caused by inexactness of the past temperature or radiation measurements, carrying out of accurate measurement is advisable to determine anew the thermodynamic temperature of the gold point with present day technique not only to do away with the confusion but also because of the gold point being the only fundamental fixed point on which all the other temperatures in radiation region depend. Reproducibility in measurement of high temperature fixed points is now 0.1 deg and so the value of the gold point is given to the decimal place as 1063.0°C on the International Temperature Scale in 1948, whereas, the accuracy of measurement in those days of Holborn, Day and Sosman was about 1 deg.

The present work was undertaken with the objects of determining the thermodynamic temperature of some high temperature fixed points by a gas thermometer and, at the same time, of examining the propriety of the old measurements at the gold and silver points.

## § 2. Theoretical

### (a) Reduction of the gas thermometer temperature by constant volume gas thermometer to the Kelvin temperature

For a definite mass of gas enclosed in a constant volume gas thermometer, the following relation holds between two temperatures $T$ and $T_0$, the ice point, on the Kelvin Scale:

$$p_0\left(\frac{V_{0p_0}}{T_{vo}}+\sum_{n=1}^{n}\frac{v_n}{T_{vn}}\right)=p_t\left(\frac{V_{tp_t}}{T_v}+\sum_{n'=1}^{n'}\frac{v_{n'}}{T'_{vn'}}\right), \qquad (1)$$

where $p_0$ and $p_t$ are the observed pressures when the gas bulb is kept at the ice point and $t$°C, $V_{0p_0}$ and $V_{tp_t}$ the volumes of the gas bulb at the ice point and $t$°C, $T_{v0}$ and $T_v$ the absolute temperatures of the ice point and $t$°C on the constant volume gas thermometer scale respectively. $T_{vn}$ is the absolute temperature of the part $n$ of the dead space $v$ at the time of measuring the ice point, and $T'_{vn'}$ is that of $v_{n'}$ at $t$°C.

The volumes of the gas bulb at 0°C and $t$°C are expressed by

$$V_{0p_0}=[V_{0p}]_{p=0.76}\,[1+\mu(p_0-0.76)] \qquad (2)$$

and

$$V_{tp_t}=[V_{0p}]_{p=0.76}(1+\lambda t) \qquad (3)$$

respectively, for the outside pressure 1 atm and the inside pressure $p_t$ which is also nearly equal to 1 atm.

Expressing the slopes of $pv$-$p$ isotherms of a gas at the ice point and $t$°C by $B_0$ and $B_t$ respectively, we have the following relation which gives the correction due to gas imperfection:

$$\frac{T_v}{T_{v0}}=\frac{T}{T_0}\frac{1}{F_t}, \qquad (4)$$

where

$$F_t=\frac{1+p_0B_0}{1+p_0B_t}. \qquad (5)$$

Hence, we have from the above equations

$$T=T_0\frac{p_t}{p_0}\cdot\frac{1+\lambda t+T_v/[V_{0p}]_{p=0.76}\sum_{n'=1}^{n'}v_{n'}/T'_{vn'}}{1+\mu(p_0-0.76)+T_{v0}/[V_{0p}]_{p=0.76}\sum_{n=1}^{n}v_n/T_{vn}}\cdot F_t\,, \qquad (6)$$

where the latter fractional expression of the right side is to correct the entire gas occupying the same volume to be at 0°C and $t$°C respectively. Thus we obtain the value of $T$ from the observations of the related quantities, using $T_0=273.15$, the value adopted at the Tenth General Conference of Weights and Measures in 1954, and $B_0$- and $B_t$-values of the thermometric gas.

For nitrogen gas which was used in the

present work, $B_t$- values have not been measured at high temperatures above 400°C, but by extrapolating Keyes'[4)] formula, we find $B_{t_{\mathrm{Au}}}=179.6\times10^{-5}$ 1/mHg and $B_{t_{\mathrm{Ag}}}=177.2\times10^{-5}$ 1/mHg for the gold and silver points respectively. Taking these $B_t$-values and $B_0=-58.7\times10^{-5}$ 1/mHg, we have as the correction factors of the gas scale for the Kelvin scale at these two fixed points:

$$F_{t_{\mathrm{Au}}}=1-0.00238\,p_0 \tag{7}$$

and

$$F_{t_{\mathrm{Ag}}}=1-0.00236\,p_0\,, \tag{8}$$

and these relations also hold at temperatures near the gold and silver point respectively.

### (b) The determination of the thermodynamic temperatures of the gold and silver points

Difference of temperatures in the neighbourhood of the gold or silver point is determined by a standard thermocouple, for which the temperature-emf relation is expressed by the equation

$$e=a+bt+ct^2\,,$$

where the constants $a, b$ and $c$ are determined by the calibrations at antimony, silver and gold points.

Expressing the emf's at the gold point $t_{\mathrm{Au}}$, the silver point $t_{\mathrm{Ag}}$ and a temperature $t$ near $t_{\mathrm{Au}}$ or $t_{\mathrm{Ag}}$ by $e_{\mathrm{Au}}, e_{\mathrm{Ag}}$ and $e_t$ respectively, we have

$$t_{\mathrm{Au}}=t+(e_{\mathrm{Au}}-e_t)\Big/\left(\frac{de}{dt}\right)_{t_{\mathrm{Au}}} \tag{9}$$

or

$$t_{\mathrm{Ag}}=t+(e_{\mathrm{Ag}}-e_t)\Big/\left(\frac{de}{dt}\right)_{t_{\mathrm{Ag}}}, \tag{10}$$

where

$$\left(\frac{de}{dt}\right)_{t_{\mathrm{Au}}}=k+2c\,\frac{t_{\mathrm{Au}}-t_{\mathrm{Ag}}}{2}\,,$$

$$\left(\frac{de}{dt}\right)_{t_{\mathrm{Ag}}}=k-2c\,\frac{t_{\mathrm{Au}}-t_{\mathrm{Ag}}}{2}$$

and

$$k\equiv\frac{e_{\mathrm{Au}}-e_{\mathrm{Ag}}}{t_{\mathrm{Au}}-t_{\mathrm{Ag}}}=\left(\frac{de}{dt}\right)_{(t_{\mathrm{Au}}+t_{\mathrm{Ag}})/2}\,.$$

We obtain $k=11.57\,\mu\mathrm{V\cdot deg^{-1}}$ and $c=1.558\times10^{-3}\,\mu\mathrm{V\cdot deg^{-2}}$, from the characteristics of one of the standard thermocouples given in Table II shown later on. Hence, we have

$$T_{\mathrm{Au}}-T=t_{\mathrm{Au}}-t=(e_{\mathrm{Au}}-e_t)\times0.0853 \tag{11}$$

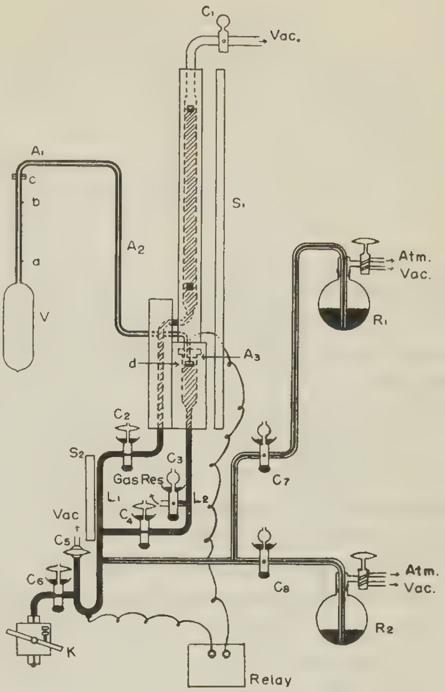

Fig. 1. The constant volume gas thermometer.

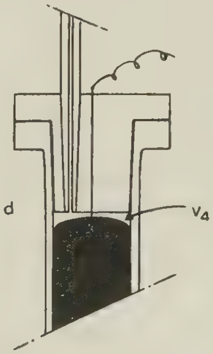

Fig. 2. Top portion of the lower tube of the manometer.

or

$$T_{\mathrm{Ag}}-T=t_{\mathrm{Ag}}-t=(e_{\mathrm{Ag}}-e_t)\times0.0876 \tag{12}$$

for a temperature near the gold or silver point respectively. Therefore, we can determine the values of the gold and silver points on the thermodynamic temperature scale from the gas-thermometric measurements at temperatures near the gold and silver points respectively.

## § 3. Experimental

### (a) The gas thermometer

The gas thermometer of the constant volume type, with the gas bulb made of silica glass,

Table I. Effect of cooling velocity on the change in volume of silica bulb.

| Method of cooling | Cooling rate (deg/hour) | $p_h$ (atm) | $p_0$ (atm) | $V_0$ (cc) | $V_0'$ (cc) | $\Delta = V_0' - V_0$ (cc) | $\lvert\Delta\rvert$ (%) |
|---|---|---|---|---|---|---|---|
| Natural cooling | 350 | 1 | 1 | 230.250 | 230.309 | +0.059 | 0.026 |
| Slow cooling | 45 | 1 | 1 | 230.113 | 230.114 | +0.001 | <0.001 |
| 〃 | 〃 | 2 | 2/5 | 230.113 | 230.161 | +0.048 | 0.021 |
| 〃 | 〃 | 1 | 1/5 | 151.540 | 151.539 | −0.001 | <0.001 |

is shown diagramatically in Fig. 1. At the mark c, a ground flange joint of 2 cm in diameter, which is pressed hard between two metal plates and the perimeters of which are cemented by Glyptal lacquer, is used to connect the capillary stem of the gas bulb to a soda glass capillary of about 0.3 mm in inner diameter which is connected to the lower tube of the mercury manometer. The whole system was assuredly made leak-proof to retain the mass of gas absolutely constant. In fact the 0°-pressure of the gas in the thermometer remained unchanged for days before the gas bulb was heated at high temperatures.

*The manometer* Top portion of the lower tube of the manometer is shown in Fig. 2. A glass lid with a ground cone joint is used at the top of the manometer. The lid and the manometer are set with flanges, carefully ground and vacuum greased, and perimeters sealed by Glyptal lacquer. The glass capillary is connected to the lid by a ground cone joint and cemented by Glyptal lacquer. Setting of the level of the mercury meniscus was made by electric contact of a platinum needle of 0.3 mm in diameter and 1 mm in length fixed to the lid which was covered with carbon black to make the observation of the meniscus easy. Fine adjustment of the contact was secured by a sensitive relay5).

The manometer tube of about 2 cm in diameter was the one previously used by one of the authors5) and the whole was encased with a series of aluminium tubes of 10 mm in wall thickness with which the temperature difference between the top and the bottom of the mercury column of about 76 cm in the manometer was reduced to about 0.5 deg under the laboratory condition in measuring high temperatures, that being about one half of what a naked column would give. Mean value of readings of mercury thermometers attached to the aluminium casing was taken as the mean temperature of the mercury column. Every thermometer was inserted in a hole drilled in an aluminium knob welded to the casing to read the temperature of the latter. An error of 0.2 deg in the mean temperature of mercury for the pressure determination at about 1 atm pressure will cause an error of 0.05 deg in the temperature of the gold point.

The gas pressure of 1 atm at the gold point was about 155 mmHg at 0°C. The aluminium casing had three holes through which each of the menisci of mercury at 1 atm, 155 mmHg and at the lower level of the manometer could be observed by comparator telescopes. The level of meniscus was observed with an accuracy of 0.005 mm. This error of 0.005 mm in the pressure determination at 0°C would give an error of 0.04 deg in the temperature of the gold point.

*The gas bulb* After heating at high temperatures, the bulb, even carefully annealed in advance, did not always come back to its original volume at 0°C. As it seemed depending on the cooling velocity, this effect was studied on two pure silica glass bulbs to learn what rate of cooling will cause the change in volume of less than 0.001% at 0°C. The result is shown in Table I, where $p_h$ and $p_0$ are the inner pressures of the bulb at about 1060°C and 0°C respectively, and $V_0$ and $V_0'$ are the volumes of the bulb at 0°C before and after heating, measured by weighing mercury filled in vacuum. With the bulb opened to the outer atmosphere, the volume increase was 0.026% by natural cooling in extinct furnace with a cooling rate of about 350 deg per hour, taking 3 hours to cool down to the room temperature. On the other hand, the volume change was negligibly small by slow cooling with a cooling rate of about 45 deg per hour, taking 24 hours to cool down to the room temperature. But with the closed bulb, permanent volume changes were observed even by slow cooling because of the temperature reaching near the softening point of silica glass and the pressure rising higher inside. However, when the gas pressure was made to become about 1 atm at high temperatures, no volume change was observed when cooled down to 0°C at which the inner pressure became about 1/5 atm.

So it was decided to use a silica glass bulb for the gas thermometer with the gas pressure to become about 1 atm at aimed-at temperatures, thus saving the trouble of going into the effect of inner pressure on the volume of the bulb and the evaluation of the pressure coefficient $\mu$ at high temperatures.

In Fig. 1, the gas bulb V made of silica glass with 4.4 cm in outer diameter and 18 cm in length is maintained at 0°C or $t$°C up to the mark a on a capillary stem of 1.0 mm in inner diameter. Its volume $V_{0p}$ at 0°C was

$$V_{0p}=205.725(1+3.7\times10^{-5}p)\text{cc}$$

for the inside pressure of $p$mHg and the outside pressure of 1 atm, with the pressure coefficient $3.7\times10^{-5}$ 1/mHg$=\mu$.

The volume $V_{tp}$ at the temperature $t$°C was

$$V_{tp}=205.725(1+3.7\times10^{-5}\times0.76)$$
$$\times(1+1.68\times10^{-6}t)\text{ cc}$$

for the pressure $p$ in the bulb which is nearly equal to 1 atm and the outside pressure of 1 atm, with the expansion coefficient $1.68\times10^{-6}$ 1/deg$=\lambda$. The expansion coefficient was taken as three times the mean linear expansion coefficient $\beta$ between 0°C and 1000°C, measured by the comparator method for a silica stem of the same quality as the gas bulb, having about 12 cm in length. The measurement was made with a horizontal electric furnace jacketed with water. The result obtained is

$$\beta=(0.56\pm0.02)\times10^{-6}\text{ 1/deg .}$$

This $\beta$-value is in agreement with the value 0.54 by Randall⁶⁾ within experimental error.

*The dead space* The volume of the dead space was divided into four parts in consideration of the temperature distribution at the time of measuring high temperatures:

$v_1$: the volume of the part of the capillary stem of the gas bulb immersed in the furnace (a-b in Fig. 1)

$v_2$: the volume of the rest of the capillary stem of the gas bulb, outside the furnace (b-c in Fig. 1)

$v_3$: the volume of the connecting glass capillary (c-d in Fig. 1)

$v_4$: the volume above the lower meniscus of mercury in the manometer (d in Fig. 1).

$v_1$, $v_2$ and $v_3$ were 0.164 cc, 0.082 cc and 0.459 cc* respectively, measured by mercury substitution.

$v_4$ was determined by the following procedure:
In Fig. 1, after the whole system was evacuated, the stop cocks $C_2, C_3, C_5$ and $C_7$ were closed, and then mercury was introduced into the lower tube of the manometer through the cock $C_8$ from the reservoir $R_2$. After closing the cock $C_8$ and by delicate manipulation of the compressor handle K, which exerts pressure on a piece of rubber tube, the mercury meniscus was adjusted to maintain its maximum height and just to touch the platinum point. Then the cock $C_6$ was closed, and mercury was introduced into $v_4$ and further into the capillary through the cock $C_7$ from the reservoir $R_1$. Thus the volume $v_4$ was obtained from the difference in the mass of mercury in the reservoir $R_1$ before and after this treatment, subtracted by the mass of mercury that occupied the part of the capillary, as

$$v_4=0.421\pm0.002\text{ cc .}$$

If there exists an error of 0.002 cc in determining the volume occupied by the gas, it would cause an error of 0.05 deg in determining the temperature of the gold point.

Let $T_1$, $T_2$, $T_3$ and $T_4$ be the mean temperatures of the gases in $v_1, v_2, v_3$ and $v_4$ at the time of measuring $p_0$, and $T_1', T_2', T_3'$ and $T_4'$ those at $p_t$ respectively. $T_1, T_2, T_3$ and $T_4$ were always equal within 0.5 deg. The temperature $T_1'$ at the part of $v_1$ was determined from the temperature distribution measured by a thermocouple as shown in Fig. 5 (an example at the silver point) as

$$T_1'{}_{\text{Au}}=273+720$$

and

$$T_1'{}_{\text{Ag}}=273+667$$

for the gold and silver points respectively. $T_2'$ was taken as the mean of the temperatures 85°C at the point of 1 cm above the upper surface of the lid of the furnace and 35°C at the point of the mark c, that is,

$$T_2'=273+60.$$

$T_3'$ was determined from the mean of the three temperatures measured by mercury thermometers placed at the points $A_1, A_2$ and

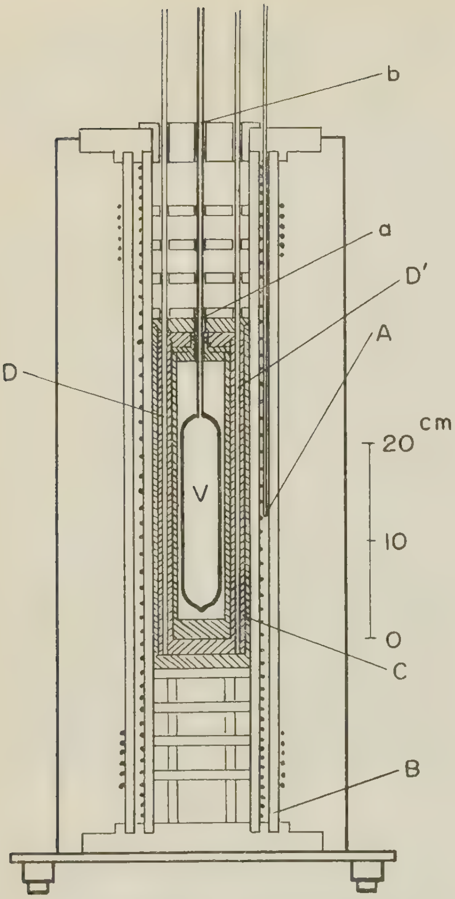

Fig. 3. The high temperature thermostat.

$A_3$ in Fig. 1, the last of which gave $T_4'$.

It would cause only an error less than 0.01 deg in the determination of the gold point, even if the mean temperature $T_m$ of $T_1$, $T_2$, $T_3$ and $T_4$ were used for the respective temperatures, ignoring the difference which was less than 0.5 deg if any.

On the other hand, an error of 30 deg in $T_1'$, 10 deg in $T_2'$ and 1 deg in $T_3'$ would cause an error of 0.04 deg, 0.06 deg and 0.04 deg respectively in the determination of the gold point.

*The gas* As the thermometer gas, nitrogen was used, which was obtained by heating a mixture of saturated solution of $NaNO_2$ and saturated solution of $NH_4Cl$ and purified by the usual method[5)].

The part $L_1L_2$ in Fig. 1 was used as a U-tube manometer to introduce nitrogen gas into the thermometer at pressures of about 155 mmHg and 168 mmHg at 0°C in the measurements of the gold and silver points respectively.

### (b) **The thermostats**

The thermostat for the ice point was the same as used previously by one of the authors[5)].

The thermostat for high temperatures, designed so as to have a constant and uniform temperature space of 5.5 cm in diameter and 25 cm in length, in which the gas bulb was maintained at a temperature near the gold or silver point, was an electric furnace of Nichrome resistance wire of vertical mounting and is shown in Fig. 3. As the main heating coil, Nichrome wire of 2.5 mm in diameter was wound on a refractory porcelain tube of 10 cm in inner diameter, 1 cm in wall thickness and 70 cm in height, the winding being made more closely toward both ends of the tube than at the center to compensate the cooling effect at the ends. The pitch of the coil was determined so that the heating energy generated at a height $x$ measured from the lower end of the porcelain tube was expressed as the function:

$$H=a+b\left(\frac{2x-L}{L}\right)^2,$$

where $L$ is the length of this tube, and constants $a$ and $b$ are to be determined empirically, by means of trial and error. Around the main coil, another porcelain tube B was mounted coaxially, each end part of which was wound with Nichrome wire of 2.0 mm in diameter used as an independent subsidiary heater.

To secure temperature uniformity in the thermostat space, a pure copper cylinder C of the inner diameter 6.2 cm, the wall thickness 1.3 cm and the height 32 cm with closed bottom and a lid, protected from oxidation with graphite cylinders of 5 mm thickness on both surfaces inside and outside and with graphite plates of 15 mm thickness at the top and the bottom, was set in contact with the inner wall of the porcelain tube of the furnace. Two thermocouple holes D and D' of 8 mm in diameter were bored through the wall of the copper cylinder parallel to its axis for insertion of thermocouple protection tubes made of silica glass. The spaces between the protection tubes and the holes were filled with graphite powder.

After several rewindings of the main heating coil and adjusting the currents flowing through the two independent subsidiary heating coils, the temperature uniformity along the wall of the copper cylinder, observed in the thermocouple holes, was ±0.3 deg as shown in Fig. 4, which was almost the same at both temperatures of the gold and silver points.

To examine the temperature distribution along the axis of the gas bulb, a silica bulb similar to the gas bulb, with a tube of 6 mm in outer diameter instead of the capillary, was set where the gas bulb would be placed. Measurements by a thermocouple inserted into the bulb through the tube showed that the uniformity along the axis was within ±0.1 deg and that the mean temperature in the bulb coincided with that in the thermocouple holes of the wall of the copper cylinder within 0.1 deg. The temperature distribution was also traced (Fig. 5) by moving the thermocouple along the 6 mm tube of the bulb up to the upper surface of the lid of the furnace, and it was used for determining the mean temperature of the part of the dead space $v_1$ between the marks a and b in Fig. 1, assuming that the temperature distribution along the capillary stem of the gas bulb was the same as that along the 6 mm tube. An error of 30 deg in determining the mean temperature at the part would cause an error of 0.04 deg in determining the gold point.

The electric power to the furnace was supplied through an induction transformer of 5 kVA, the output voltage of which was regulated automatically at 100±0.2 volts.

Using a standard thermocouple A, as a temperature indicator, inserted in the furnace between the main heating coil and the outer porcelain tube B, and by means of a simple temperature control device as shown in Fig. 6, the temperature of the thermostat was maintained constant within ±0.1 deg with the "on-off ripple" of about ±0.02 deg for a long duration of time.

The temperature of the thermostat was determined by taking a slight correction in the measurements by two standard thermocouples in silica protection tubes of 6 mm diameter, inserted in the thermometer holes of the wall of the copper cylinder.

### (c) The standard thermocouples

Before and after each set of gas-thermometric measurements, the standard thermocouples, made of platinum to 90 platinum-10 rhodium, were calibrated at the gold or silver point. For the calibration, standard metals, 1600 g gold of 99.998% and 900 g silver of 99.994% in purity, were used, which were melted in crucibles of 3 cm in inner diameter, 1 cm in wall thickness and 15 cm in depth, made of pure artificial graphite.

The standard thermocouples had a reproducibility of 0.5 microvolts in emf, determined from their cooling curves at the calibration points. The emf was measured by a Diesselhorst compensator, combined with a galvanometer of a sensitivity of $5\times10^{-8}$ volts/mm. Accuracy of the calibration was the same even when the quantity of gold was reduced to about 1000 g in the same crucible. A result

of calibration, conforming to the definition of the International Temperature Scale in 1948, within the limits admitted for the standard thermocouple, is shown in Table II.

## § 4. The Result of Measurements

The measurements were made in the following order: that is, first the ice point, then the gold or silver point and lastly the ice point again.

The results obtained for the silver and gold points are given in Tables III and IV respectively, in which the value for the silver point, reported preliminary to the Session in 1954 of the Comité Consultatif de Thermométrie under the Comité International des Poids et Mesures[7], was corrected for a part of the dead space.

By the constant volume nitrogen gas-thermometer at $p_0=167$ mmHg, the Kelvin temperature of the thermostat at a temperature near the silver point was obtained by Equation (6), taking $T_0=273.150$, $T_{v0}=272.99$, and $F_t=0.999606$ by Equation (8). Finally, the thermodynamic temperature of the silver point was obtained by Equation (12).

In the measurements at the gold point, $F_t=0.999624$ and $0.999633$, obtained by Equation (7), were used for $p_0=158$ and 154 mmHg respectively.

If the gas did not at all diffuse through the walls of the gas bulb at any temperature, there would be no difference between 0°-pressures $p_{0i}$ and $p_{0f}$ taken before and after the measurements at high temperatures. It is known that nitrogen gas diffuses through silica wall at high temperatures when there exists a difference in partial pressure of the gas at both sides of the wall. It was, however, found that the diffusivity became smaller after the gas bulb was maintained at high temperatures for many hours and increased gradually after the lapse of time at a room temperature.

The result of experiments showed that $\Delta p$

$=p_{0f}-p_{0i}$, which was 0.2 mmHg with previous heating of the bulb at a high temperature for one day, was reduced to about 0.03 mmHg when the heating was continued for two or three days. So, the measurements were taken after heating the bulb for a few days and $p_0=\frac{1}{2}(p_{0i}+p_{0f})$ was used as 0°-pressure in calculation.

## § 5. Discussion of the Result

Errors estimated in the value of the gold point, which might have been affected by the random error involved in every related experimental quantity, are listed in Table V.

In a single set of measurements, the value of the gold point would have been affected by 0.1 deg or less by the random errors in the measurements as shown in Table V.

In addition to the above random errors, the items which would have involved systematic errors in the value of the gold point should be considered. They are shown in Table VI. But, in general, it is difficult to estimate reasonably their amounts of error.

An important subject to be discussed is that the gas becomes impure by diffusion through the walls of the bulb from the outer atmosphere when the bulb is kept at high temperatures. As the bulb was surrounded by graphite, it is likely that the outer atmospheres of the bulb were mainly nitrogen and carbon dioxide. Hence, the pressure increase 0.4 mmHg in the 0°-pressure of 154 mmHg in the whole course of the experiments would have been mostly contributed by carbon dioxide. Error in the correction for the gas imperfection caused by intermixing of a small quantity of a different gas can be estimated by Equation (5).

For carbon dioxide, $B_0$ was measured previously by one of the authors[8], giving $B_0=-0.00921$ 1/mHg. $B_r$-values were measured at high temperatures up to 600°C and expressed analytically as a function of temperature by MacCormack and Schneider[9]. We find $B_{t_{\text{Au}}}=0.00121$ 1/mHg for the gold point by extrapolating the formula.

In the measurements in which impure nitrogen was used as the thermometric gas, the temperature obtained might not be true when $B_0$- and $B_t$-values for pure nitrogen are taken in the correction factor for the gas imperfection. Now if the impure gas consists of pure nitrogen of 0°-pressure $p_0$ and carbon dioxide of $p_0'$ as the impurity, $B_t$-value for impure nitrogen may be taken approximately as

$$(B_t)_{\text{impure N}_2}=\frac{1}{p_0+p_0'}\,[p_0(B_t)_{\text{N}_2}+p_0'(B_t)_{\text{CO}_2}]$$

for the temperature $t$. Supposing that the pressure increase of 0.4 mmHg were all by carbon dioxide and substituting $B_0$- and $B_{t_{\text{Au}}}$-values mentioned above for nitrogen and carbon dioxide in the above equation, we have

$$(B_0)_{\text{impure N}_2}=-60.9\times10^{-5}\ 1/\text{mHg}$$

and

$$(B_{t_{\text{Au}}})_{\text{impure N}_2}=179.5\times10^{-5}\ 1/\text{mHg}\ ,$$

$B_0$ being affected by 3.7% and $B_{t_{\text{Au}}}$ little affected by the impurity, the former affecting the value of the gold point by 0.004 deg. So, the gas impurity produced by the diffusion of gas through the walls of the gas bulb will result no appreciable error in the value of the gold point in the present experiment.

The next subject to be discussed is on the inequality of the gas quantity in the measurements at the ice point and the gold or silver point. In raising and lowering the temperature to and from the gold or silver point respectively, if nearly equal hours are taken at the temperature region at which gases would diffuse through the walls of the gas bulb, such being the case with the present experiment, it may be considered that the quantity of the gas was the same at the ice and gold or silver points in case $p_0=\frac{1}{2}(p_{0i}+p_{0f})$ was taken as the 0°-pressure in calculation. But the value of the gold point would be affected by about 0.13 deg, if $p_{0i}$ or $p_{0f}$ was used singly in place of $p_0$ in calculation.

Although the mean values of the gold and silver points on the thermodynamic temperature scale were obtained with the standard deviation of 0.016 and 0.038 deg respectively, by taking into consideration that some independent systematic errors might have been involved in the measurements as discussed above, we take the temperatures of the gold and silver points, which were adopted as 1063.0°C and 960.8°C respectively on the International Temperature Scale in 1948, as

$$T_{\text{Au}}=1336.84\pm0.05\,^\circ\text{K},\quad t_{\text{Au}}=1063.69\pm0.05\,^\circ\text{C}$$

and

$$T_{\text{Ag}}=1234.43\pm0.05\,^\circ\text{K},\quad t_{\text{Ag}}=961.28\pm0.05\,^\circ\text{C}$$

respectively.

Several investigations on the gold and silver points had been made in the early period of development of the gas thermometry. The most precise ones are those by Holborn and Day in 1901⁽¹⁾ and Day and Sosman in 1910⁽²⁾, the results of which are listed in Table VII with the present authors'.

Table VII. The gold and silver points by the authoritative workers and the present authors.

| Author | Year | $t_{Au}$ | $t_{Ag}$ |
|---|---|---|---|
| Holborn and Day | 1901 | 1063.5 | 961.5 |
| Day and Sosman | 1910 | 1062.4 | 960.0 |
| The present authors | 1955 | 1063.69 | 961.28 |

Accuracy was ±0.8 deg in the measurements by Day and Sosman, and also perhaps the same in those by Holborn and Day, while it is ±0.03 deg in the present measurements.

For the high temperature gas-thermometric work, higher accuracy would have been obtainable by using a double walled gas bulb so that the pressure between the walls could be made always equal to that in the bulb by the same gas, provided that the determination of the temperature of the high temperature thermostat, the measurements and corrections were able to be made with higher accuracies in the present work.

## Acknowledgments

Special financial support by the Institute enabled the present work to be completed, for which the authors express their appreciation to President Dr. S. Uchida. A part of the expence was borne by the Grant in Aid for Fundamental Scientific Research from the Ministry of Education. The authors wish to express their hearty thanks to Mr. T. Nemoto, Director of the Japan Electric Association, and Dr. M. Kinoshita who gave them their favourable supports for the completion of this work. They also appreciate to Dr. K. Okada of the Electro-Technical Laboratory in Osaka for his encouragement and valuable suggestions. The authors are indebted to Mr. K. Okabe, President of the Nippon Mining Co. Ltd., and Dr. H. Ishizuka, Director and Chief of the Metallurgy Section, for taking trouble in refining gold and silver, and producing the elements of the standard thermocouple. Crucibles and other graphite articles were all made at and contributed by the Nippon Carbon Co. Ltd., for which the authors express their appreciation to Mr. A. Kikkawa, Vice-President. The authors are also indebted to Dr. T. Aoki of the Electro-Technical Laboratory for his kind cooperation in calibrating the Diesselhorst compensator.

# Statistical Study of Electron Avalanches in Gaseous Discharge

By Shoji KOJIMA and Kiyoe KATO

*Faculty of Science, Tokyo University of Education, Otsuka, Tokyo*

(Received October 28, 1955)

Size distributions of electron avalanches were observed at a potential several percent below the breakdown value. The distributions at low pressure discharge agreed well with Wijsman's formula which was derived from the Townsend theory in the absence of space charge effect. The distributions at atmospheric pressure, however, are different from this formula in that the pulses had a tendency to become uniform in size. This tendency was accounted by the space charge effect. In connection with these mesurement the pulses of corona discharges were also measured.

## § 1. Introduction

As a method to study the breakdown process the measurements of the formative time lag have been performed by many authors[1][2][3]. A study of electron avalanches which are observed at a potential several percent below the breakdown value is also valuable as another method to attack the problem.

In the view of the Townsend mechanism the distribution of pulses in gaseous discharge, each of which was due to an electron avalanche, was studied theoretically by Wijsman[4]. The probability that an electron started from the cathode has grown to an avalanche of $n$ electrons was expressed by

$$p(n)=(1/\bar{n})\exp(-n/\bar{n}) , \qquad (1)$$

in which

$$\bar{n}=\exp\int_0^d \alpha dx , \qquad (2)$$

where $d$ was the gap length and $\alpha$ was Townsend's first ionization coefficient. Recently Legler obtained the same formula using another method[5]. Lacking suitable experimental data he compared the theory with the measurement which was carried out on a proportional counter by Curran, Cockroft and Angus[6]. We intended to give a more detailed measurement for pulse distribution in low pressure discharges where the Townsend mechanism seemed to be valid, and to extend the measurement to atmospheric pressure where the discharge might rather support the streamer mechanism than the Townsend one. Furthermore, experiments on corona discharge were carried out.

## § 2. Method of Measurement

The pluse caused by an electron avalanche was amplified by an audio-frequency amplifier of four stages whose gain was about 100 db. The output of the amplifier was put into a discriminator of a counting device. The shape of the pulse was simultaneously observed by an oscilloscope. The diagrams of the input circuits are shown in Fig. 1. The connection $a$, by which the voltage pulse was taken up, was used mainly at low applied voltage. On the other hand the connection $b$, by which the current pulse was picked up, was used mainly at high applied voltage. Either of the connections, however, gave the same result for the same applied voltage.

Measurements were carried out in the following way. At first the applied voltage was gradualy increased until a breakdown occurred, and then the voltage was fixed at a potential several percent below the breakdown value. At this condition sufficient number of pulses were not observed except the cases of atmospheric

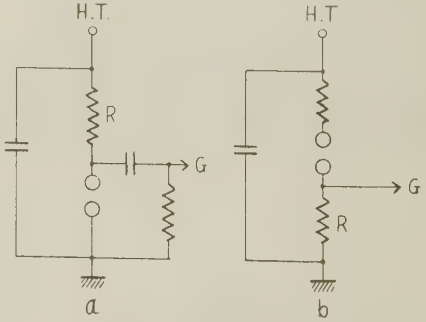

Fig. 1. Input circuits. ($a$) $R$=20 MΩ ($b$) $R$=50 KΩ $G$: Grid of the first tube.

pressure. Therefore the cathode was irradiated by visible rays or ultraviolet rays.

Since the pulse was detected by the discriminator, the height of the pulse alone was observed. From the observed pulse height, $V$, the number of electron in the avalanche was estimated by the formula.

$$n=\frac{1}{R}\frac{V}{G}\frac{\tau}{e} \qquad (3)$$

where $R$ was the series resistance shown in Fig. 1, $G$ the gain of amplifier, $e$ the electronic charge and $\tau$ the obsreved duration of the pulse. Although the formative time of avalanche should be very small, the observed duration of the pulse was about $10^{-4}$ sec., which was mainly due to the time constant of the input circuit and to the band width of the amplifier. The numbers of electrons calculated from Eq. (3) had an error which came from the rough estimation of $\tau$. This error, however, did not affect upon the study of distribution where the relative values were important.

The reading of the counting device gives integrated number of avalanches which are larger than a cirtain value. From Eq. (1), the integrated value of avalanches larger than $n$ electrons, $\nu(n)$, is expressed by

$$\nu(n)=\nu_0 \exp(-n/\bar{n}) , \qquad (4)$$

where $\nu_0$ is the number of electrons emitted from the cathode in unit time. Eq. (4) indicates that the semi-logarithmic plots of $\nu(n)$ give linear form. Therefore the measured results were plotted in a semi-logarithmic diagram.

In order to extend the experiment to atmospheric pressure a power source of several thousands volts with high stability was required. The stabilization was achieved with the discharge tubes made by Gosho*, by which the fluctuation of the voltage could be reduced below 2 volts.

## § 3. Experimental Results

### (*a*) *Uniform field at low pressure* ($pd$=6 mmHgmm)

Two discharge tubes, of which electrodes were made of aluminum disk of diameter of 3 cm, were used. One of the tubes, $A$, had a gap length of 5 mm and was filled with air at 1.2 mmHg. The other tube, $B$, had a gap length of 20 mm and was filled with air at 0.3 mmHg. So that $pd$'s of both tubes were 6 mmHgmm. One of the results of the experiment with the tube $A$ was shown in Fig. 2. The distributions of avalanches were always linear. This result agrees well with Wijsman's formula (4). The intersecting points between the lines and the ordinate axis give $\nu_0$'s, which are almost independent of the applied voltage. The average sizes of the avalanches, $\bar{n}$, which were determined from the increment of the lines are shown in Fig. 3.

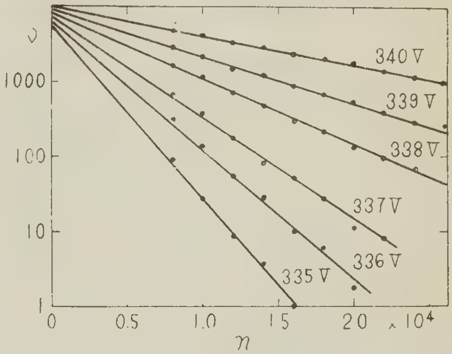

Fig. 2. Pulse size distribution at low pressure. ($p$=1.2 mm Hg air, $d$=5 mm, breakdown potential=311 V.) $n$ is the number of electrons in the avalanche, ν is the number of occurrence per minute of avalanches, which contain more than $n$ electrons, Figures on the line are the applied voltages.

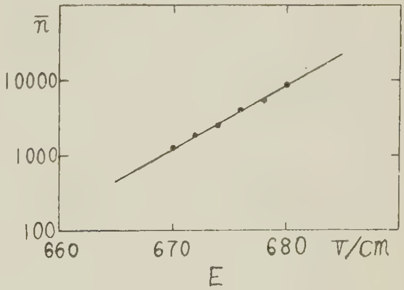

Fig. 3. Average sizes of the avalanches, $\bar{n}$, *vs* applied field $E$.

Townsend's ionization coefficient, $\alpha$, which was calculated by the aid of Eq. (2), was 15 at $p$=1.2 mmHg and $E$=670 V/cm or 4.3 at $p$=0.3 mmHg and $E$=219.75 V/cm. These values seem to be in reasonable order. More precise discussion, however, is not adequate because of rough determination of the pressure and the time of duration.

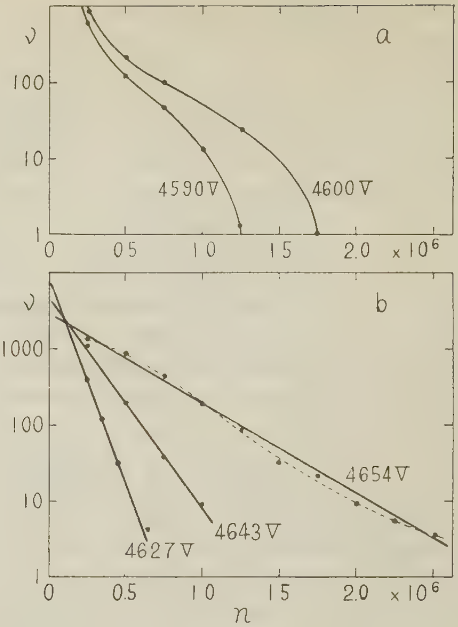

Fig. 6. Pulse size distributions ($p$=760 mmHg air, $d$=1 mm).

### ($b$) *Uniform field at* 300 mmHg

Two discharge tubes of same size were prepared, having the disk electrodes of 3 cm diameter and the 1 mm gap length. The electrodes of both tubes were made of graphite. One of the tubes was filled with air at 300 mmHg and the other with chlorine at the same pressure. The semi-logarithmic plots of the observed points were linear for both tubes. The result for the tube filled with chlorine is shown in Fig. 4.

### ($c$) *Uniform field at atmospheric pressure*

With sphere to plane gaps, pulse distributions were studied at various gap lengthes. The anode was a sphere of diameter of 4 cm, the cathode was a disk of 6 cm and the gap length was varied between 2.5 mm and 0.2 mm. The observed typical distributions are shown in Fig. 5. These distributions were plainly different from the cases of low pressure in such a way that larger pulses occurred less frequently.

With the same graphite electrodes which were used in the experiment at 300 mmHg, pulse distributions were also studied at atmospheric pressure. One of the observations yielded a curved distribution as shown in Fig. 6 $a$. Another observation, which was carried out several days later, yielded almost linear character as shown in Fig. 6 $b$, although this distribution slightly deviated from a line and a few pulses of very large sizes were observed, as the case of the positive corona which will be mentioned below. (*cf.* Fig. 8 $b$) Consequently, there were two types of distributions: the curved distribution and the nearly linear distribution. When the curved distributions were seen, the voltage region

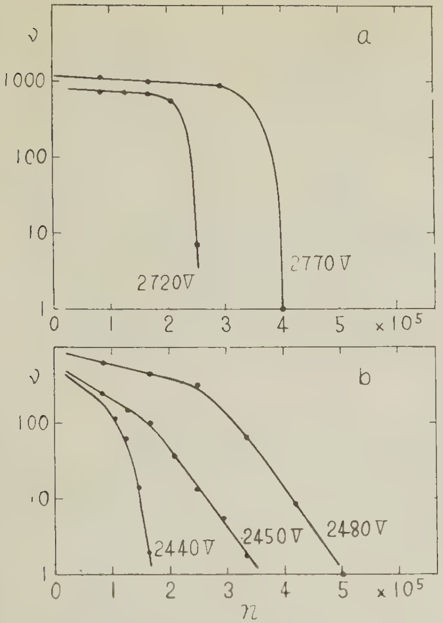

Fig. 7. Pulse size distribution with needle to plane gap (negative needle). (*a*) Gap length=5 mm, breakdown potential=3000 V. (*b*) Gap length=2.5 mm, breakdown potential=2500 V.

between the pulse on-set potential* and the breakdown potential was larger than when the nearly linear distributions were observed.

What condition did yield these different distributions? We tested surface condition with metal sphere electrodes. When the surface of the anode was rough and the surface of cathode was smooth, the nearly linear distributions were more often observed. On the contrary, the opposite condition gave more frequently the curved distributions.

(*d*) *Non-uniform field*

Size distributions of pulses at pre-breakdown were studied with needle to plane gaps. When the needle was negative, the distribution was curved as shown in Fig. 7. The fact that this distribution was like as the distribution in uniform field at atmospheric pressure might give an interpretation that the observed pulses in sphere gaps were due to corona pulses. But the differences in the breakdown potentials and in the size of avalanches seem to make this interpretation unlikely.

When the needle was positive, the distributions are shown in Fig. 8. The curve shown in Fig. 8*a* seemed to consist of two parts. One was represented by a inclined line which gave a continuous distribution and the other

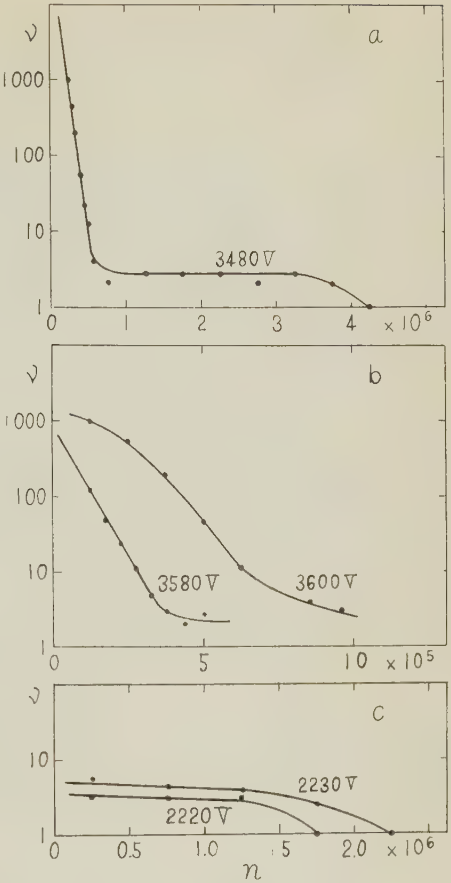

Fig. 8. Pulse size distribution with needle to plane gap (positive needle). (*a*) Gap length=5 mm, breakdown potential=3700 V. (*b*) Same as *a*, but this shows a part of small size pulses as analysed at higher amplifier gain. (*c*) Gap length=1 mm, breakdown potential=2250 V.

was represented by a horizontal line which gave a line spectrum. The curves shown in Fig. 8*c* lacked the continuous part. It seemed to be due to the smallness of pulses.

## § 4. Discussion and Conclusion

At the low pressure discharges where the Townsend mechanism is valid the measured distributions were linear and agreed well with Wijsman's formula. At atmospheric pressure the measured distributions showed a saturation character such that the number of large pulses were depressed. It suggests that the pulses at large *pd* have a tendency to become more uniform in size.

---

* The pulse on-set potential means the potential, above which the pulses are observed with the present amplifire. This potential depends on the apparatus and is not so definite as the breakdown potential.

The decrease of the large pulses might be explained by the attachment of the electron on a neutral atom, by which the ionization power of the electron is lost. The experiment of the avalanches in chlorine gas, however, makes this mechanism implausible.

To electron avalanches at atmospheric pressure the space charge effect has been introduced by many authors[1)7)8)]. In the theory of time lags of spark breakdown Fletcher estimated the number of electrons at which the space charge first became important, and gave it the value of the order of $10^4$ electrons from the observed time lags. The sizes of avalanches observed in the present experiment are greater than this order. It is plausible that the space charge effect accounts for the saturation character and the tendency to make uniform pulses. This mechanism is supported by a strong saturation character of the pulses of the negative corona, where the space charge effect is predominant because of its geometry.

The largest sizes of the avalanches at atmospheric pressure were about $2.5 \times 10^6$ electrons for sphere gap of 2.2 mm, and $5 \times 10^5$ electrons for negative needle-plane gap of 2.5 mm.

In the above discussion on the space charge effect we have assumed that the observed pulses were due to a single avalanche. This assumption seems to be reasonable under the condition that the applied potential is considerably below the breakdown potential*. Indeed, it is known that the negative corona gives rise to a self-quenching Geiger discharge where the single pulse contains successive avalanches[9)11)]. The mechanism of self-quenching due to space charge[10)11)] probably gives a uniform distribution in size. In our experiment, when the applied potential was increased, such pulses were observed, although these pulses were much larger than the pulses treated in this paper. The plane gaps at atmospheric pressure exhibit another type of distribution, as shown in Fig. 6 *b*. This was nearly linear distribution accompanying a small number of the large pulses, and this was observed mainly when the surface of the anode was rough. It is interesting to compare this distribution with that of the positive needle to plane gaps. The latter distribution indicated that it consisted of a line spectrum and a continuous spectrum expressed in a nearly linear curve. This result alone might be insufficient to give a definite interpretation on the mechanism. However, by several reasons it seems to be plausible that the large uniform pulses of the line spectrum are due to the streamer mechanism and that the pulses belonging to the continuous spectrum is caused by the avalanches started from intermediate space between the electrodes. In view of the interpretation of this distribution the nearly linear distribution in the case of uniform field are also attributed to the avalanches started from the intermediate space in addition to the avalanches from the cathode. When the all avalanches started from the cathode, the curved distribution as shown in Fig. 6 *a* will be seen. A few pulses of the large sizes which were observed on the side of the nearly linear distribution seem to be due to the streamer mechanism.

The authors wish to thank Prof. Honda of Tokyo University for valuable discussions. Also, the authors are indebted to Mr. Kono who prepared the discharge tubes. This work was partially supported by the Scientific Research Expenditure of the Ministry of Education.

## Ferromagnetic Resonance Absorption in a Pyrrhotite Single Crystal

By Tadao FUJIMURA and Yosiharu TORIZUKA
*Research Institute for Scientific Measurements, Tohoku University, Sendai, Japan*

(Received Sept. 17, 1955)

Pyrrhotite is an iron sulfide in which the sulfur content is slightly greater than in the stoichiometric compound FeS, and its chemical formula is written as $FeS_{1+x}$. The spontaneous magnetization of Pyrrhotite was first explained by K. Yosida1) on the basis of ferrimagnetism which is composed of magnetic ions $Fe^{2+}$ and $Fe^{3+}$.

The Pyrrhotite single crystal used in this experiment is the same as that studied by Kaya and Miyahara2). We performed a resonance experiment on a disk-formed specimen at a frequency of 47,000 Mc/sec at room temperature.

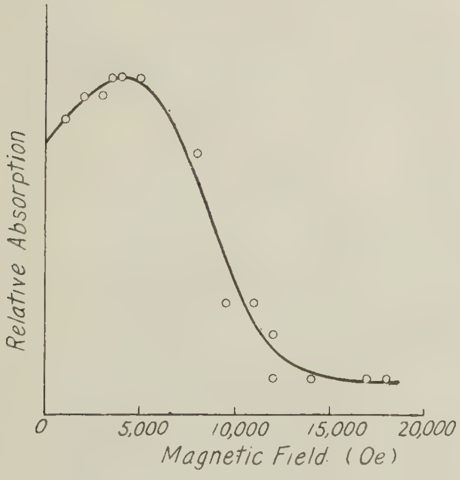

Fig. 1. Absorption curve of Pyrrhotite at 47,000 Mc/sec in the direction of easy magnetization.

The crystal was cut at a plane containing the hexagonal axis (the direction of difficult magnetization) into a diskformed specimen, which was mounted on the bottom of the resonant cavity so as to make the above plane consistent with the direction of both the *rf* magnetic field and the static magnetic field. When the crystal is rotated in the direction of easy magnetization (perpendicular to the hexagonal axis) parallel to the static magnetic field, we can observe the resonance absorption as shown in Fig. 1.

The absorption line width is about 10,000 Oe, and this width is extremely large as that obtained using single crystals in other ferromagnetic resonance absorption experiments.

When the crystal is rotated by more than 10 degrees from the above direction, the resonance absorption disappears in the presently available range of magnetic field, $0\sim2\times10^4$ Oe, and this disappearing may be due to a large magnetic anisotropy energy in Pyrrhotite.

The extremely broad absorption line cannot be explained by magnetic interaction in the ferroing magnetic. Néel suggested, referring to R. Pauthonet's experimental results, that Pyrrhotite might be composed of microcrystals, causing the broadening of absorption line3).

In the experiment using disk specimen containing the plane of easy magnetization showed the similar absorption as shown in Fig. 1, but we could not detect the variation of resonance field in the easy plane.

Neglecting any ordinary demagnetizing effects, because of the low saturation value for Pyrrhotite, and anisotropyenergy within the basal plane, then the Kittel's resonance formula4)5) for directions in the basal plane of hexagonal crystals is given by

$$(\omega/\gamma)^2 = H_{app}(H_{app}+H_A), \qquad (1)$$

were $\gamma = ge/2mc$
$H_{app}$ = applied magnetic field
$H_A$ = anisotropic field

Pyrrhotite has come to be known through the study of the gyromagnetic ratio by Coeterier3) yielding the extraordinary value $g=0.67$. But it is difficult to recognize this value from the composed magnetic ions and total magnetic moments in Pyrrhotite. The deviation of $g$-factor from 2 which corresponds to spin only would be small, so we may assume $g=2$ in Pyrrhotite.

When we taken $H=4\times10^3$ Oe, equation (1) gives the value of anisotropy energy as $H_A=6.6\times10^4$ Oe.

# Variation of the Young's Modulus of the Alloy $Mg_3Cd$ with the Order-Disorder Transition

By Kayako TANAKA, Hidetaro ABE
*Department of Physics, Faculty of Science Ochanomizu University, Tokyo*
and Hideyo MANIWA
*Department of Physics Tokyo Institute of Technology, Tokyo*

(Received Sept. 20, 1955)

The order-dependent changes of Young's modulus of the alloy $Mg_3Cd$ with temperature and with time at various annealing temperatures below the transition point are obtained by measuring the change of resonant frequency of forced longitudinal vibration applied to the polycrystalline rod of dimensions, 1.12 cm in diameter and 13.25 cm in length.

The curve, ***ABC***, in Fig. 1 is obtained upon heating the specimen in the perfect ordered state at the rate of 1°C/min. Point ***D*** showing the equal as-quenched value from both 200°C and 400°C, falls on the extrapolation of the line ***CB***. Then, it is clearly observed that the value of Young's modulus, $E$, decreases continuously from room temperature to 160°C as a consequence of the gradual evanescence of equilibrium long-range order. The $dE/dT$ curve, also shown in Fig. 1, is very similar to the specific heat and the expansion coefficient versus temperature curves1)-3). Moreover, it seems that in conformance with other measurements the order-disorder transition in this alloy is of the second-order, since a discontinuous change cannot be detected at the transition point, $T_c$,1)-3) which corresponds to 160°C.4)

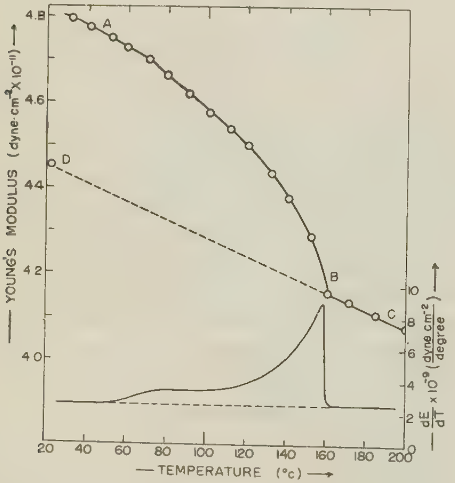

Fig. 1. The Temperature Variation of Young's Modulus.

The isothermal variation of $E$ with time, accompanied by the ordering process, is shown in Fig. 2 and indicates that the equilibrium order is achieved in monotonous way of increase. The variation is obtained as follows: After quenching from 200°C into water, the specimen is annealed at the various temperatures below $T_c$ and the measurements are made at room temperature by re-quenching into water from those annealing temperatures. Let $\tau_h$ denote the time required, at an absolute temperature $T$ °K, for attaining the half value of the equilibrium state. Then, the linear relationship between $\log_e \tau_h$ and $1/T$ is observed in Fig. 3. The upward deviation at above 100°C may be attributed partly to the too much shortness of $\tau_h$ to be measured with proper accuracy. The activation energy for the ordering process determined from the linear relationship is 19.5 Kcal/mol.

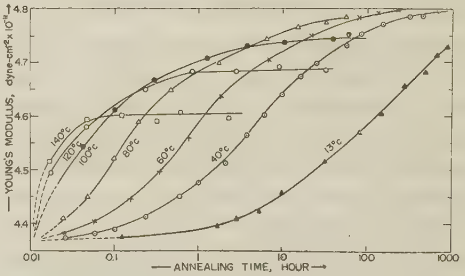

Fig. 2. The Isothermal Variation of Young's Modulus with Time at Various Temperatures.

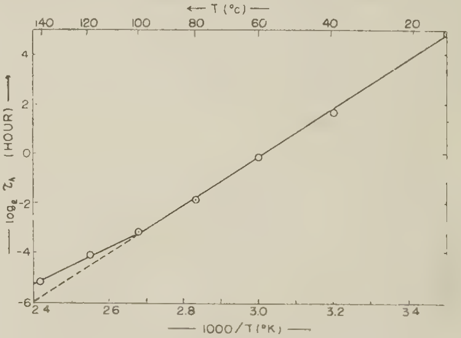

Fig. 3. The Temperature Variation of the Rate of Ordering, $\tau_h$.

On the temperature dependence of the internal friction, determined from the half value width of the resonant frequency curve, a distinct change depending on the order-disorder transition is not detected.

Together with results on MgCd, pure Mg and pure Cd, full report will be published later in the Nat. Sci. Rept. of the Ochanomizu University.

## Graphical Solution of Linear Heat Flow with Radiation

By Mashige NAGAI

*Matsuda Research Laboratory,*
*Tokyo Sibaura Electric Co. Kawasaki, Japan*

(Received December 13, 1955)

It is well known that differential equation of the linear heat flow with surface radiation which determines the temperature distribution on a uniform wire or plate is

$$\frac{d^2\theta}{dx^2}=-\frac{A\varepsilon\sigma}{J\kappa S}\left(\frac{q}{A\varepsilon\sigma}+\theta_0{}^4\right)-\frac{A\varepsilon\sigma}{J\kappa S}\theta^4\,, \qquad (1)$$

where

$\theta$: the absolute temperature of the wire (deg.)
$x$: the distance along the wire (cm.)
$A$: the surface area of the wire per unit length (cm)
$\varepsilon$: the emissivity of the wire
$\sigma$: the Stefan-Boltzmann constant (Joule./cm$^2$, sec, deg$^4$)
$J$: the mechanical equivalent of heat (Jonle/cal.)
$\kappa$: the conductivity of the wire (cal./cm, sec, deg.)
$S$: the sectional area of the wire (cm$^2$)
$q$: the heat yield per unit length (Joule/cm, sec.)
$\theta$: the ambient temperature (deg.)

It has been considered that tedious calculations are inevitable to obtain a numerical solution of this equation whose analytical solution probably can not be expressed in terms of elementary functions.[1] But in the following way, the general solutions of this equation are given by an array of curves in a graph and one can immediately obtain temperature distributions corresponding to various conditions.

For simplicity we assume that only variables are $\theta$ and $x$, others being constant. Furthermore we put the constant terms as follows

$$q/A\varepsilon\sigma+\theta_0{}^4=t^4 \qquad (2)$$

$$A\varepsilon\sigma/J\kappa S=a \qquad (3)$$

then Eq. (1) becomes

$$d^2\theta/dx^2=-at^4+a\theta^4. \qquad (4)$$

This can be further normalized using new dimensionless variables:

$$\eta=\theta/t \qquad (5)$$

$$\xi=x/\sqrt{5/2at^3} \qquad (6)$$

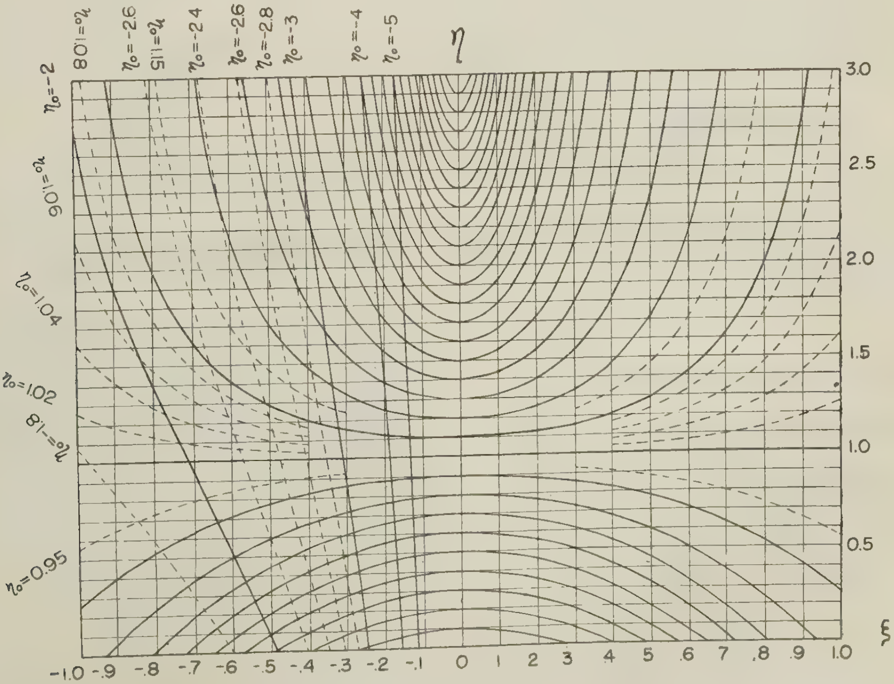

Fig. 1.

which reduce Eq. (4) to

$$d^2\eta/d\xi^2=5/2(\eta^4-1) \tag{7}$$

Integration of Eq. (7) gives

$$(d\eta/d\xi)^2=\eta^5-5\eta-C\,, \tag{8}$$

where $C$ is an integration constant.

The result obtained by direct integration of Eq. (8) includes two integration constants, requiring two paramaters in the graphical representation of the solution. Fortunately the origin of $\xi$, however, can be chosen arbitrarily.

In order to reduce the number of the parameter, let us choose this origin at the extreme value of $\eta$ or the point of

$$d\eta/d\xi=0 \qquad (\xi=0) \tag{9}$$

This requires that the solution of Eq. (8) should always have an extreme value or

$$\eta^5-5\eta-C=0 \tag{10}$$

should have a real root.

This is always true, if we allow $\eta$ to have negative value. From the physical point of view $\eta$ must be positive, but the derivation of the above equations are free from such a limitation. So we can carry out the integration without considering the sign of $\eta$, if only the positive region of $\eta$ is adopted as the final result.

Then let $\eta_0$ be a real root of Eq. (10) so that

$$d\eta/d\xi=0 \quad \text{at} \quad \xi=0 \quad \text{and} \quad \eta=\eta_0\,.$$

From above conditions the solution of Eq. (8) becomes

$$\xi=\pm\int_{\eta_0}^{\eta}\frac{d\eta}{\sqrt{\eta^5-5\eta-(\eta_0^5-5\eta_0)}}\,. \tag{11}$$

The graph shows this integral in the practical range of $\xi$ and $\eta$ with $\eta_0$ taken as a parameter.

# Hydration of Ions and Coordinate Bond

By Isao Oshida and Ohi Horiguchi

*Kobayasi Institute of Physical Research, Kokubunzi, Tokyo*

(Received December 16, 1955)

It has been generally accepted that the energy of hydration of ions is of electrostatic nature, since Born's expression[1] for the decrease $Q$ of electrostatic energy when a sphere with the ionic charge $Ze$ and the ionic radius $r$ enter a medium with dielectric constant $\varepsilon$ from vaccuum

$$Q=\frac{Z^2e}{2r}\left(1-\frac{1}{\varepsilon}\right) \tag{1}$$

serves as the rough measure of the energy of hydration of monatomic ions. Latimer *et al*[2] showed that a better quantitative agreement with experimental values is obtained if we use for $r$ in (1) the effective radius, somewhat larger than the true ionic radius.

We have determined the experimental heats of hydration for about seventy ions from the recent thermochemical data such as heat of formation, heat of solution, heat of sublimation, ionization potential, electron affinity and energy of dissociation of diatomic molecule[3]. The plot of $Q$ against ionic radius do show the general downward trend with the increasing radius (Fig. 1).

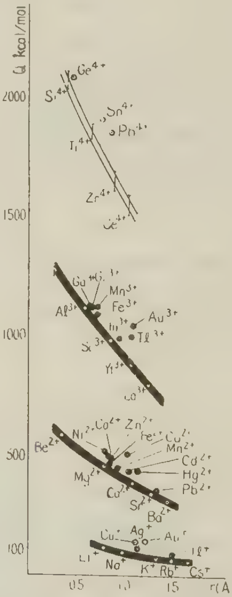

Fig. 1. Hydration-heat *versus* ionic radius (Goldschmidt's crystal radius).

It can be seen from Fig. 1, however, the rare-gas type ions have always smaller energy than the ions with incomplete electronic shell, if we compare the ions of same charge and same radius.

For example, the ions with eighteen-electron shell of each valency lie on the curves about 50 kilocalories higher than the corresponding curves for the rare-gas type ions. This suggests that the hydration results from the *electronic* interaction, rather than the *electric* interaction, between the central ion and the surrounding water molecules.

The study of the ionic hydration of the transition metals can draw a clearer picture in this connection. The heats of hydration of the divalent cation of transition metals plotted against the ionic

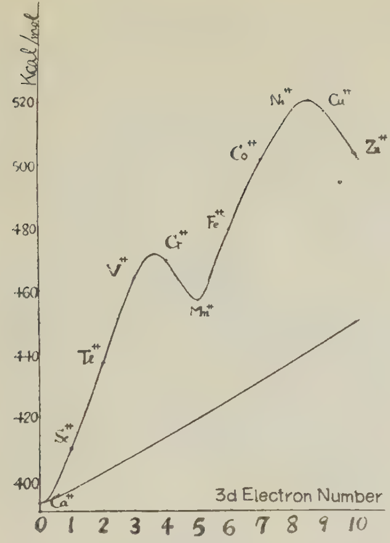

Fig. 2. Hydration-heat of transition metal ion (II). *versus* 3d electron number.

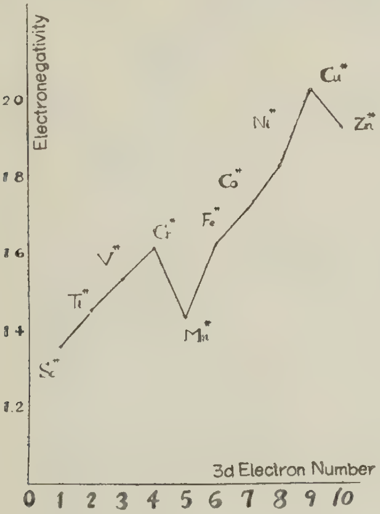

Fig. 3. Electronegativity of transition metal ion (II). *versus* 3d electron number.

radius or the number of 3d electron show two maxima (Fig. 2). On the other hand, the electronegativities of these ions have been known in recent by Haïssinsky[4], and by Ito and Kuroda[5]. Though the latter values are obtained by calculation, they are in very good agreement with Haïssinsky's values empirically induced. The plot of Ito and Kuroda's electronegativity has striking resemblance to Fig. 2, showing that the hydration is proportional to the electronegativity of the central ion (Fig. 3). As for the trivalent ions, though the lack of the data prevents us from deriving a definite conclusion, there seems to exist similar parallelism. Thus we can conclude that in the phenomena of hydration, the formation of coordinate bonds between the central ion and the water molecules plays an important role.

The details will be published elsewhere.

## A Note on the Theory of Dislocation in Germanium

By Takuzo SHINDO

*The Electrical Communication Laboratory*
*Musashinoshi, Tokyo, Japan*

(Received December 19, 1955)

Recently Read[1] has proposed a theory of dislocation in germanium and pointed out that the number of trapped electrons in the dangling bonds is determined by a different statistics from that of Fermi. We have studied the same problem employing the principle of detailed balance and found more general expression for $f$, the fraction of sites that are full in the dangling sites.

To begin with, we shall derive the Nijboer formula from the principle of detailed balance. Let there be $N$ impurity levels and $N_e$ electrons per cm³, of which, at temperature $T$, $n$ are excited. Let $\Delta E$ be the energy required to remove an electron from an impurity level into the conduction band. In thermal equilibrium, the principle of detailed balance requires

$$\left(1-\frac{N_e-n}{N}\right)P_r(E)F(E)\mathfrak{N}(E)dE$$
$$=\frac{N_e-n}{N}P_i(E)\mathfrak{N}(E)dE\,, \qquad (1)$$

where $P_r(E)$ is the recombination probability of the conduction electron of energy $E$ and $P_i(E)$ is the ionization probability of the trapped electron and $\mathfrak{N}(E)$ is the number of energy levels in the conduction band, given by

$$\mathfrak{N}(E)=4\pi(2m^*)^{3/2}h^{-3}V\overline{E}\,,$$

and $F(E)$ is the probability of finding an electron of energy $E$ in the conduction band. Usually the probabilities $P_i(E)$ and $P_r(E)$ are complicated functions depending upon the number of phonons associated with the transitions[2)3)]. But their ratio, $P_i(E)/P_r(E)$, has rather simple form and we have, according to Shockley and Read[4)],

$$P_i(E)/P_r(E)=\exp[-(E+\Delta E)/kT]\,. \qquad (2)$$

On the other hand, in a steady state we may put

$$F(E)=A\cdot\exp(-E/kT),$$

where $A$ is a constant to be determined by the condition:

$$\int_0^\infty F(E)\mathfrak{N}(E)dE=n\,.$$

Thus we obtain

$$A=n/N_c\,,\quad N_c=2(2\pi m^*kT/h^2)^{3/2}\,. \qquad (3)$$

From the Eqs. (1), (2) and (3), we have

$$\frac{n(N-N_c+n)}{N_c-n}=2\left(\frac{2\pi m^*kT}{h^2}\right)^{3/2}\exp(-\Delta E/kT).$$

This is the well known Nijboer's formula.

In the case of dangling bonds in nonpolar crystals $\Delta E$ depends on $f$, as was pointed out by Read, and was shown to be

$$\Delta E=E_2-\varepsilon^*(f)\,,$$

in which $E_2$ is an energy required to remove an electron from a dangling site, when $f=0$, into the conduction band and $\varepsilon^*(f)$ is the work done in forming the space charge cylinder with the line of evenly spaced electrons along its axis. Read has calculated $\varepsilon^*(f)$ in the form

$$\varepsilon^*(f)=\varepsilon_0 f\left(ln\frac{f}{f_0}-0.232\right)\,.$$

Let $N_s$ be the total number of dangling sites per unit volume, of which, at temperature $T$, $n_t$ are filled with electrons, and $n_i$ be the concentration of donor centers, then we have, in place of Eq. (1),

$$\left(1-\frac{n_t}{N_s}\right)P_r(E)F(E)\mathfrak{N}(E)dE=\frac{n_t}{N_s}P_i(E)\mathfrak{N}(E)dE\,. \qquad (4)$$

The Eq. (4) holds in the saturation range, where the donors are completely ionized. In the same way as before we have

$$\frac{f}{(1-f)(1-N_sf/n_i)}=\frac{n_i}{2}\left(\frac{2\pi m^*kT}{h^2}\right)^{-3/2}\exp\{[E_2-\varepsilon^*(f)]/kT\}\,, \qquad (5)$$

where $n_t=N_sf$.

In the low temperature range, where no electrons are excited into the conduction band, we have

$$\frac{f^2}{(1-f)(1-N_sf/n_i)}=\frac{n_i}{N_s}\exp\{[E_2'-\varepsilon^*(f)]/kT\}\,, \qquad (6)$$

where $E_2'$ is an energy difference between the donor level and the dangling level at $f=0$. When the trapped electrons in the dangling sites, $n_t$, are small compared with $n_i$, the Eq. (5) reduces to

$$\frac{f}{1-f}\sim\frac{n_i}{2}\left(\frac{2\pi m^*kT}{h^2}\right)^{-3/2}\exp\{[E_2-\varepsilon^*(f)]/kT\}\,. \qquad (7)$$

The Eq. (7) is identical with Eq. (9.1) of Read.

The author thanks Mr. Y. Uemura for his valuable discussions.

# Electrostatic Deflection of a Cyclotron Ion Beam

By Jun Kokame and Sukeaki Yamashita
*Institute for Chemical Research,*
*University of Kyoto*

(Received December 28, 1955)

Ions accelerated by a cyclotron to the maximum energy are usually extracted by an electrostatic deflector. In this case, it is necessary to know the ion trajectory for designing the deflector, dees and the vacuum chamber, and the design is usually performed by drawing ion paths step-by-step, corresponding to an instantaneous radius of rotation of the ion in the field of the cyclotron magnet and deflecting channel. If the ion trajectory could be represented in the form of an analytical function of $R, \theta$, the tedious procedures of drawing the path could be avoided. Although the remarkable contributions have been made by Coggeshall[1)] about the mathematical analysis of the motion of charged particles in non-uniform crossed electric and magnetic field, and Courant-Bethe[2)] also investigated theoretically an electrostatic deflection of a betatron or synchrotron beam, their works are not immediately available in our case.

The differential equation describing the ion path was investigated and solved using the measured fringing field of the magnet of the Kyoto University cyclotron (pole diameter 42″, beam energy ~16 Mev of deuteron). The following relation was obtained.

$$\frac{d^2R}{d\theta^2}=R-\frac{R^2}{r}\,, \qquad (1)$$

with

$$r=\frac{2E}{e(H\beta-V)}.$$

$R$ and $\theta$ are the radial and azimuthal coordinates of the deflected ion in the median plane of the magnetic field respectively, $r$ the radius of rotation, $E$ the energy of deflected ion in erg, $-e$ the electron charge in e.s.u., $H$ the magnetic field strength in gauss, $V$ the electric field strength in the deflecting channel in e.s.u., $\beta=v/c$ and $v$ is the velocity of the deflected ion. The origin of the coordinate system being fixed at the pole centre of the magnet, the $R-\theta$ relation indicates the deflected ion path. Eq. (1) is more accurate than the equation deduced by Courant and Bethe[2].

Integrating Eq. (1) we obtain

$$\left(\frac{dR}{d\theta}\right)^2\Big|_{R_1}^{R}=(R^2-R_1^2)-2\int_{R_1}^{R}\frac{R^2}{r}dR, \qquad (2)$$

in which

$$\int_{R_1}^{R}\frac{R^2}{r}dR=\frac{e\beta}{2E}\int_{R_1}^{R}HR^2dR-\frac{e}{2E}\int_{R_1}^{R}VR^2dR, \qquad (3)$$

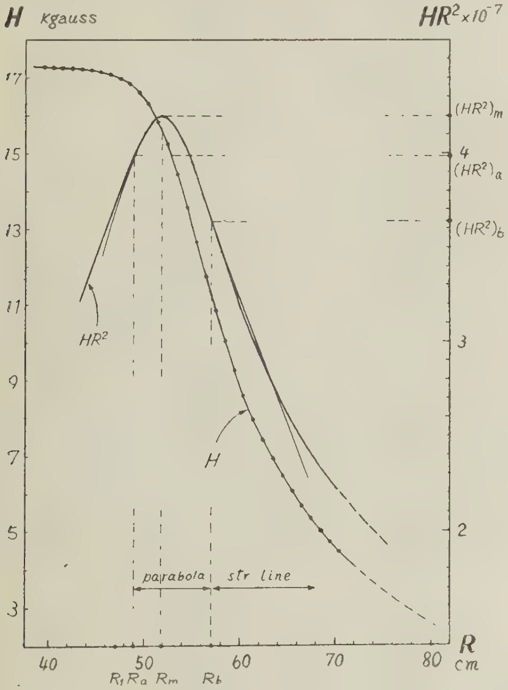

Fig. 1. The magnetic field profile and the curve of $HR^2$.

where $R_1$ is the radius at which the ion enters the deflecting channel. If we assume that $V/H$ is equal to a constant over the whole range in the deflector (this assumption is not so far from the actual condition, of which the minute discussion will be given elsewhere), the second term of the right-hand side of Eq. (3) becomes

$$\frac{e}{2E}\frac{V}{H}\int_{R_1}^{R}HR^2dR. \qquad (4)$$

Then Eq. (2) becomes

$$\left(\frac{dR}{d\theta}\right)^2=\left(\frac{dR}{d\theta}\right)^2_{R_1}+(R^2-R_1^2)-\frac{e}{E}\left(\beta-\frac{V}{H}\right)\int_{R_1}^{R}HR^2dR. \qquad (5)$$

On the other hand, from the measured values of $H$ along the radial direction from the centre, $HR^2$ can be calculated (cf. Fig. 1). The curve of $HR^2$ has a rather simple shape. It is expressed by a parabola in a considerably wide range of $R$ and by a straight line in other part with good accuracy. In the range $R_a(49\text{ cm})\leqq R<R_b(57\text{ cm})$, $HR^2$ is expressed by the formula $HR^2=(HR^2)_m-\alpha(R_m-R)^2$, where $(HR^2)_m$ is the maximum value of $HR^2$ at $R=R_m$, where the $n$-value of the magnetic field is equal to 2 (see Fig. 1); and in the range $R_b\leqq R$, $HR^2=(HR^2)_b-\gamma(R-R_b)$. At large $R$ some deviation from real $HR^2$ occurs, but $H$ is sufficiently small in this range so that there is no practical trouble. In the case when a more accurate path in this range is wanted, it is better to use another curve of the second degree for $HR^2$. If the deflector entrance might be set at so small radius that the deviation of $HR^2$ from the parabola $[(HR^2)_m-\alpha(R_m-R)^2]$ would become a considerable amount, the value of $HR^2$ in the range $R_a>R$ should be represented by another straight line, for in this range the magnetic field is so strong that even a little difference of $HR^2$ exerts an influence on the ion path.

Thus, Eq. (5) can be written in the following form:

$(dR/d\theta)^2=f(R^3, R^2, R)$ in the parabola range (6)

or

$(dR/d\theta)^2=\varphi(R^2, R)$ in the straight line range (7)

Eqs. (6) and (7) can be solved by usual procedure, and $R-\theta$ relation is expressed by elliptic functions and logarithmic functions respectively.

Ion trajectories through the fringing field of the cyclotron obtained from above calculation were compared with those obtained from step-by-step drawing. Good agreements between them were obtained. It seems to be useful to apply the above-mentioned method for designing deflector instead of using tedious drawing process.

The authors wish to express sincere thanks to Prof. K. Kimura for his kind discussion and criticism, and to Assistant Prof. R. Ishiwari for his kind advice and encouragement. We are also indebted to the staff of our laboratory for the data of magnetic field.

## Microwave Spectra of Formaldehyde and Methylamine in the SHF Region

By Hiromasa HIRAKAWA, Akira MIYAHARA and Koichi SHIMODA

*Department of Physics, Faculty of Science, University of Tokyo*

(Received January 14, 1956)

Microwave spectra of formaldehyde and methylamine have been observed in the frequency range from 2700 to 8100 Mc/sec using Stark modulation of 110 Kc/sec. The absorption cell was constructed of 4 meters length of 29×58 mm copper waveguide, with copper Stark septum and polystyrene supports. Klystron oscillators, 2K25, 2K26, 2K22, 2K56, 726A and 726C were used as the microwave source, while silicon diodes 1N23B and 1N21C were used as detectors. The spectrum was displayed on a CRO screen. The accuracy of the frequency measurement is ±0.01 Mc/sec for strong lines, while for very weak lines errors incurred in determining the centre of lines are as much as ±0.5 Mc/sec, being the minimum detectable absorption coefficient around $1\times10^{-8}$ cm$^{-1}$.

Six lines of $C^{12}H_2O^{16}$, three of $C^{13}H_2O^{16}$, and one of $C^{12}H_2O^{18}$ have been measured and they are tabulated in Table I. For $C^{12}H_2O^{16}$, Lawrance and Strandberg[1] analysed the centrifugal distortion effect of this molecule, and determined the molecular constants together with the centrifugal coefficients. Frequencies calculated from their constants agree well to our observations.

Table I. Observed Frequencies of Formaldehyde Spectrum.

| Transition $J_{K_{-1},K_{+1}}$ $\rightarrow J_{K_{-1},K'_{+1}}$ | Observed Frequency (Mc/sec) | Calculated Frequency (Mc/sec) | Intensity |
|---|---|---|---|
| (1) $C^{12}H_2O^{16}$ | | | |
| $1_{1,1}\rightarrow 1_{1,0}$ | 4829.73 | 4829.6 | S |
| $6_{2,5}\rightarrow 6_{2,4}$ | 4954.76 | 4954.62 | S |
| $12_{3,10}\rightarrow 12_{3,9}$ | 3225.58 | 3224.11 | MS |
| $13_{3,11}\rightarrow 13_{3,10}$ | 5136.58 | 5136.12 | S |
| $20_{4,17}\rightarrow 20_{4,16}$ | 3518.85 | 3518.65 | MW |
| $21_{4,18}\rightarrow 21_{4,17}$ | 5138.57 | 5138.50 | W |
| (2) $C^{13}H_2O^{16}$ | | | |
| $1_{1,1}\rightarrow 1_{1,0}$ | 4593.26 | | W |
| $7_{2,6}\rightarrow 7_{2,5}$ | 8012.56 | | W |
| $14_{3,12}\rightarrow 14_{3,11}$ | 6752.31 | | W |
| (3) $C^{12}H_2O^{18}$ | | | |
| $1_{1,1}\rightarrow 1_{1,0}$ | 4388.85 | | WW |

Fourty-four observed lines of methylamine molecule and their Stark patterns are listed in Table II. The classiffcations of the Starkeffects are as follows:

1( i ) or 1( O ): the first order effects with inner or outer components stronger than outer or inner ones.

2(+) or 2(−): the second order effects, with positive or negative Stark shifts.

1→2: Superposition of first and second order effects which are comparable at the field strength of $E\sim50$ V/cm.

Most of these lines could be assigned according to the interpretation already described by Nishikawa et al[2].

## *l*-Type Doubling Spectra of HCN and DCN in the SHF Region

By Akira MIYAHARA, Hiromasa HIRAKAWA and Koichi SHIMODA

*Department of Physics, Faculty of Science, University of Tokyo*

(Received January 14, 1956)

Bending vibration of a linear triatomic molecule such as HCN is peculiarly coupled to rotation of the molecule, and it introduces a splitting of each rotational level known as *l*-type doublets. We have observed three lines of HCN and three lines of DCN, corresponding to the direct transitions between *l*-type doublets, in the frequency ranges between 2600 and 7900 Mc/sec. The same Stark modulation spectrometer of 4 meters long was used as that described in the preceeding note. The observed frequencies of HCN and DCN are given in Table I. These values have been obtained by extrapolating the observed frequencies at various Stark fields to those at zero field, considering that the Stark effects are of the second order. According to Nielsen's theory[1], the *l*-type doubling constant $q(=\nu/J(J+1))$ can be written as

$$q=q_0-\varepsilon J(J+1)\ .$$

Plotting of $\nu/J(J+1)$ from observed values against $J(J+1)$ shows a good linear relation. Using above results together with the observed frequencies of HCN for $J$ from 6 to 12, given by Westerkamp[2], we obtain the *l*-type doubling constant as $q=224.478-0.002667\,J(J+1)$ Mc/sec for HCN. As to the constant for DCN, $q=186.193-0.002197\,J(J+1)$ Mc/sec is obtained from the six observed frequencies, given by Weatherly and Williams[3] and by us.

Table I.

(1) HCN observed frequencies.

| $J$ | $\nu$(Mc/sec) | $q(=\nu/J(J+1))$ | $q=224.478$ $-0.002667\,J(J+1)$ |
|---|---|---|---|
| 3 | 2693.35±0.02 | 224.446 | 224.446 |
| 4 | 4488.50±0.01 | 224.425 | 224.425 |
| 5 | 6731.95±0·01 | 224.398 | 224.398 |

(2) DCN observed frequencies.

| $J$ | $\nu$(Mc/sec) | $q(=\nu/J(J+1))$ | $q=186.193$ $-0.002197\,J(J+1)$ |
|---|---|---|---|
| 4 | 3722.98±0.02 | 186.149 | 186.149 |
| 5 | 5583.85±0.02 | 186.128 | 186.127 |
| 6 | 7816.20±0.02 | 186.100 | 186.101 |

The absorption coefficient $\alpha$, computed from the following values, $\mu=2.96$D, $\nu_2=712\ \text{cm}^{-1}$, $T=290°$K, $\Delta\nu/P=25$ Mc/sec/mmHg, for the $J=3$ line of HCN, is $2\times10^{-7}\text{cm}^{-1}$, which differs from Collier's[4] calculation by about a factor of 7. Our observed intensity of the $J=3$ line seems rather consistent with our calculation. It is also confirmed by the observed ratio of intensity of this line to the lines of formaldehyde molecule.

# On the Ionization-energy Relation for Alpha-particles in Air

By Ryutaro ISHIWARI, Sukeaki YAMASHITA, Kazunori YUASA[*],
*Institute for Chemical Research, University of Kyoto, Kyoto*
and Kozo MIYAKE
*Department of Physics, Faculty of Science, University of Kyoto, Kyoto*

(Received November 25, 1955)

To investigate the effect of columnar recombination on the ionization measurement in air, the ratio of the specific ionizations at two fixed residual ranges for polonium alpha-particles was measured with a shallow ionization chamber under various field strengths and angles between the field and the alpha-track. It was found that the observed ratio varies appreciably with varying field strength and angle. It was shown that the observed variation of the ratio can be explained by the effect of columnar recombination and agrees qualitatively with Jaffé's theory. The value of the parameter $b$ in Jaffé's formula, which gives the best agreement with the experiments, was newly determined as $9.5\times10^{-4}$ for alpha-particles in atmospheric air.

The observed specific ionization curve was corrected for recombination by Jaffé's theory. Then, the corrected curve was integrated and the true ionization-range relation free from recombination was determined. By comparing this relation with the fixed points of the range-energy relation obtained from nuclear reaction data, an empirical formula for the average energy loss per ion pair for alpha-particles in air relative to polonium alpha-particles, $w$, was obtained as;

$$w=0.948+\frac{0.119}{\sqrt{E}}\ ,$$

where $E$ is the initial alpha-energy in Mev. This formula is valid at least for the alpha-energy down to 1 Mev.

## §1. Introduction

For many years, it has been well known that the average energy expended by a heavy charged particle to produce one ion pair in gases is nearly constant and almost independent of the particle energy. The method to determine the particle energy by measuring the total ionization produced by the particle and assuming the proportionality between the total ionization and the energy of the particle, has, therefore, been universally adopted. However, recent progress in accuracy of the experiments in nuclear physics has come to require more precise information on the relationship between $W$, the average energy to produce one ion pair, and the particle energy for different gases and for different types of particles.

Gray[1] has summarized the experimental data up to 1942, and concluded that $W$ for alpha-particle in air depends appreciably upon the particle energy at low energies. More recently Jesse et al.[2][3] performed a series of experiments on the ionization-energy relation for alpha-particles in argon and in air. According to their result, $W$ in argon is constant independently of the particle energy, whereas $W$ in air increases considerably with the decreasing energy. On the basis of this result, Jesse et al.[3] and Bethe[4] have revised the range-energy curve for alpha-particles in air given by Holloway and Livingston[5], which was derived from an experimental range-ionization curve in the energy region below 5 Mev under the assumption of the strict proportionality between the ionization and the particle energy in air. The revised range-energy curve is in satisfactory agreement with the data[6] obtained from some nuclear reactions in which accurate values for energies and ranges of emitted particles have been determined independently from each other.

Recently, nevertheless, some evidences conflicting with the result of Jesse et al. on the ionization-energy relation have been reported by several authors. Cranshaw and Harvey⁷⁾ have measured the total ionizations produced by natural alpha-particles in argon, and obtained such a result that $W$ in argon depends on the energy of alpha-particles. They gave an empirical formula for the relation between $W$ and the particle energy in argon. In succession to this, Hanna⁸⁾, Bichsel, Hälg, Huber and Stebler⁹⁾, and Rhodes, Franzen and Stephens¹⁰⁾ have measured the total ionization of the $B^{10}(n, \alpha)Li^7$ reaction in argon and its separate ionizations respectively. Their results all in concert conflict with the constancy of $W$, but agree with the result of Cranshaw and Harvey. Tunnicliffe and Ward¹¹⁾ have also reported similar result that indicates the variation of $W$ with the particle energy in argon mixed with a small amount of helium and methane.

---

[*] Present address: Department of Physics, Konan University, Kobe.

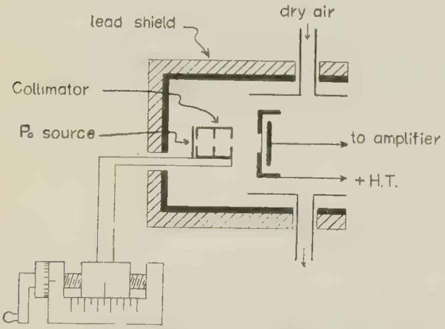

Fig. 1. The schematic diagram of the ionization chamber.

In a previous paper¹²⁾, on the other hand, we have pointed out that the effect of columnar recombination should be carefully treated in the discussion of the ionization-energy relation in air. If the field strength is not sufficient to prevent columnar recombination, the degree of saturation will decrease with the decrease of the particle energy because of the increasing ion density. This results in an apparent decrease of the observed ionization, i.e. an increase of $W$, in the low energy region. Experimental evidence has also been presented about the fact that the result of Holloway and Livingston is not free from the effect of columnar recombination and $W$ in air may be more nearly constant than reported by Jesse et al..

Thus, it can be concluded that there are still many doubtful points about the behaviour of $W$ in argon as well as in air, on which the revision of the range-energy relation made by Jesse et al. and Bethe is based, although their revised range-energy relation is useful from the practical point of view.

In the present paper, we have studied the effect of columnar recombination on the ionization measurement in air more quantitatively than the previous work, and determined the true range-ionization relation free from the recombination effect for alpha-particles in air. Further, comparing this relation with the fixed points on the range-energy relation obtained from the nuclear reaction data, we have attempted to establish an empirical formula for the energy dependency of $W$ in air.

## § 2. Apparatus

We have measured the specific ionization for polonium alpha-particles with a shallow ionization chamber. The arrangement of the equipments is similar to that of Holloway and Livingston⁵⁾ as shown in Fig. 1. The depth of the chamber is 1 mm, and the diameter of the collecting electrode is 15 mm. The front window is 8 mm in diameter, and is covered with aluminium foil of $0.41_2$ mg/cm² thick instead of metal gauze to prevent the inequality of the field and the possible occurrence of corona discharge when a high voltage is applied. Pure polonium newly deposited on a silver foil was used as the alpha-particle source. The source was mounted on a screw micrometer stage with a divided drum of 0.5 mm pitch, and moved perpendicular to the front face of the chamber. Alpha-particles were collimated by three thin ebonite sheets with small holes placed in front of the source at intervals of 5 mm. Three sets of collimeters with different hole diameters were prepared as described later. The time constant of the amplifier was chosen as $2\times10^{-3}$ sec which was adequately larger than the collecting time of ions even when the lowest voltage was applied. The gain and the linearity of the amplifier were frequently checked with a pulse generator during the measurement. The output of the amplifier was connected to a register with a thyratron discriminator and an oscilloscope in parallel.

At the operation of this apparatus, the shallowness of the chamber and the use of aluminium foil at the window have required special precautions to avoid the microphonic noise. The outside of the chamber was covered with lead shield of 3 mm thick and wrapped with thick felt sheet. Further, the source stage and the chamber together with the preamplifier were mounted in a sound arresting box tamped with rock wool. These precautions made it possible to work with sufficiently low noise level. The signal to peak noise ratio in the measurement at the peak of the specific ionization for alpha-particles was 12 to 14, that is, the peak value of the noise corresponds to about 20 Kev. Air admitted into the chamber was desicated by $CaCl_2$, but the elimination of $CO_2$ was not made.

## § 3. Experimental Procedure

According to Jaffé's theory(13) of columnar recombination, the saturation of the observed ionization depends upon the field strength and the angle between the field and the track of the particle as well as the ion density. So we have investigated the effect of columnar recombination by means of changing the field strength and its relative angle respectively.

### A. *Effect of Variation of Field Strength*

In order to investigate straightforwardly the effect of columnar recombination, we have measured the ratio of the pulse heights at two fixed points on the specific ionization curve under the various field strengths. As the fixed points, we have chosen the peak of the specific ionization curve (the residual range at this point is 4.5 mm; henceforth referred to as point P) and the point 18 mm off the peak (the residual range at this point is 22.5 mm; henceforth referred to as point F). The specific ionization at the point F is about half that at the point P.

The degree of columnar recombination at each point, if its effect is present, is different in accordance with the difference of the ion density under the same experimental conditions of the field and its relative angle. That is, the pulse height observed at the point P suffers the greater effect of columnar recombination than that at the point F because of the greater ion density, and so the ratio of the pulse heights at P and F is smaller than the ratio of the true ionizations produced primarily. Since the degree of recombination decreases with the increase of the field strength, the observed ratio of the pulse heights increases with the increasing applied voltage and comes to be equal to the ratio of the true ionizations as the perfect saturation is attained.

The applied voltages were chosen as 50 volts and 135 volts that have hitherto been considered as appropriate for a chamber of 1 mm depth, and also 1,140 volts was chosen as an extraordinary high voltage. That is, the field strength in each case is 500 volts/cm, 1,350 volts/cm and 11,400 volts/cm respectively. The diameter of the hole of the collimator used was 1.5 mm.

The pulse height was measured with the thyratron discriminator by determining the half-maximum point of the number-bias curve. More than one thousand pulses were always counted for each bias setting.

The positions of the source corresponding to the point P and the point F were determined by taking account of the correction for the pressure and the temperature of air and the change of the stopping power of the aluminium foil with the alpha-energy. The position of the source for the point P was determined by the following procedure. First the specific ionization curve near the peak was measured carefully with the field strength of 500 volts/cm, and the shape of the observed curve was compared with the curve(14) of Holloway and Livingston. The point was sought on the scale of the measured relative distance in such a way that the two curves give the best fit, and thus the position of the point P and the absolute scale of the distance measurement were determined*. The change of the stopping power of the foil was also determined experimentally. An additional foil cut from the same sheet as used at the window was inserted at proper distances from the source corresponding to the point P and the point F, and then the number-distance curve was measured. The air equivalent values for the stopping power of the foil for the alpha-energies at the point P and the point F can be obtained from the change of the half-maximum point of the number-distance curve measured with and without the additional foil, and they are 2.09 ±0.06 mm N.T.P. (15°C, 760 mm Hg) air at the point P and 2.48±0.06 mm N.T.P. air at the point F respectively. So, if the source is moved by 18.39 mm in N.T.P. air from the position corresponding to the point P, it in effect corresponds to the position 18.39−(2.48−2.09)=18.00±0.09 mm off the point P, i.e. the position of the point F.

---

* As discussed in detail by Holloway and Livingston, the present experimental arrangement is not suited for the precise determination of the absolute range corresponding to the measurement with zero bias. The method adopted here is fairly sensitive, and the absolute scale related to the precise determination of Holloway and Livingston can be easily determined within 0.2 mm.

It has several advantages to measure the ratio of the pulse heights at these two points, as follows.

I) The change of the ratio of the amplifier time constant to the collecting time caused by the change of the chamber voltage, does not prevent to study purely the effect of the field strength*.

II) The effect of gas multiplication, even if it occurs under the highest field strength (11,400 volts/cm), is eliminated and does not affect the result.

III) The change of the effective chamber depth due to different atmospheric pressures in different runs is also eliminated automatically.

IV) The result is easily compared with that of previous works, especially of Holloway and Livingston, on the effect of columnar recombination.

### B. *Effect of Variation of Angle*

When the incident beam of alpha-particles is approximately parallel with the field as in this experiment, the effective angle between the alpha-track and the field depends upon the collimating condition. Because the method used for determining the pulse height is to measure the half-maximum of the number-bias curve, the effective angle $\tilde{\theta}$ should be defined in such a way that the number of alpha-particles with angles greater than $\tilde{\theta}$ is equal to that with smaller angles. Now, let $b$ denote the length of the collimator and $2a$ denote the diameter of the collimating hole, the effective angle $\tilde{\theta}$ as defined above is given by

$$\tilde{\theta}=0.891\,a/b \quad \text{in radian,}$$

provided that the polonium source is uniform and alpha-particles are emitted spherically symmetrically. The following three collimators were used.

$2a=1.0$ mm: $\tilde{\theta}=2.55°$

$2a=1.5$ mm: $\tilde{\theta}=3.83°$

$2a=2.0$ mm: $\tilde{\theta}=5.11°$

Of each one the length $b$ was 10 mm. Using these collimators, the ratios of the pulse heights at the point P and the point F were determined by the same procedure as described above with applied voltages of 50 volts and 135 volts. Since Jaffé's theory indicates that the degree of recombination decreases as the angle increases, it is expected that if any effect of recombination is present the ratio of the pulse heights increases with the angle $\tilde{\theta}$. The error, introduced into the determination of the source position by the oblique incidence as a result of the change of $\tilde{\theta}$, is less than 0.1% and no correction was made for this.

### C. *Measurement of Whole Specific Ionizations*

Further, we have measured the whole specific ionizations of residual range below 22 mm applying the voltages of 50 volts and 1,140 volts. In this case, the pulse heights were measured directly on the screen of the oscilloscope. The accuracy of this method is somewhat lower than the preceding measurements using thyratron discriminator. That is, when the pulse height corresponding to the maximum specific ionization was about 30 mm on the screen, the standard deviation of several determinations of the pulse height amounted to 0.3 mm to 0.5 mm. The collimator of $2a=1.5$ mm, $\tilde{\theta}=3.83°$ was used. All distance measurements were corrected to N.T.P. as before.

## § 4. Experimental Results

### A. *Effect of Variation of Field Strength*

The observed values of the ratio of the pulse heights at the two points P and F for

---

* In many of previous works, the voltage saturation of the pulse height was often measured under a certain geometry with the purpose of preventing columnar recombination. But, such a method is not adequate for this purpose because of the fact that the change of the pulse height with the applied voltage is affected in complicated ways by the change of the ratio between the amplifier time constant and the collecting time. Moreover, when the chamber is fairly deep, the observed saturation is responsible only for the average ion density over the total length of the track, so it is difficult to certify the saturation at the most dense part of the track.

Table I. The ratio of the pulse heights at the points P and F observed for different voltages with $\tilde{\theta}=3.83°$.

| No. of run | Applied voltage | | |
|---|---|---|---|

| 4 | $1.90_9$ | $1.91_2$ | $1.92_2$ |
| Average | $1.90_9$ <br> $\pm 0.004$ | $1.92_7$ <br> $\pm 0.009$ | $1.94_0$ <br> $\pm 0.008$ |

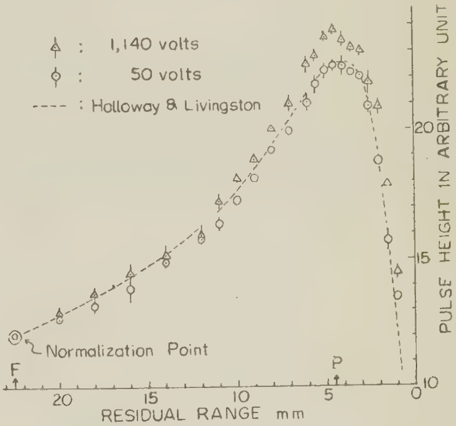

Fig. 2. The specific ionizations for polonium alpha-particles under the field strengths 500 volts/cm and 11,400 volts/cm.

different voltages are shown in Table I* and Fig. 3.

The error given to the average value is the standard deviation of the observed values. In each run the error of the ratio caused by the uncertainties in the pulse height measurement is of the order of ±0.011 to ±0.015, and well accords with the standard deviations given above.

As obviously seen from Table I, the observed ratio increases with the rise of the applied voltage. And this is consistent with the expected effect of columnar recombination.

B. *Effect of Variation of Angle.*

The ratios of the pulse heights observed for different effective angles $\tilde{\theta}$ with the two fixed voltages (50 volts and 135 volts) are shown in Tables II and III, and also in Fig. 4.

The error is also the standard deviation. It is clearly seen that the value of the ratio increases with the effective angle, and this is explained by the effect of columnar recombination. Moreover, the fact that the increase of the ratio with $\tilde{\theta}$ is prominent in the case of 50 volts than 135 volts, and that for each value of $\tilde{\theta}$ the ratio is greater in the case of 135 volts than 50 volts, is characteristic of columnar recombination.

C. *Measurement of Whole Specific Ionizations*

In Fig. 2 are shown the whole specific ionization curves observed with 50 volts and 1,140 volts applied. As the absolute value of the pulse height is changed for different voltages by the time constant to collecting time ratio even when an adequately large time constant is adopted, the curves in the figure are normalized at the point F. In the figure, the curve of Holloway and Livingston is also

---

* The values given in Table I are the same data as reported in the previous paper, but corrected for the fact that in dynamic operation the flashing bias voltage of the thyratron used is shifted by about 1.5 volts from the value determined statically. As a consequence, in the previous paper the values for the ratio were too high by about 2 percent.

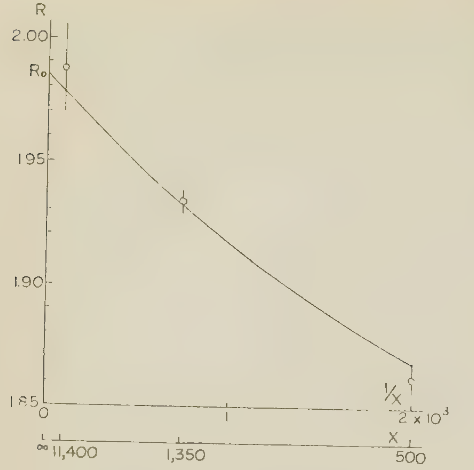

Fig. 3. The ratios of the pulse heights at the two points P and F for different field strengths with $\tilde{\theta}=3.83°$. The solid curve represents the values calculated by Jaffe's theory. The points at $X=$ 500 and 1,350 volts/cm are the averages of the values given in Tables I, II and III.

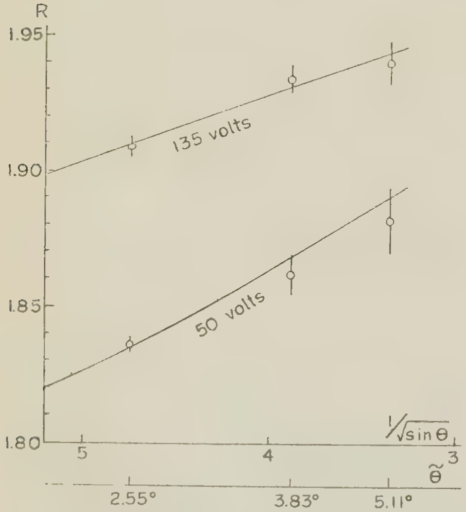

Fig. 4. The ratios of the pulse heights at the two points P and F for different effective angles with the voltages 50 volts and 135 volts. The solid curves represent the theoretical values. The points at $\tilde{\theta}=3.83°$ are the averages of the values given in Tables I, II and III.

shown by a dotted curve. The curve observed with 1,140 volts shows larger ionization around the peak than that with 50 volts in accord with the results of Table I. The latter curve nearly agrees with the curve of Holloway and Livingston.

## § 5. Comparison with Jaffé's Theory

We have tried to compare our result with Jaffé's theory[13] of columnar recombination, and examined to what extent the observed phenomena are quantitatively explained by the effect of columnar recombination.

According to Jaffé's theory, the fraction of the ions escaping from recombination, $Y$, is given by*

$$Y=1\Big/\left\{1+\frac{\alpha N_0}{8\pi D}\sqrt{\frac{\pi}{z}}S(z)\right\},$$

$$z=\frac{b^2k^2X^2\sin^2\theta}{2D^2},$$

where $N_0$ denotes the linear inonization density produced primarily, $\alpha$ the volume recombination coefficient, $D$ the diffusion coefficient, $k$ the ionic mobility, $X$ the field strength, $\theta$ the angle between the alpha-track and the field, and $b$ is the parameter representing the radius of the ion column. And $S(z)$ is expressed by using Hankel function[15] as

$$\sqrt{\frac{\pi}{z}}S(z)=\frac{\pi}{2}e^{z/2}\cdot iH_0^{(1)}(iz/2)\,.$$

Now, if we denote the ion densities at the points P and F by $N_P$ and $N_F$, and the values for $Y$ by $Y_P$ and $Y_F$ respectively, the observed ratio of the pulse heights, $R$, is expressed by

$$R=\frac{N_PY_P}{N_FY_F}=R_0\frac{Y_P}{Y_F},$$

with

$$R_0\equiv\frac{N_P}{N_F}\,.$$

Here, $R_0$ represents the ratio of the true ionizations primarily produced. For the numerical calculation, the following values were used for the constants:

$$\alpha=1.66\times10^{-6}\ \mathrm{cm^3/sec}\,,$$

$$D=0.055\ \mathrm{cm/sec/cm^2}\,,$$

$$k=2.22\ \mathrm{cm/sec/volt/cm}.$$

$b$ is undetermined from the theory and must be adjusted to fit the experimental result.

First, assuming the energy loss at the point P to be 2.4 Mev/cm and the value of $W$ to be 35.6 ev/ion, we can put

$$N_P=2.4\times10^6/35.6=6.74\times10^4\,.$$

Since $R_0$ is known to be nearly equal to 2, we took for the first approximation

$$N_F=N_P/2=3.37\times10^4\,.$$

---

* This formula is not valid for very small angles. Though the angles are considerably small in the present experiment, the condition for the theory to be valid is well satisfied.

Table IV. The values of $Y_P$, $Y_F$ and the ratio $R=1.985\ Y_P/Y_F$ calculated for different field strengths with $\tilde{\theta}=3.83°$.

| Field strength (volts/cm) | 500 | 1,350 | 11,400 | ∞ |
|---|---|---|---|---|
| $Y_P$ | 0.8816 | 0.9460 | 0.9931 | 1 |
| $Y_F$ | 0.9367 | 0.9720 | 0.9965 | 1 |
| $R$ | $1.868_3$ | $1.931_9$ | $1.978_2$ | $1.98_5$ |

Table V. The values of $Y_P$, $Y_F$ and the ratio $R=1.985\ Y_P/Y_F$ calculated for different angles with the field strength 500 volts/cm.

| Effective angle $\tilde{\theta}$ | 2.55° | 3.83° | 5.11° |
|---|---|---|---|
| $Y_P$ | 0.8474 | 0.8816 | 0.9040 |
| $Y_F$ | 0.9168 | 0.9367 | 0.9492 |
| $R$ | $1.834_7$ | $1.868_3$ | $1.890_4$ |

Table VI. The values of $Y_P$, $Y_F$ and the ratio $R=1.985\ Y_P/Y_F$ calculated for different angles with the field strength 1,350 volts/cm.

| Effective angle $\tilde{\theta}$ | 2.55° | 3.83° | 5.11° |
|---|---|---|---|
| $Y_P$ | 0.9239 | 0.9460 | 0.9586 |
| $Y_F$ | 0.9602 | 0.9720 | 0.9787 |
| $R$ | $1.910_0$ | $1.931_9$ | $1.944_2$ |

Using these value for $N_P$ and $N_F$, $Y_P$ and $Y_F$ were calculated for different values of $b$. Substituting the latter values into the equation $R=R_0Y_P/Y_F$ and adjusting the value of $R_0$, the calculated values for $R$ were compared with the experiment. The best fit was obtained for the following values:

$$R_0=1.98_5\ ,$$

and

$$b=9.5\times10^{-4}\ .$$

The final values for $R$ were calculated again by using the above values for $R_0$ and $b$ and $N_F=N_P/1.98_5$. The results of the calculation are shown by solid curves in Figs. 3 and 4 together with the observed values.

The calculated curves are in good agreement with the observed points within the experimental error in each case that either the voltage or the angle was changed. Thus, the observed change of the ratio with the field strength and the angle is considered to be entirely explained by the effect of columnar recombination. Especially, this conclusion is supported by the fact that remarkable variations of the ratio are observed for the moderate field strengths, i.e. 500 volts/cm and 1,350 volts/cm, and that the ratio is affected definitely by the collimating conditions.

The calculated values of $Y_P$ and $Y_F$ for the present experimental conditoins are tabulated in Tables IV, V and VI.

## § 6. Discussion on Experimental Results

The highest field strength 11,400 volts/cm applied in this experiment is much higher than the fields hitherto usually used. But there is no fear that gas multiplication or other secondary effects may disturb the measurement. The procedure of taking the ratio of the pulse heights removes such effects, so far as the number of secondary ions is proportional to the initial ionization. Furthermore, it is not likely that gas multiplication should occur in this experiment. The first Townsend coefficient $\alpha$ for atmospheric air has been accurately measured by Sanders[16]. According to Sanders, the lowest observable value is $\alpha/p=3.4\times10^{-5}$ at $X/p=20$, and he gave an empirical formula for $\alpha/p$ in the range of $X/p$ from 20 to 36. For the field strength 11,400 volts/cm in this experiment, $X/p$ is equal to 15 and this is fairly smaller than the lowest of Sanders's experiment. If we extend the empirical formula of Sanders down to $X/p=15$, the multiplication factor for this experiment is calculated as 1.00045. Such disturbance, even if it exists, is smaller than the experimental uncertainty involved in the pulse height determination. The second Townsend coefficient is much smaller than the first coefficient and is, of course, out of the question. Thus, according to the conclusion of § 5, the ratio of the true specfic ionizations at the points P and F can be estimated as $1.98_5$ by the help of Jaffé's theory.

The corresponding ratio obtained from the specific ionization curve of Holloway and Livingston is 1.87. This indicates definitely that the experiment of Holloway and Livingston was considerably subjected to the effect of columnar recombination. Taking $R_0=1{,}98_5$, the values for $Y_P$ and $Y_F$ giving the observed value of $R=1.87$ are estimated as $Y_F=0.8830$ and $Y_F=0.9373$ respectively.

For the sake of comparison, the corresponding ratios were also obtained from the results of other authors. The curve of

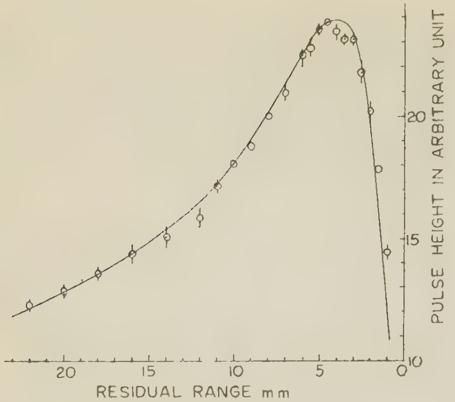

Fig. 5. The specific ionizations for the field strength 11,400 volts/cm. The solid curve is Holloway and Livingston's curve corrected by Jaffé's theory and normalized at the residual range 22.5 mm.

Stetter and Jentschke[17)] gives $R=1.95$. Their experiment was performed with $\theta=90°$ and $X=240$ volts/cm. Since in Jaffé's formula the role of the field is the same as the angle, this condition is equivalent to ours when $\tilde{\theta}=3.83°$ and $X=3,600$ volts/cm is applied. From our calculation, $R=1.964$ is expected for this condition. The earlier work of Curie and Behounek[18)] gives $R=1.85$ for both polonium and RaC′ alpha-particles. The results of Henderson[19)] give $R=1.93$ for RaC′ and 1.79 for ThC′.

The straggling of the polonium source used was determined from the number-distance curve. The straggling parameter, defined by Holloway and Livingston, was about 0.2 cm, this being somewhat larger than the value 0.084 cm quoted by Holloway and Livingston for newly prepared source. It is not clear whether this is due to the thickness of the source or to the straggling effect in the aluminium foil. In any case, the straggling phenomenon has the tendency to lower the observed ratio to some extent. However, this effect may be thought to be not large, since our specific ionization curved observed with 500 volts/cm well accords with that of Holloway and Livingston.

The value for $b$ used in this paper is considerably smaller than the value $1.79\times10^{-3}$ originally used by Jaffé to explain Moulin's experiment[20)]. This discrepancy is caused by the difference in the estimation of the ion density $N_0$, because $b$ is very sensitive to the estimate of $N_0$. If we use the recent data to estimate the value of $N_0$, Moulin's experiment is explained as well by the present values for the constants.

The value of $W$ 35.6 ev/ion assumed in our calculation is the one given by Gray[1)] as an average value of $W$ for polonium alpha-particles. If $W$ depends upon the initial energy of the particle, the instantaneous values of $W$ corresponding to the points P and F would be different from 35.6 ev/ion. But no further calculation was carried out, although in principle it is possible to proceed with the successive approximation by using the relation between $W$ and the particle energy described later.

## § 7. Establishment of Ionization-energy Relation for Alpha-particles in Air

Now, we can correct the specific ionization curve observed under a certain experimental condition by the help of Jaffé's theory, and obtain the true ionization-range relation which is not subjected to the effect of columnar recombination. The solid curve shown in Fig. 5 is the curve obtained by correcting the original curve of Holloway and Livingston. In Fig. 5 also are shown the observed points measured with the field strength 11,400 volts/cm in this experiment. The pulse heights are normalized at the residual range of 22.5 mm. These points are in good agreement with the solid curve, since the saturation of the ionizations at the points P and F are 0.9931 and 0.9965 as shown in Table IV.

Taking into account the fact that in the experiment of Holloway and Livingston the determination of the absolute distance seems to be more accurate than the present experiment and that the correction for the finite depth of the chamber was also carried out in their experiment, we have adopted the corrected Holloway and Livingston curve given above as the true specific ionization curve free from recombination, and the following arguments are based on this curve.

The true total ionization versus range relation may be obtained by integrating the true specific ionization curve determined above. If the integrated relation is normalized to the polonium energy 5.2984 Mev at the polonium range, we get a provisional range-energy relation for alpha-particles in air which is based on the assumption of the constancy of $W$ in the same manner as the original range-energy relation of Holloway and Livingston. If this relation deviates from the true range-energy relation, it can be concluded that $W$ in air depends upon the particle energy.

Now, let $E$ be the alpha-energy for a given range $R$, and $E'$ be the energy value obtained from the provisional range-energy relation (i.e. essentially the total ionization) for the same range, the ratio of $E$ to $E'$, $w$ say, may represent the average energy loss per ion pair in air for an alpha-particle of energy $E$ relative to that for the polonium alpha-particle (5.2984 Mev),

$$w \equiv E/E' = W(E)/W_{\mathrm{Po}} \, .$$

To perform the integration of the true specific ionization curve from zero to the polonium range (3.842 cm), the $dE/dR$ curve obtained from the original Holloway and Livingston range-energy curve was utilized in the region 2.8 to 3.842 cm, and was made to connect smoothly with the corrected specific ionization curve shown in Fig. 5 at the point of 2.8 cm. Since the variation of the ion density along the track is relatively small in the range 2.8 to 3.8 cm, the error introduced by this substitution is expected to be negligibly small. The integration was performed graphically and normalized to the polonium energy at the polonium range*.

The results are tabulated in the third column of Table VII. In the second column of this table are given the energy values from Jesse's revised relation, while in the fourth column the ratios of Jesse's value to the provisional energy value given in the third column. Since it is known that Jesse's revised relation nearly agrees with the fixed points obtained from some nuclear reactions, the ratio given in the fourth column stands for the approximate value of $w$ above defined. It is obvious from the table that the value of $w$ depends upon the alpha-energy.

Table VII. The provisional energy values derived in this experiment and the comparison with Jesse's values.

| Range (mm) | Energy values of Jesse (Mev) | Provisional energy values derived in this exp. (Mev) | Ratio of Jesse's values to provisional values |
|---|---|---|---|
| 1 | | 0.075 | |
| 2 | 0.271 | 0.235 | 1.152 |
| 3 | 0.508 | 0.451 | 1.127 |
| 4 | 0.761 | 0.685 | 1.111 |
| 5 | 0.994 | 0.919 | 1.081 |
| 6 | 1.214 | 1.146 | 1.059 |
| 7 | 1.422 | 1.362 | 1.044 |
| 8 | 1.624 | 1.565 | 1.038 |
| 9 | 1.816 | 1.757 | 1.034 |
| 10 | 1.995 | 1.940 | 1.029 |
| 11 | 2.162 | 2.113 | 1.023 |
| 12 | 2.321 | 2.279 | 1.018 |
| 14 | 2.620 | 2.592 | 1.011 |
| 16 | 2.907 | 2.885 | 1.008 |
| 18 | 3.174 | 3.160 | 1.004 |
| 20 | 3.425 | 3.420 | 1.002 |
| 22 | 3.668 | 3.665 | 1.001 |
| 24 | 3.896 | 3.898 | 1.000 |
| 26 | 4.103 | 4.118 | 0.997 |
| 28 | 4.300 | 4.326 | 0.994 |
| 30 | 4.502 | 4.526 | 0.995 |
| 33 | 4.798 | 4.812 | 0.997 |
| 35 | 4.987 | 4.996 | 0.998 |
| 38.42 | 5.298 | 5.2984 | 1.000 |

Table VIII. The comparison of the provisional range-energy relation with the fixed points obtained from the nuclear reactions.

| Reaction | Observed range (cm) | Observed energy $E$ (Mev) | Provisional energy $E'$ (Mev) | Ratio of $E$ to $E'$, $w$ |
|---|---|---|---|---|
| $B^{10}(n, \alpha)Li^{7*}$ | 0.720 | 1.474 | 1.403 | $1.050_3$ |
| $Li^6(p, \alpha)He^3$ | 0.85 | 1.726 | 1.662 | $1.038_5$ |
| $B^{10}(n, \alpha)Li^7$ | 0.868 | 1.779 | 1.697 | $1.048_3$ |
| $Li^6(n, \alpha)H^3$ | 1.04 | 2.060 | 2.010 | $1.024_9$ |
| Sm-$\alpha$ | 1.12 | 2.18 | 2.147 | $1.015_4$ |

Further, in Table VIII the provisional range-energy relation is compared with the fixed points[6)] obtained from the nuclear reactions for which the ranges and energies of the emitted alpha-particles have been independently determined. In the fifth column are given the ratios of the observed energy value $E$ to the value $E'$ from the provisional curve corresponding to its range. These ratios can be considered as the observed values of $w$.

---

* For the sake of contrast, the original specific ionization curve of Holloway and Livingston was integrated and normalized by the same procedure. And it was ascertained that the result agrees with the original range-energy curve given by Holloway and Livingston within about 2 Kev.

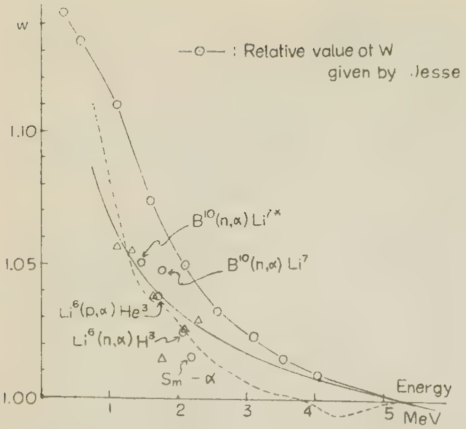

Fig. 6. The values of $w$, the average energy loss per ion pair in air for an alpha-particle of the energy $E$ relative to that for the polonium alpha-particle (5.2984 Mev). The solid curve shows the values obtained from the present experiment. The dotted curve shows the ratios of Jesse's values to the provisional energy values given in the fourth column of Table VII.

Cranshaw and Harvey[7] reported that $W$ for alpha-particles in argon can be represented by a formula of the type:

$$W=A+B/\sqrt{E}\ .$$

After this, we have assumed a formula of the same type for $w$ in air, as follows:

$$w=a+b/\sqrt{E}\ .$$

The values of the constants $a$ and $b$ were determined by the method of least squares to agree with the five observed values for $w$ as shown in Table VIII, obtaining

$$a=0.948 \quad \text{and} \quad b=0.119\ .$$

Hence,

$$w=0.948+0.119/\sqrt{E}\ ,$$

where $w$ is the relative value of $W$ for alpha-particles in air to that for the polonium alpha-particles, and $E$ is the initial alpha-energy in Mev. The result is shown by the solid curve in Fig. 6. The dotted curve in the figure represents the ratio of Jesse's value to the provisional energy value at the corresponding range given in the fourth column of Table VII. The latter curve becomes less than unity for energies above 4 Mev. This is probably due to the fact that Jesse has actually revised the curve only up to the range of 2.8 cm (4.3 Mev) and joined this to the original range-energy curve of Holloway and Livingston at the range of 2.8 cm as stated in his paper. In the figure is also shown the variation of $W$ in air reported by Jesse. The five observed values for $w$ given in Table VIII are represented by the small circles.

Freeman and Burcham[21] have made a relative measurement of the ranges for alpha-groups emitted from several $(p, \alpha)$ reactions, $F^{19}(p, \alpha)O^{16*}$, $B^{10}(p, \alpha)Be^7$, and $Be^9(p, \alpha)Li^6$, for which the energies are accurately known from the $Q$-values. They found that, if the range for the alpha-group of energy $2.272\pm 0.010$ Mev emitted from the $F^{19}(p, \alpha_1)$ reaction is assumed to be 1.157 cm from the revised curve of Bethe, all the other observed ranges agree with the revised curve down to 1.113 Mev except for small discrepancy of about 10 Kev. We have compared the result deduced by them with our provisional range-energy relation, and calculated the ratio $w=E/E'$ in the same manner as above. These values for $w$ are shown in Fig. 6 by the small triangles, and well accord with the empirical formula for $w$ obtained in this experiment. Consequently, this formula is considered to be valid at least for the alpha-energy down to 1 Mev.

## § 8. Conclusion

The effect of columnar recombination on the ionization measurement in air was examined by measuring the ratio of the specific ionizations for alpha-particles at two fixed points under various field strengths and various angles between the field and the alpha-track. It was found that the observed change of the ratio with the field and the angle can be completely explained by Jaffé's theory of columnar recombination. The value of the parameter $b$ which appears in Jaffé's theory was determined anew so as to give the best agreement with the experiments. By the help of this theory, the observed specific ionization curve of Holloway and Livingston was corrected for columnar recombination and the true ionization-range relation for alpha-particle in air was obtained. Comparing this relation with the fixed points of the range-energy relation obtained from nuclear reaction data, an empirical formula representing the energy dependency of the average energy loss per ion pair for alpha-particles in air relative to polonium alpha-particle, $w$, was deduced.

The energy dependency of *w* deduced in the present experiment is considerably smaller than the conclusion of Jesse et al..

It was also made clear that the experiment of Holloway and Livingston, on which the revision of the range-energy relation made by Jesse et al. or Bethe was based, was certainly subjected to the effect of columnar recombination. Therefore, we should consider that the success of the revised range-energy relation may be attributed to the incidental compensation of several factors.

The fact that in air the effect of columnar recombination is severe, is of cource an indefensible defect of air for the filling gas of ionization chambers. However, De Juren and Rosenwasser[22] have recently pointed out that even in argon the effect of columnar recombination is also serious and cannot be ignored. The results of the present study have made it possible to correct the observed ionization in air for columnar recombination by the help of Jaffé's theory. In addition, in some cases it is also an useful method[23] to plot the reciprocals of the pulse heights measured with various field strengths against the reciprocal of the field strength and to extrapolate the plot to infinite field strength. In consequence, the empirical formula for *w* obtained in the present study can be applied effectively to the corrected results of the ionization measurements which are free from recombination, and may be of use in the accurate determination of the energy of alpha-particles.

In conclusion, the authors wish to express their sincere thanks to Prof. K. Kimura for his valuable suggestions and continual encouragements throughout the work, and to Mr. S. Kimura for his help in the measurements. Thanks are also due to Prof. H. Yamaguchi of Osaka University who kindly presented us with radon tubes for the preparation of the polonium source. Finally, this work was financially supported by a grant-in-aid for Fundamental Scientific Research of the Ministry of Education.

# The Multiple Scattering of Fast Electrons

By Seizaburo Kageyama

*Physical Institute, Tokyo University of Education*

(Received December 17, 1955)

The angular distribution, caused by the multiple scattering, of the fast electron with an energy of 1.66 MeV passing through thin foils of Al, Cu and Pb has been investigated.

The experimental results obtained were in good agreement with Moliere's theory modified by Hanson et al. on the basis of their experimental data. The theoretical $1/e$ width values given by Shinohara were also in good agreement with those observed in light elements, but they seem to be slightly larger in heavy elements.

## § 1. Introduction

The experimental investigation of the scattering of electrons by multiple collisions in passing through various materials has been carried out by Kulchitsky and Latyshev[1] with 2.25 MeV electrons and by Sheppard and Fowler[2] with 6.2 MeV electrons. Their results were in good agreement with the theories of Williams[3] and Goudsmit and Saunderson[4] for the light elements if the electron-electron scatterings were accounted by replacing Z with $(Z^2+Z)^{1/2}$. For heavy elements, however, the 1/e width of the angular distribution curves obtained by them were from 10 to 15% narrower than the theoretical predictions.

Thereafter, Moliere[5] has been able to solve the scattering problem, making the only assumption that all scattering angles are small. He has given the scattering into the angular interval $d\theta$ at $\theta$ in a power series of $1/B$:

$$f(\vartheta)d\vartheta = \vartheta d\vartheta[f^{(0)}(\vartheta)+B^{-1}f^{(1)}(\vartheta)+B^{-2}f^{(2)}(\vartheta)+\cdots] \tag{1}$$

where

$$\vartheta=\theta/\chi_c B^{1/2},\quad \chi_c{}^2=4\pi e^4 Z(Z+1)Nt/(pv)^2,$$

$$f^{(n)}(\vartheta) = n!\int_0^\infty ydyJ_0(\vartheta y)\exp\left(-\frac{1}{4}y^2\right)\left[\frac{y^2}{4}ln\left(\frac{y^2}{4}\right)\right]^n$$

and the parameter $B$ is defined as follows by the characteristic screening angle $\chi_a$ and $\chi_c$.

$$B-lnB=ln\left(\frac{\chi_c{}^2}{1.167\,\chi_a{}^2}\right)$$

The first term $f^{(0)}$ in the above expression is the well-known Caussian. The angle at which the intensity drops to 1/e of the maximum is

$$\theta_w=\chi_c=B^{1/2} \tag{2}$$

while the second term goes over into the single scattering formula at large angle and the third is a correction. The evaluations of each term have been done by him and Bethe[6] as a function of variable $\vartheta$.

For small angles, $\vartheta<2$, the dominant term is the Gaussian $f^{0)}$. In this region Hanson et al[7]. have pointed out that a better agreement with the experimental results could be obtained by assuming a Gaussian distribution of which 1/e width is given by

$$\theta_w=\chi_c(B-1.2)^{1/2} \tag{3}$$

rather than by Eq. (2).

The same problem has been treated by Shinohara[8], by the same method as Williams, on the assumption that the electrons are diffracted by minute crystals forming the foil. The distribution given by him shows a slightly smaller scattering than those of Williams and Goudsmit and Saunderson, and is in better agreement with most of the experiments, especially for heavy elements. But in the case of Al, his theory is not in good agreement with the experimental result obtained by Kulchitsky and Latyshev, which was already in fairly good agreement with Williams' theory.

In the present work, we have observed the angular distribution of electrons scattered by multiple collisions in passing through thin Al, Cu and Pb foils and compared both with Moliere's formula modified empirically by Hanson et al. and with Shinohara's theory.

## § 2. Experimental Arrangement

The experimental arrangement used was similar to the one employed by Kulchitsky and Latyshev. A homogeneous and almost paral-

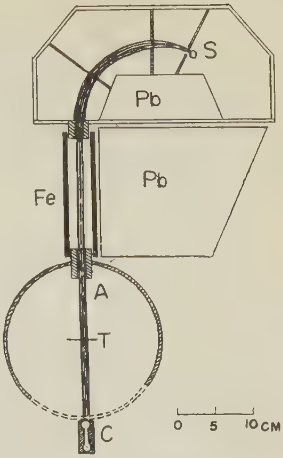

Fig. 1. Experimental arrangement for the measurement of angular distribution. S, the source, Fe, iron pipe, A, the last slit, T, the target and C, the G–M counters. The dotted line in front of C shows that the scattering chamber has a window in this part.

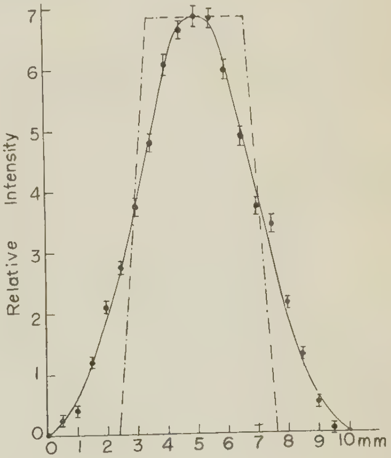

Fig. 2. Horizontal angular distribution of incident beam observed at C with the coincidence counter. The dash-point curve gives the distribution of incident beam calculated.

lel beam of fast electrons was obtained by placing a thin-walled glass tube of about 4 mg/cm², containing Rn of about 50 MC, at “S” (Fig. 1) in the magnetic field. The electrons described an arc of about 116° on the radius of about 10 cm in the magnetic field.

As can be seen from Fig. 1, electrons after passing a series of slits were focused on the scattering foil (T) placed at the center of a brass scattering chamber 8 cm high and 20 cm in diameter. The scattered electrons were detected by two G-M counters placed just behind a thin mica window of scattering chamber and working in coincidence. The thickness of mica of the scattering chamber and the counter was about 4.5 mg/cm². The hole in the last slit A was 3.0 mm in diameter.

The energy of the electron beam used was estimated from the energies and spread of internal conversion lines of RaC and RaC′ observed at the center of the scattering chamber. The precise estimation of the energy and spectral constitution of the beam employed was done by replacing the scattering chamber with the second $\beta$-ray spectrometer described in the previous paper[9]. Applying the correction of the most probable energy loss for conversion electrons, we have obtained the value of 1.66±0.04 MeV for our electron beam.

In order to estimate the divergence of the incident beam, the angular distribution of electrons in the horizontal and vertical plane were measured in front of the last slit (A), at the center of the scattering chamber (T), and at the position C with a single G-M tube. As an example, the horizontal distribution of incident beam measured at the position C with the coincidence G-M tubes used in the main experiment was shown in Fig. 2.

The dash-point curve in the figure shows the angular distribution of incident electron beams from which the theoretical angular distributions of transmitted beam have been calculated. From these distributions, we have found that the diameter of the beam is about 4 mm at *T* and that the angular divergence of electrons from the central beam does not exceed 1/3°.

The scattering materials examined were Al, Cu and Pb foils of following thicknesses;

| | | | | | |
|---|---|---|---|---|---|
| Al: | 3.43 | 6.86 | 10.3 | 13.7 | mg/cm² |
| Cu: | | 6.3 | 12.6 | | mg/cm² |
| Pb: | | 6.2 | | | mg/cm². |

## § 3. Experimental Results and Comparison with Theories

The observed angular distributions of scattered electrons are shown in Figs. 3 and 4. The theoretical distributions calculated from the original theory of Moliere are shown by broken line in Fig. 3. The solid lines in both figures represent the corrected distribution, in

Table I. 1/*e* width of the angular distribution curve.

| Material | Thickness of foil (mg/cm²) | Theoretical | | | | Observed |
|---|---|---|---|---|---|---|
| | | Williams | G–S | Shinohara | Moliere (Eq. 5) | |
| Al | 3.5 | 3.5 | 3.6 | 3.4 | 3.4 | 3.4±0.1 |
| | 7.0 | 5.7 | 5.6 | 5.5 | 5.4 | 5.4±0.2 |
| | 10.5 | 7.4 | 7.2 | 7.3 | 7.3 | 7.3±0.3 |
| | 14.0 | 8.8 | 8.6 | 8.7 | 8.4 | 8.4±0.3 |
| Cu | 6.3 | 7.9 | 7.9 | 7.9 | 8.2 | 8.0±0.3 |
| | 12.6 | 12.2 | 11.8 | 12.2 | 12.6 | 12.2±0.4 |
| Pb | 6.2 | 12.6 | 12.6 | 13.5 | 11.5 | 11.2±0.4 |

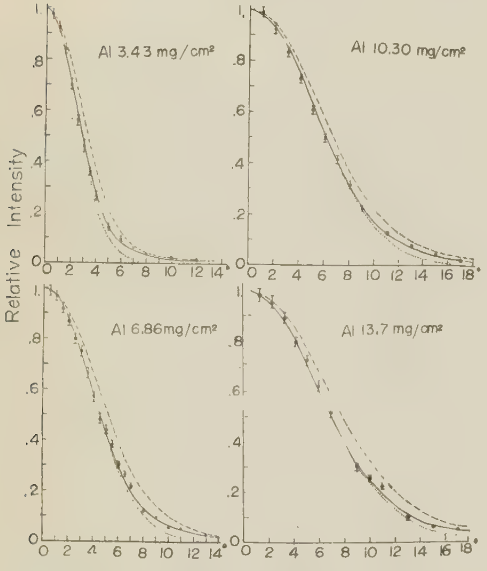

Fig. 3. Comparison between theoretical and experimental angular distributions of multiple scattering by Al foils. The broken lines are calculated according to the original Moliere's theory. The solid lines are modified empirically by Hanson et al. The dotted lines are a Gaussian distribution drawn through the observed point at the 1/*e* intensity.

which Eq. (3) was adopted instead of Eq. (2) for the 1/e width of $f^{(0)}$ in Eq. (1). The experimental results were in good agreement with the solid lines over all the region examined within the experimental errors. The Gaussian distribution drawn through the observed point at the 1/e intensity are shown by the dotted curves. In very small angle ($\vartheta < 1$), this distribution coincides completely with the solid lines.

The 1/e widths of the distribution curves obtained are tabulated in Table I, together with the theoretical values calculated from the formulae of Williams, Goudsmit and Saunderson, Shinohara and Moliere. All the theoretical values were corrected for the finite dimension and the divergence of electron beam.

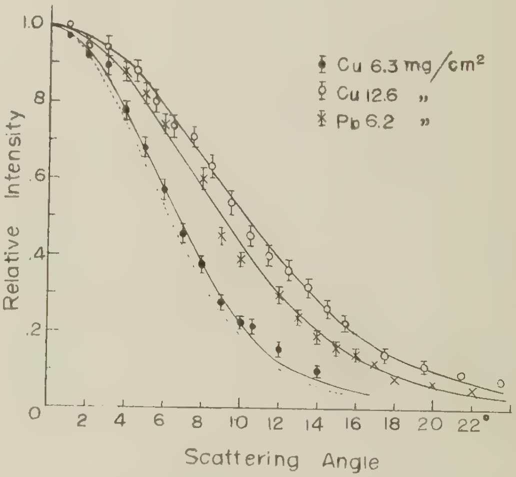

Fig. 4. Comparison between the modified Moliere's theory of multiple scattering of electrons and the experimental angular distribution for Cu and Pb. The broken line was calculated with $Z_{eff}=Z$. The solid curves were all calculated with $Z_{eff}=Z(Z+1)$.

According to Shinohara's theory, the 1/e width of the Gaussian distribution of projection angle is given by

$$\theta_w = 2\overline{\alpha}^2$$

$$\overline{\alpha}^2 = \nu\overline{\theta}^2$$

$$\nu = N_1 \sigma t$$

where $\nu$ is the average number of collisions of electron in passing through the foil, $N_1$ the number of minute crystals per unit volume $\delta$V, $t$ the thickness of the foil, and $\sigma$ the cross section of the minute crystal and

$$\overline{\theta^2} = \frac{1}{\sigma}\Big(\pi\sum\cdot\chi_i{}^3\int_0^{\chi_c} f_{1i}(\chi)d\chi + \pi\int_0^{\chi_c}\chi^3 f_2(\chi)d\chi + \frac{D}{3}\delta V\Big)$$

$$D=\frac{16e^4Z^2}{m^2v^4v_a}$$

where $v_a$ is the volume of the unit cell. The first term in the right-hand side of the upper expression represents the contribution of the beam reflected from a net plane of crystals, the second the temperature diffuse scattering and the third the contribution of the single greater than $\chi_c$. The effect of the inelastic scattering is not included in the above expression.

Under the assumption that the minute crystal are kept at the room temperature (290°K), the calculation has been numerically for the first term and graphically for the second$^{10)}$. The 1/e width calculated for the electrons of total energy 2.16 MeV (wave length $\lambda=7.42$ $10^{-11}$cm) are given in the fifth column of the Table 1.

In light elements, the experimental results for the 1/e width of angular distribution are in good agreement with all the theoretical predictions within the experimental errors. However, in heavy elements, the differences between theoretical and experimental values are outside of the experimental errors except for Moliere's theory. The observed value is about 10 and 20% lower than those given by the theories of Williams, Goudsmit and Saunderson, and Shinohara. As Shinohara has pointed out, it may be responsible for this discrepancy that the thickness of Pb foil examined was too thin to examine his theory.

Inelastic collisions with atomic electrons also contribute to multiple scattering, especially in light element, but are disregarded in the theories of Moliere and Shinohara. Thereafter, Bethe, Fano$^{11)}$ and Spencer and Blunchard$^{12)}$ have shown that the electron-electron collisions brought corrections to the elastic scattering of the order of 2% in Au, and that the effect of inelastic collision should be accounted for approximately by increasing the cross section by the factor $(Z+1)/Z$. This procedure has already been suggested experimentally by Kulchitsky and Latyshev and is in complete agreement with the present results, as shown in Fig. 4.

Moreover, Fano has shown that the Moliere's B must be increased by

$$(Z+1)^{-1}\{ln[0.160\,Z^{-2/3}(1+3.33\,Ze^2/\hbar v)]-U_{in}\}$$

where $-U_{in}$ is defined as an integral over the incoherent scattering function whose value is about 5.

This contribution, however, is too small to be tested with our results.

In conclusion, the author expresses his cordial thanks to Prefessor Mitsuo Miwa for the helpful suggestions and valuable discussions. The author wishes to express his thanks to the Japanese Foundation for Cancer Research for the supply of Rn through Dr. K. Tsukamoto and Mr. Y. Onai. Thanks are also due to Mr. K. Nishimura for his cooperation in this work. This study was supported by the Scientific Research Expenditure of the Ministry of Education.

# Theory of the Lattice Vibration of Graphite

By Akio Yoshimori and Yoshiharu Kitano

*Department of Physics, University of Osaka Prefecture,*
*Mozu-Higashi, Sakai*

(Received November 9, 1955)

A theory of the lattice vibration and specific heat of graphite, which has a typical lamellar structure, is worked out using the Born-von Kármân method. Four types of restoring forces are assumed; the first and second ones are associated with changes in the bond lengths and bond angles of the honey-comb net planes, respectively, the third with change in distance between neighoring atoms on adjacent net planes, and the fourth with the bending of the net planes. We have obtained modes whose polarizations are parallel and perpendicular to the planes. The former are essentially two-dimensional, but the latter are of more complex characters and play a particular role in the temperature range 45° to 100°K. As our main interest is in this and higher temperature ranges, we neglect the shearing forces between neighboring net planes which are effective at much lower temperatures. For small wave numbers, our theory naturally reduces to the semi-continuum theory developed by Komatsu and Nagamiya (1951) and Komatsu (1955). The calculated specific heat curve is in good agreement with the one observed by DeSorbo (1954) in the temperature range 45° to 300°K. We have concluded that the discrepancy found by Komatsu at temperatures higher than 60°K between his theoretical values of the specific heat and the observed ones is due to the failure of his semi-continuum treatment.

## § 1. Introduction

Graphite is a typical substance with lamellar structure and is well known, since old days, to show at low temperatures a specific heat which is remarkably different from that of ordinary substances of less anisotropic character. Recently, with renewed interest in the specific heat of substances with anisotropic lattices, there appeared a number of investigations, both experimental and theoretical[1)-10)], on the low temperature specific heat of graphite. The measurements of specific heat by DeSorbo and Tyler[2)] and more recently by DeSorbo[8)] in the temperature range from 13° to 300°K gave results that it follows apparently the $T^2$-law from 13° to 54°K. Another series of measurements by Bergenlid, Hill, Webb and Wilks[6)] in a lower temperature range from 1.5° to 90°K showed that the specific heat deviates from the apparent $T^2$-law below 15°K and varies with temperature as $T^{2.4}$ below about 10°K.

Komatsu[7)] explained satisfactorily such behaviors of the specific heat of graphite below 60°K down to 1.5°K, improving the semi-continuum treatment of this problem made by Komatsu and Nagamiya[1)]. In his work, the graphite crystal is considered as an assembly of elastic plates equally spaced and with compressional and shearing couplings between adjacent plates. The elastic constants of each plate, except for the bending modulus, were estimated from the force constants of benzen molecule with a modification of taking account of the different bond strengths in benzene and graphite; the compressional coupling constant was determined from the observed compressibility and the shearing modulus theoretically (actually, three times the theoretical value was needed to attain a perfect agreement). The remaining undetermined modulus, i. e. the bending modulus of each plate, was so determined as to obtain the best fit of the calculated specific heat curve to the experimental one in the temperature range where the shearing modulus could be neglected. This theory, however, could not satisfactorily account for the observed specific heat curve above 60°K. The discrepancy must be due to his oversimplification of replacing the atomic honeycomb net planes by continuous elastic plates. Evidently, such a continuum treatment describes correct aspects of the lattice vibrations for low frequencies and small wave numbers but is not valid for high frequencies or large wave numbers, so that even if the model employed by Komatsu is adequate at low temperatures, we cannot expect it to explain the experimental specific heat over the whole temperature range. A more rigorous theory must be based upon the Born-von Kármán approach.

The aim of our paper is to develop such a theory of the lattice vibration of graphite. We shall assume four types of restoring forces among atoms. The first and second are the restoring forces of the valence force type, the first being associated with changes in the bond lengths and the second with changes in the bond angles of the honey-comb net planes. The third is of the central force type and is related to changes in the distance between those atoms which are on adjacent planes and are neighbors along the $c$-direction. The fourth is the bending force constant of each honey-comb net plane; this is of the non-central force type and may conveniently be defined as the force for the displacement of each atom relative to the average of the normal displacements of the three neighboring atoms in the same net plane.

There may be other central forces than the third force mentioned above, namely, forces among other pairs of atoms in adjacent (or more distant) net planes. They will give rise to additional compressional, as well as shearing, forces among different net planes. However, as was shown by Komatsu7), the shearing forces are so weak that they become effective only at extremely low temperatures where the specific heat shows a deviation from the $T^2$-law, whereas in the present paper we confine our arguments to higher temperatures. Furthermore, these compressional forces could be absorbed, to a good approximation, into the single force constant of the third type mentioned above, for the net planes of graphite are so stiff that the relative displacements of atoms of each net plane would be small compared with the relative displacements of adjacent planes and, consequently, the net planes would behave as if they were locally rigid when they interact with one another.

## § 2. Analysis of the Normal Modes

The definition of the four force constants introduced in the previous section is illustrated in Fig. 2, in which we give also expressions for the corresponding increases in potential energy. We denote these force constants by

$\kappa$: for the change in each bond length of the honey-comb net plane,

$\mu$: for the change in each bond angle of the honey-comb net plane,

$\kappa'$: for the change in distance between two atoms which are on adjacent net planes and are neighbors in the $c$-direction,

$\mu'$: for the bending of the honey-comb net plane.

Fig. 2.

Using these constants, the total harmonic potential energy is given as a quadratic form of displacement $\boldsymbol{u}(X, r_i)$ of atom $X$ in unit cell $i$ whose translation vector is $r_i$:

$$V=(1/2)\sum_{i,j}\sum_{X,Y}\boldsymbol{u}(X,\boldsymbol{r}_i)\cdot\boldsymbol{V}(X,Y;\boldsymbol{r}_i-\boldsymbol{r}_j)\cdot\boldsymbol{u}(Y,\boldsymbol{r}_j)\,, \tag{1}$$

where $X$ or $Y$ runs over $A, B, C$ and $D$ atoms in the unit cell (see Fig. 1), and $\boldsymbol{V}(X, Y;\ \boldsymbol{r}_i-\boldsymbol{r}_j)$ are given as follows:

$$\begin{aligned}
&\boldsymbol{V}(A,A;\ 0)=\boldsymbol{V}(D,D;\ 0)\\
&=\{(3/2)\kappa+(15/2)\mu\}(\boldsymbol{i}_1\boldsymbol{i}_1+\boldsymbol{j}_1\boldsymbol{j}_1)\\
&\quad+\{\kappa'+(4/3)\mu'\}\boldsymbol{kk}\,,\\
&\boldsymbol{V}(B,B;\ 0)=\boldsymbol{V}(C,C;\ 0)\\
&=\{(3/2)\kappa+(15/2)\mu\}(\boldsymbol{i}_1\boldsymbol{i}_1+\boldsymbol{j}_1\boldsymbol{j}_1)+(4/3)\mu'\boldsymbol{kk}\,,\\
&\boldsymbol{V}(A,B;\ (\boldsymbol{a}_3-\boldsymbol{a}_2)/3=\boldsymbol{V}(B,A;\ (\boldsymbol{a}_2-\boldsymbol{a}_3)/3)\\
&=\boldsymbol{V}(C,D;(\boldsymbol{a}_3-\boldsymbol{a}_2)/3)=\boldsymbol{V}(D,C;\ (\boldsymbol{a}_2-\boldsymbol{a}_3)/3)\\
&=-(\kappa/2)\boldsymbol{i}_1\boldsymbol{i}_1-3\mu\boldsymbol{j}_1\boldsymbol{j}_1-(\mu'/3)\boldsymbol{kk}\,,\\
&\boldsymbol{V}(A,A;\boldsymbol{a}_1)=\boldsymbol{V}(B,B;-\boldsymbol{a}_1)\\
&=\boldsymbol{V}(C,C;a_1)=\boldsymbol{V}(D,D;-\boldsymbol{a}_1)\\
&=-\mu\boldsymbol{j}_2\boldsymbol{j}_3+(\mu'/9)\boldsymbol{kk}\,,\\
&\boldsymbol{V}(A,A;-\boldsymbol{a}_1)=\boldsymbol{V}(B,B;\ \boldsymbol{a}_1)\\
&=\boldsymbol{V}(C,C;-\boldsymbol{a}_1)=\boldsymbol{V}(D,D;\ \boldsymbol{a}_1)\\
&=-\mu\boldsymbol{j}_3\boldsymbol{j}_2+(\mu'/9)\boldsymbol{kk}\,,\\
&\boldsymbol{V}(A,D;\boldsymbol{c}/2)=\boldsymbol{V}(A,D;-\boldsymbol{c}/2)\\
&=\boldsymbol{V}(D,A;\boldsymbol{c}/2)=\boldsymbol{V}(D,A;-\boldsymbol{c}/2)\\
&=-\kappa'\boldsymbol{kk}\,,
\end{aligned} \tag{2}$$

The above $\boldsymbol{V}$'s and those which one obtains from them by permuting cyclically the suffices (1, 2, 3) are the only nonvanishing $\boldsymbol{V}$'s. $\boldsymbol{j}_i (i=1, 2, 3)$ and $\boldsymbol{k}$ are unit vectors along the primitive translation vectors $\boldsymbol{a}_i$ and $\boldsymbol{c}$, respectively, and $\boldsymbol{i}_i$ is the unit vector perpendicular to $\boldsymbol{a}_i$ and $\boldsymbol{c}$ (see Fig. 2). Thus

$$\boldsymbol{j}_i=\boldsymbol{a}_i/|\boldsymbol{a}_i|,\quad \boldsymbol{k}=\boldsymbol{c}/|\boldsymbol{c}|,\quad \boldsymbol{i}_i=\boldsymbol{j}_i\times\boldsymbol{k}\,.$$

Equation of motion for this vibrating system is

$$M\ddot{\boldsymbol{u}}(x,\boldsymbol{r}_j)=-\mathrm{grad}_u V\,, \tag{3}$$

which has a solution of the form

$$\boldsymbol{u}(X,\boldsymbol{r}_j)=\boldsymbol{e}(X,\boldsymbol{q})\exp\{i(\boldsymbol{q}\cdot\boldsymbol{r}_j-\omega t)\}\,, \tag{4}$$

where $\boldsymbol{q}$ is the wave vector, $\omega$ the angular frequency and $\boldsymbol{e}(X, \boldsymbol{q})$ the polarization vector. $\omega$ and $\boldsymbol{e}(X, \boldsymbol{q})$ are determined by the equation

$$M\omega^2\boldsymbol{e}(X,\boldsymbol{q})=\sum_{Y,\boldsymbol{r}_l}\exp(i\boldsymbol{q}\cdot\boldsymbol{r}_l)\boldsymbol{V}(X,Y;\ \boldsymbol{r}_l)\cdot\boldsymbol{e}(X,\boldsymbol{q})\,.$$

Owing to the properties of $\boldsymbol{V}(X, Y; \boldsymbol{r})$, expressed by (2), the secular determinant of these equation separates into two parts: one gives modes whose polarization vectors are in the honey-comb net plane (which we shall designate as vibrations in the plane) and the other those whose polarization vectors are perpendicular to the net plane (which we shall designate as vibrations perpendicular to the plane).

(*A*) *Vibrations in the plane*

The equation determining $\omega$ and $\boldsymbol{e}$ is

$$\begin{bmatrix}\boldsymbol{U}-\lambda\cdot\boldsymbol{S}_0 & -\boldsymbol{W}\\ -\boldsymbol{W}^* & -\boldsymbol{U}-\lambda\cdot\boldsymbol{S}_0\end{bmatrix}\cdot\begin{bmatrix}\boldsymbol{e}(A,\boldsymbol{q})\\ \boldsymbol{e}(B,\boldsymbol{q})\end{bmatrix}=0\,, \tag{5}$$

where

$$\begin{aligned}
&\boldsymbol{k}\cdot\boldsymbol{e}(X,\boldsymbol{q})=0\,,\\
&\lambda=M\omega^2-(3/2)\kappa-(15/2)\mu\\
&\qquad-(\mu/2)X(\boldsymbol{q})-\mu\boldsymbol{X}(\boldsymbol{q})\,,\\
&\boldsymbol{U}=(\sqrt{3}/2)\mu Y(\boldsymbol{q})\boldsymbol{S}_2\,,\\
&\boldsymbol{W}=\{\kappa+6\mu)/2\}\{X(\bar{\boldsymbol{q}}/\sqrt{3})+iY(\bar{\boldsymbol{q}}/\sqrt{3})\}\boldsymbol{S}_0\\
&\qquad+\{(\kappa-6\mu)/2\}\{\boldsymbol{X}(\bar{\boldsymbol{q}}/\sqrt{3})+i\boldsymbol{Y}(\bar{\boldsymbol{q}}/\sqrt{3})\}\,,
\end{aligned} \tag{6}$$

and

$$\begin{aligned}
&X(\boldsymbol{q})=\sum_{j=1,2,3}\cos(\boldsymbol{a}_j\cdot\boldsymbol{q})\,,\\
&Y(\boldsymbol{q})=\sum_j\sin(\boldsymbol{a}_j\cdot\boldsymbol{q})\,,\\
&\boldsymbol{X}(\boldsymbol{q})=\sum_j\boldsymbol{S}_1^{(j)}\cos(\boldsymbol{a}_j\cdot\boldsymbol{q})\,,\\
&\boldsymbol{Y}(\boldsymbol{q})=\sum_j\boldsymbol{S}_1^{(j)}\sin(\boldsymbol{a}_j\cdot\boldsymbol{q})\,,
\end{aligned} \tag{7}$$

$$\begin{aligned}
&\boldsymbol{S}_0=\boldsymbol{i}_j\boldsymbol{i}_j+\boldsymbol{j}_j\boldsymbol{j}_j\,,\\
&\boldsymbol{S}_1^{(j)}=\boldsymbol{i}_j\boldsymbol{i}_j-\boldsymbol{j}_j\boldsymbol{j}_j\,,\\
&\boldsymbol{S}_2=(1/i)(\boldsymbol{i}_j\boldsymbol{j}_j-\boldsymbol{j}_j\boldsymbol{i}_j)\,.
\end{aligned} \tag{8}$$

$\boldsymbol{S}_0$ and $\boldsymbol{S}_2$ are independent of $j$, and $\bar{\boldsymbol{q}}$ is a vector into which $\boldsymbol{q}$ is transformed by a rotation through $\pi/2$ about the $\boldsymbol{k}$-axis, i. e.,

$$\bar{\boldsymbol{q}}=\boldsymbol{q}\cdot i\boldsymbol{S}_2=(\boldsymbol{q}\cdot\boldsymbol{i})\boldsymbol{j}-(\boldsymbol{q}\cdot\boldsymbol{j})\boldsymbol{i}\,.$$

Equation for $\begin{pmatrix}\boldsymbol{e}(C,\boldsymbol{q})\\ \boldsymbol{e}(D,\boldsymbol{q})\end{pmatrix}$ has the same form as (5), that is, two adjacent honey-comb net planes, which are crystallographically different each other, have the same vibrations in the plane in our treatment. $\boldsymbol{e}(A, \boldsymbol{q})$ and $\boldsymbol{e}(B, \boldsymbol{q})$ are two-dimensional vectors so that the above secular equation is four-dimensional. It is laborious to solve this equation for general $\boldsymbol{q}$, but quite easy for certain special values of $\boldsymbol{q}$. Solutions for two special cases $\boldsymbol{q}=q\boldsymbol{i}_j$ and $\boldsymbol{q}=q\boldsymbol{j}_j$ (Fig. 3) are obtained as given below. Further, the frequencies of the vibrations in the plane are independent of the $\boldsymbol{k}$-component of $\boldsymbol{q}$, as we can see from expressions (5), (6) and (7). Hence, the contours of constant frequency in the $\boldsymbol{q}$-space are cylindrical with axes parallel to $\boldsymbol{k}$.

($A1$) The case of $\boldsymbol{q}=q\boldsymbol{i}_j$

The secular equation simplifies also in this case and its roots are found to be

$$\omega^2=M^{-1}\{(3/2)\kappa+9\mu-\sqrt{\alpha_1^2+\beta_1^2}\}\,, \quad (9)$$

$$\omega^2=M^{-1}\{(3/2)\kappa+9\mu+\sqrt{\alpha_1^2+\beta_1^2}\}\,, \quad (10)$$

$$\omega^2=M^{-1}\{(3/2)\kappa+7\mu+2\mu\cos(\sqrt{3}\,aq/2)-\sqrt{\alpha_2^2+\beta_2^2}\}\,, \quad (11)$$

$$\omega^2=M^{-1}\{(3/2)\kappa+7\mu+2\mu\cos(\sqrt{3}\,aq/2)+\sqrt{\alpha_2^2+\beta_2^2}\}\,, \quad (12)$$

where

$$\alpha_1=\kappa\cos(\sqrt{3}\,aq/3)+\{(\kappa/2)+9\mu\}\cos(\sqrt{3}\,aq/6),$$

$$\beta_1=\kappa\sin(\sqrt{3}\,aq/3)-\{(\kappa/2)+9\mu\}\sin(\sqrt{3}\,aq/6)\,,$$

$$\alpha_2=6\mu\cos(\sqrt{3}\,aq/3)+\{(3/2)\kappa+3\mu\}\times\cos(\sqrt{3}\,aq/6)\,,$$

$$\beta_2=-6\mu\sin(\sqrt{3}\,aq/3)+\{(3/2)\kappa+3\mu\}\times\sin(\sqrt{3}\,aq/6)\,.$$

These four solutions correspond, in the given order, to acoustical and optical longitudinal waves and acoustical and optical transverse waves.

($A2$) The case of $\boldsymbol{q}=q\boldsymbol{j}_j$

We find the following roots of the simplified secular equation;

$$\omega^2=M^{-1}\{2\kappa+(9/2)\mu+(\mu/2)\cos aq-(\kappa/2)-4\mu)\cos(aq/2)-\sqrt{\alpha_3^2+\beta_3^2}\} \quad (13)$$

$$\omega^2=M^{-1}\{\kappa+(21/2)\mu+(\mu/2)\cos aq+((\kappa/2)-2\mu)\cos(aq/2)+\sqrt{\alpha_4^2+\beta_4^2}\}\,, \quad (14)$$

$$\omega^2=M^{-1}\{\kappa+(21/2)\mu+(\mu/2)\cos aq+((\kappa/2)-2\mu)\cos(aq/2)-\sqrt{\alpha_4^2+\beta_4^2}\}\,, \quad (15)$$

$$\omega^2=M^{-1}\{2\kappa+(9/2)\mu+(\mu/2)\cos aq-((\kappa/2)-4\mu)\cos(aq/2)+\sqrt{\alpha_3^2+\beta_3^2}\}\,, \quad (16)$$

where

$$\alpha_3=((\kappa+6\mu)/2)+\mu\cos aq+(\kappa+5\mu)\cos(aq/2)\,,$$

$$\beta_3=-(\sqrt{3}/2)\mu\sin aq+(\sqrt{3}/2)(\kappa-4\mu)\sin(aq/2)\,,$$

$$\alpha_4=((\kappa+6\mu)/2)-\mu\cos aq+(\kappa+7\mu)\cos(aq/2)\,,$$

$$\beta_4=(\sqrt{3}/2)\mu\sin aq+(\sqrt{3}/2)(\kappa-8\mu)\sin(aq/2)\,.$$

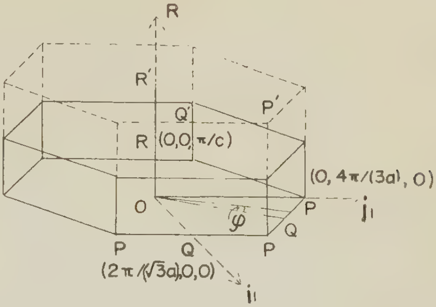

Fig. 3. The upper half of the Brillouin zone.

These also correspond, in the given order, to the acoustical and optical longitudinal waves and acoustical and optical transverse waves, though they are not linearly polarized but elliptically polarized in general cases. When, however, $q$ is small, they reduce exactly to longitudinal or transverse waves. (Waves in the direction of $\boldsymbol{q}=q\boldsymbol{i}_j$, that is, those dealt with in ($A1$) are always linearly polarized.) Another remarkable fact in the present case is that for longitudinal waves the acoustical mode and the optical mode degenerate at the corners of the Brillouin zone, $\boldsymbol{q}=\pm(4\pi/(3a))\boldsymbol{j}_j$ (i.e. $P$ in Fig. 3). This degeneracy is due to the symmetry of the crystal.

There are other cases that the above two where the equation (5) is soluble, for example, $\boldsymbol{q}\approx0$ and $\boldsymbol{q}\approx\pm(4\pi/(3a))\boldsymbol{j}_j$.

When $\boldsymbol{q}$ is small, we find, with the help of the perturbation theory, that the frequencies of the longitudinal and transverse acoustical modes are given by

$$\omega=(\kappa a^2/M)^{1/2}\{(\kappa+18\mu)/(8(\kappa+6\mu))\}^{1/2}|\boldsymbol{q}|\,, \quad (17)$$

$$\omega=(\kappa a^2/M)^{1/2}\{3\mu/(2(\kappa+6\mu))\}^{1/2}|\boldsymbol{q}|\,. \quad (18)$$

Sound velocities determined by these equation agree completely with those calculated on the basis of the semi-continuum theory by Komatsu and Nagamiya[1]. The values of $\kappa$ and $\mu$ estimated by them from the observed force constants of planar vibrations of benzen molecule are

$$\kappa=6.71\times10^5\ \text{dyne/cm}$$

$$\mu=0.48\times10^5\ \text{dyne/cm}\,.$$

($B$) *Vibration perpendicular to the plane*

The normal modes of vibrations perpendicular to the plane are determined from the remaining one of the two separated secular equations;

$$\begin{bmatrix} 2\kappa'-\lambda & -W' & 0 & -2\kappa'\cos(\boldsymbol{c}\cdot\boldsymbol{q}/2) \\ -W'^{*} & -\lambda & 0 & 0 \\ 0 & 0 & -\lambda & -W' \\ -2\kappa'\cos(\boldsymbol{c}\cdot\boldsymbol{q}/2) & 0 & -W'^{*} & 2\kappa'-\lambda \end{bmatrix} \cdot \begin{bmatrix} e(A,\boldsymbol{q}) \\ e(B,\boldsymbol{q}) \\ e(C,\boldsymbol{q}) \\ e(D,\boldsymbol{q}) \end{bmatrix} = 0 . \tag{19}$$

where

$$e(X,\boldsymbol{q})=e(X,\boldsymbol{q})\boldsymbol{k} ,$$
$$\lambda=M\omega^2-(4/3)\mu'-(2/9)\mu'X(\boldsymbol{q}) ,$$
$$W'=(2/3)\mu'\{X(\bar{\boldsymbol{q}}/\sqrt{3})+iY(\bar{\boldsymbol{q}}/\sqrt{3})\} , \tag{20}$$

It is easy to solve this secular equation. The roots are found to be

$$\omega^2=M^{-1}\{(4/3)\mu'+(2/9)\mu'X(\boldsymbol{q}) + \alpha_1'-\sqrt{\alpha_1'^2+|\beta'|^2}\} , \tag{21}$$
$$\omega^2=M^{-1}\{(4/3)\mu'+(2/9)\mu'X(\boldsymbol{q}) + \alpha_1'+\sqrt{\alpha_1'^2+|\beta'|^2}\} , \tag{22}$$
$$\omega^2=M^{-1}\{(4/3)\mu'+(2/9)\mu'X(\boldsymbol{q}) + \alpha_2'-\sqrt{\alpha_2'^2+|\beta'|^2}\} , \tag{23}$$
$$\omega^2=M^{-1}\{(4/3)\mu'+(2/9)\mu'X(\boldsymbol{q}) + \alpha_2'+\sqrt{\alpha_2'^2+|\beta'|^2}\} , \tag{24}$$

where

$$\alpha_1'=\kappa'\{1-\cos(\boldsymbol{c}\cdot\boldsymbol{q}/2)\} ,$$
$$\alpha_2'=\kappa'\{1+\cos(\boldsymbol{c}\cdot\boldsymbol{q}/2)\} ,$$
$$\beta'=(2/3)\mu'\{X(\bar{\boldsymbol{q}}/\sqrt{3})+iY(\bar{\boldsymbol{q}}/\sqrt{3})\} .$$

when the projection of $\boldsymbol{q}$ on the net plane, $\boldsymbol{q}\cdot\boldsymbol{S}_0$, is small, the formulas (21) and (23) reduce to

$$\omega^2=\{\mu' a^4/(144\,M)\}|\boldsymbol{q}\cdot\boldsymbol{S}_0|^4 + (2\kappa'/M)\begin{cases}\sin^2(\boldsymbol{c}\cdot\boldsymbol{q}/4) \\ \cos^2(\boldsymbol{c}\cdot\boldsymbol{q}/4) .\end{cases} \tag{25}$$

when we neglect higher order terms of $\kappa'/\mu'$ than the first order. This formula has the same form as that derived of the basis of semi-continuum model[1]. Komatsu[7] estimated the numerical value of $\{\kappa'/(2M)\}^{1/2}$ from the observed compressibility and determined the value of $(1/(2\pi)^2)\{\mu' a^4/(144\,M)\}^{1/2}$ by making the calculated specific heat curve fit the experimental one in the temperature range from 15° to 60°K. Using his results, the values of $\kappa'$ and $\mu'$ are determined to be

$$\kappa'=5.57\times10^3\ \text{dyne/cm}$$
$$\mu'=2.92\times10^5\ \text{dyne/cm} .$$

We employ these values for $\kappa'$ and $\mu'$. The ratio of $\kappa'$ to $\mu'$ is of order $10^{-2}$, so we are allowed to neglect the higher order terms of $\kappa'/\mu'$.

A remarkable fact in the vibrations perpendicular to the plane is that when $\boldsymbol{c}\cdot\boldsymbol{q}=0$ the lower frequencies (25) are proportional to $|\boldsymbol{q}|^2$.

## § 3. Frequency Distribution

### (*A*) *Vibrations in the plane*

For these branches we employ the method developed by Houston[11] for cubic lattice. First, we define $f(\nu,\varphi)$ as frequency distribution function along a line of azimuthal angle $\varphi$ in the basal hexagon of the Brillouin zone (see Fig. 3). Since the contours of constant frequency in the $\boldsymbol{q}$-space are cylindrical with axes parallel to $\boldsymbol{k}$, as was mentioned in section 2 (A), we can confine ourselves to the basal plane. From the symmetry about the $\boldsymbol{k}$-axis in the Brillouin zone we can expand $f(\nu,\varphi)$ in a Fourier series of $\cos 6n\varphi (n=0,1,2,\cdots)$ as

$$f(\nu,\varphi)=f_0(\nu)+f_1(\nu)\cos6\varphi+\cdots , \tag{26}$$

We have solved the secular equation along two different directions $\boldsymbol{q}=q\boldsymbol{i}_j$ and $\boldsymbol{q}=q\boldsymbol{j}_j$. Hence two distribution functions, $f(\nu,0)$ and $f(\nu,\pi/6)$, along these particular directions have become available. We take the first two terms of (26) and neglect the higher terms. To this approximation $f_0(\nu)$ can be determined by the simultaneous equations:

$$f(\nu,0)=f_0(\nu)+f_1(\nu) ,$$
$$f(\nu,\pi/6)=f_0(\nu)-f_1(r) .$$

With a further simplification of replacing the basal hexagon by a circle of the same area, the total distribution function becomes

$$f(\nu)=(2\pi/c)\int_0^{2\pi} f(\nu,\varphi)d\varphi=\{(2\pi)^2/c\}f_0(\nu)$$
$$=\{(2\pi^2)/(2c)\}\{f(\nu,0)+f(\nu,\pi/6)\} . \tag{27}$$

Curves for the total frequency distribution functions corresponding to the four branches ear shown in Fig. 4 to Fig. 7.

### (*B*) *Vibrations perpendicular to the plane*

Though we have rigorous solutions (21)–(24) for these vibrations, it is very laborious to calculate the frequency distribution functions from them. We shall replace the contours of

constant frequency in the Brillouin zone by approximate ones from which we can easily obtain the frequency distribution functions in simple closed forms.

First, let us consider the lower frequency branches (21) and (23). Instead of considering these two, we extend the Brillouin zone to a size twice as large in the direction of $\boldsymbol{k}$ as the original one and consider the branch (21) only; this is allowed since $\alpha_2'$ of (23) in the original zone is replaced by $\alpha_1'$ of (21) in the extended part of the zone. Then, for (21), we employ the approximate frequency formula of the form

$$\nu^2=A^2(1+\mathcal{E}\cos 6\varphi)|\boldsymbol{q}\cdot\boldsymbol{S}_0|^4+B^2\sin^2(\boldsymbol{c}\cdot\boldsymbol{q}/4)\,, \tag{28}$$

$\nu_0'=(2\pi)^{-1}(2\kappa'/M)^{1/2}=3.76\cdot 10^{12}\ \mathrm{sec}^{-1}$
$(\Theta_0'=h\nu_0'/k=180°\mathrm{K})$

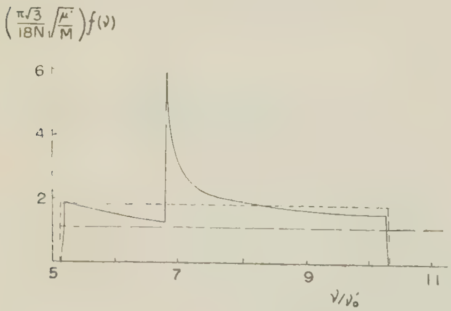

Fig. 12. The frequency distribution function for the higher frequency modes of the vibrations perpendicular to the plane.

which is a modification of (25). For each given $\nu$-value $A$, $\mathcal{E}$ and $B$ are so determined that the approximate contour given by (30) passes the points where the true contour cuts the lines OP, OQ and OR′ in Fig. 3. In this way we get $A$, $\mathcal{E}$ and $B$ as functions of $\nu$. In particular, $B(\nu)$ turns out to be nearly constant and equal to $(2\pi)^{-1}(\kappa'/M)^{1/2}$. The curves of $A(\nu)$ and $\mathcal{E}(\nu)$ are shown in Fig. 8 and the contours of constant frequency in the enlarged Brillouin zone are shown in Fig. 9.

With a further simplification of replacing the Brillouin zone by a circular cylinder, the number of modes, $N(\nu)$, with frequencies less than $\nu$ becomes

$$N(\nu)=\{V/(2\pi)^3\}\int_0^{2\pi}\int_{-q_{z,m}}^{q_{z,m}} q\cdot S_0|^2 dq_z d\varphi \tag{29}$$

where $V$ is the volume of crystal and $q_{z,m}$ is

$$q_{z,m}=\begin{cases}(4/c)\sin^{-1}(\nu/\nu_0') & (\nu/\nu_0')\leq 1\\ 2\pi/c & (\nu/\nu_0')\geq 1\ ,\end{cases}$$

$\nu_0$ is $B$, i.e. $(2\pi)^{-1}(2\kappa'/M)^{1/2}$. The frequency distribution function is given by differentiating $N(\nu)$ with respect to $\nu$:

$$f(\nu)=dN(\nu)/d\nu\ ,$$

From (30) and (31) $f(\nu)$ is calculated to be

$$\begin{aligned}f(\nu)=&\{2V/(4\pi^2)\}(C(\nu)/A(\nu))\\&\times[(\nu/\nu_0')K(\nu/\nu_0')-\nu_0\{(A'(\nu)/A(\nu))\\&-(C'(\nu)/C(\nu))\}\\&\times\{(1-(\nu/\nu_0')^2K(\nu/\nu_0')-E(\nu/\nu_0')\}]\\&\quad\text{for } (\nu/\nu_0')\leq 1\ ,\\f(\nu)=&\{2V/(4\pi^2)\}(C(\nu)/A(\nu))\\&\times[K(\nu_0'/\nu)+\nu\{(A'(\nu)/A(\nu))\\&-(C'(\nu)/C(\nu))\}\\&\times E(\nu_0'/\nu)]\\&\quad\text{for } (\nu/\nu_0')\geq 1\ ,\end{aligned}\tag{30}$$

where $C(\nu)$ is

$$C(\nu)=(2/\pi)(1+\mathcal{E}(\nu))^{-1/2}\times K(\{2\mathcal{E}(\nu)/(1+\mathcal{E}(\nu))\}^{1/2})\ ,$$

$K(x)$ and $E(x)$ are eliptic integrals of the first and second kinds, and $A'(\nu)$ and $C'(\nu)$ are the derivatives of $A(\nu)$ and $C(\nu)$ with respect to $\nu$.

For the higher frequency branches, (22) and (24), we employ in the enlarged Brillouin zone a single approximate contour expressed by

$$\nu^2=\nu^2_m-A_1(1+\mathcal{E}_1\cos 6\varphi)|\boldsymbol{q}\cdot S_0|^2+B^2\sin^2(\boldsymbol{c}\cdot\boldsymbol{q}/4)\ , \tag{31}$$

$\nu_m$ being the maximum frequency of these modes. In the same manner as above, we get $f(\nu)$ for the higher frequency modes, after simpler calculations. The curves of $A_1(\nu)$ and $\mathcal{E}_1(\nu)$ are shown in Fig. 10. The courves of $f(\nu)$ are shown in Fig. 11 and Fig. 12.

## § 4. Specific Heat

The specific heat at constant volume of the lattice vibrations is given by the formula

$$C_v=k\int_0^{\nu_{\max}}(h\nu/kT)^2\exp(h\nu/kT)\times\{\exp(h\nu/kT)-1\}^{-2}\}f(\nu)d\nu \quad (32)$$

where $k$ is the Boltzmann constant. Using the results of the previous section for $f(\nu)$, we get $C_1$ and $C_2$ which are contributions from the vibrations in the plane and perpendicular to the plane, respectively. However, for the optical branches we need not use the results calculated in the previous section for $f(\nu)$; it is sufficient to use its mean values given by $(\nu_2-\nu_1)^{-1}\int_{\nu_1}^{\nu_2}f(\nu)d\nu$ where $\nu_1$ and $\nu_2$ are the lower and upper limits of the optical branch; the errors produced by this procedure are negligible. The constant distribution functions with this mean value are shown by dotted lines in Fig. 6, Fig. 7 and Fig. 12.

Contributions from the electronic specific heat is negligible below 300°K as confirmed by Komatsu and Nagamiya1). The values of the $C_p-C_v$ correction are calculated by the formula

$$C_p-C_v=AC_p^2T\,,\quad A=\alpha^2V/(C_p^2K)$$

with values $\alpha=2.2\times10^{-5}\text{deg}^{-1}$, $C_p=1.88$ cal $\text{deg}^{-1}\text{mol}^{-1}$ at 300°K and $K=2.98\times10^{-12}\text{cm}^2$ dyne. The results of the calculation are shown in Fig. 13 and Table I.

## § 5. Conclusion and Discussion

The calculated specific heat values are in very good agreement with the recent measurements by DeSorbo8) with Ceylon natural graphite whose crystallite size is larger than 400Å in the direction of the ***c***-axis. The agreement is within experimental errors in the temperature range 45°K to 300°K. The measurements by DeSorbo and Tyler2) in 1953 (dotted curve in Fig. 11) were made with Acheson graphite, CS grade, whose crystallite size in the ***c***-direction was about 230 Å. Considerably large differences between these two series of measurements might be due to the effect of the crystallite size. Our culculated values can be better compared with the measurements with Ceylon natural samples.

The semi-continuum treatment made by Komatsu and Nagamiya1) explained the general behaviors of the specific heat curve over the whole temperature range and its refinement made by Komatsu7) explained in an excellent way the behaviors below 60°K down to 1.5°K. The latter calculation showed small deviations of the theoretical values from the observed ones above 60°K, which may be attributed to the failure of his semi-continuum treatment, particularly as regards the vibrations perpendicular to the planes. The present calculation eliminates such deviations up to 300°K. However, the following points must be noted in spite of the excellent agreement. First, the force constants determined by Komatsu in the manner mentioned in § 1 and used by the present calculation without alteration, cannot be claimed to be very accurate, since three of them were determined in certain approxi-

mate ways and the remaining one in such a way as to obtain the best fit with experiment; hence possible errors in the former must have been cancelled to a certain extent by that of the latter. Secondly, our $f(\nu)$'s are approximate and particularly crude near the zone boundary, though the details of the frequency distribution in this region cannot appreciably affect the specific heat curve. Anyhow, however, the success of the present theory supports the reasonableness of our assumption of the types of forces and the magnitudes of the adopted force constants.

It should, in principle, be possible to derive significant informations about the interatomic forces from the specific heat data in highly anisotropic cryatals, such as graphite, by a proper theoretical interpretation. For such substances, even the low frequency part of the spectrum consists of a number of branches whose frequency spectra are of different structures, so that the specific heat at low temperatures is a superposition of components with various temperature dependences. In graphite, the specific heat in the temperature range 15°K to about 100°K consists approximately of two components. One of them comes from the vibrations in the plane and obeys the simple two-dimensional $T^2$-law and the other from the vibrations perpendicular to the plane and has a more complex temperature dependence. The latter vibrations are not simply two-dimensional and are characteristic of the graphite-like lattice. They relate to weak restoring forces associated with changes in distances between adjacent sets of planes and to strong bending forces of the planes($\kappa' \ll \mu'$). When both $|\boldsymbol{q}\cdot\boldsymbol{S}_0|$ and $(\boldsymbol{q}\cdot\boldsymbol{k})$ are small, the frequency distribution has a linear $\nu$-depencence according to the frequency equation, $4\pi^2\nu^2=\{\mu' a^4/(144M)\}|\boldsymbol{q}\cdot\boldsymbol{S}_0|^4+\{\kappa' c^2/(8M)\}(\boldsymbol{q}\cdot\boldsymbol{k})^2$, Both terms of the right-hand side are effective and the specific heat is proportional to $T^2$. When $\nu$ is large enough so that the contour of constant $\nu$ crosses the upper and lower surfaces of the enlarged Brillouin zone (see § 3 (*B*)), one can neglect the second term in (25); then only the bending forces become effective. In the semi-continuum theory the frequency distribution function in this higher frequency range is almost independent of $\nu$, that is, it is nearly constant and the specific heat curve comes nearer to a straight line. In the Born-von Kármán treatment (see Fig. 8), this $\nu$-independent part is more obscure since equation (25) is not valid in this range of $\nu$. Furthermore, the frequency distribution function in the latter treatment tends to infinity at $\nu=\nu_0'$ and $\nu=3.4\,\nu_0'$ (see also Fig. 8). Owing to these facts the specific heat arising from the vibrations perpendicular to the plane shows a complex temperature dependence, as shown in Fig. 14. Only at very low temperatures (below about 10°K) does it strictly obey the $T^2$-law. In the range 15° to 60°K, the specific heat obeys only approximately the $T^2$-law. More specifically speaking, the difference in the range 45° to 100°K between the experimental curve and the calculated $C_1$ shows such theoretical predictions but, below 45°K, they show more complicated behaviors which could only be explained by taking account of the influence of the shearing forces.

Newell⁹⁾, in discussing the vibrations perpendicular to the plane in a qualitative way, considered the following three possible types of forces: (1) central forces between atoms on different planes, (2) non-central forces between neighboring atoms in the same plane, which are proportional to their relative perpendicular displacements, and (3) valence forces for the bending of the planes. He showed that the modes of the vibrations are mostly determined by the relative magnitudes of these three types of forces. If the forces of type (1) and type (3) prevail, one obtains the same results as ours, but if the forces of type (1) and type (2) prevail, the results are as those found by Krumhansl and Brooks²⁾. However, the origin of the forces of type (2) is yet unclear.

We might consider the following situation. Atoms other than those directly in contact simply attract each other, so that the springs between nearest neighbors in each net plane will not be in their natural state. Attractions between atoms in the same net plane will have caused them shrink. Attraction between atoms on different net planes will bring the net planes together and cause them shrink, too, but, on the other hand, repulsions between for instance, $B$ atoms and $C$, $D$ atoms in Fig. 2 will cause the hexagons formed by the latter two kinds of atoms expand. We do not know whether the springs are elongated or compressed in the equilibrium state of the whole lattice. In order to take account of this situation, one is evidently not allowed to confine himself, beside forces (1) and (3), to merely non-central forces of the type (2) proposed by Newell, though his forces (or the negative of them) might approximately care for the surface tension (or pressure) of the planes. The general conclusion to be attained when such fine details of the interaction and the shearing force introduced by Komatsu are considered is that the low-frequency part of the lattice vibrations is essentially three-dimensional and consequently that the specific heat is proportional to $T^3$ at sufficiently low temperatures. Possibly the shearing force considered by Komatsu⁷⁾ is most important in view of his success at low temperatures.

We wish to express our deep thanks to Professor T. Nagamiya of Osaka University and Doctor K. Komatsu of our University for their continual kind advices and discussions. We are indebted to Doctor Warren DeSorbo of the General Electric Company Research Laboratory for supplying his experimental data and to Doctor Gorden F. Newell of Brown University for supplying copies of his works before publication.

# Virial Coefficients and Intermolecular Potential for Small Nonspherical Molecules

By Taro KIHARA, Yukio MIDZUNO and Shobu KANEKO

*Department of Physics, Faculty of Science, University of Tokyo*

(Received November 10, 1955)

It has been proved that for a special model of nonspherical intermolecular potential the nonspherical correction to the virial coefficients is equivalent to the quantum correction. The second and third virial coefficients of hydrogen has been investigated by use of this model, and the intermolecular potential has been determined, which can be compared with the result of quantum-mechanical calculations. The model has also been applied to the second virial coefficient between argon and hydrogen.

## § 1. Introduction

The equation of state of gases may be expressed in the form

$$pv=kT(1+Bv^{-1}+Cv^{-2}+\cdots)\,, \tag{1.1}$$

where $p$ is the pressure, $v$ is the volume per molecule, $k$ is the Boltzmann constant, and $T$ is the temperature. In this expression $B$, $C$, $\cdots$, which are functions of the temperature, are called second, third, $\cdots$ virial coefficients. These coefficients indicate the deviation of a real equation of state from that of the ideal gas. They have been given in terms of the interaction between molecules, or the intermolecular potential.

With regards the interaction between molecules, let us assume as usual the additivity of the intermolecular potential; we assume namely that the total potential energy be equal to the sum of the potential energies between pairs of molecules. Under this assumption the second and third virial coefficients have been calculated[1] for the Lennard-Jones potential between two molecules,

$$U(r)=\frac{U_0}{n-6}\left[6\left(\frac{r_0}{r}\right)^n-n\left(\frac{r_0}{r}\right)^6\right], \tag{1.2}$$

with two parameters $U_0$ and $r_0$, $n$ being chosen as 9 and 12. Here $r$ indicates the distance between the centers of molecules.

For this intermolecular potential the quantum-mechanical effect has also been calculated in the form of the series

$$B=B^{(0)}+\frac{\hbar^2}{4mkT}B^{(1)}+\left(\frac{\hbar^2}{4mkT}\right)^2B^{(2)}+\left(\frac{\hbar^2}{4mkT}\right)^3B^{(3)}+\cdots, \tag{1.3}$$

$$C=C^{(0)}+\frac{\hbar^2}{4mkT}C^{(1)}+\cdots \tag{1.4}$$

up to the terms explicitely given above[2]. Here $\hbar$ is Planck's constant divided by $2\pi$; $m$ is the mass of a molecule. Except the case of helium, terms proportional to the fourth or higher powers of $\hbar$ may be neglected at moderate temperatures. (We do not take account of the quantum-statistical effect, which is always negligible at temperatures where expansions (1.3) and (1.4) are practical.)

For monatomic molecules the intermolecular potential is a function of $r$ only and may be approximated by (1.2). The aim of the present paper is to treat *small* nonspherical molecules whose intermolecular potential is slightly different from the spherically symmetric potential (1.2). By means of a suitable model of molecules and by virtue of a relationship in regard to the model, the treatment is simple and perhaps instructive.

There are several investigations on the second virial coefficient of nonspherical molecules[3]; the third virial coefficient of nonspherical molecules is for the first time treated in this paper.

## § 2. A Molecular Model and a Formula

Let us assume within each molecule a distribution $\rho\geqq 0$ of potential source with normalized volume integral

$$\int\rho(\boldsymbol{s})d\boldsymbol{s}=1\,. \tag{2.1}$$

Here $\boldsymbol{s}$ is the radius vector to the source element from the molecular center defined by the "mean value" of the distribution, so that

$$\int \boldsymbol{s}\rho(\boldsymbol{s})d\boldsymbol{s}=0\ . \tag{2.2}$$

The intermolecular potential $V$ is assumed to be a superposition of a usual potential function $U$(e. g. of the type (1.2)) between source elements $\rho_1(\boldsymbol{s}_1)d\boldsymbol{s}_1$ of one molecule and those $\rho_2(\boldsymbol{s}_2)d\boldsymbol{s}_2$ of the other:

$$V=\iint \rho_1(\boldsymbol{s}_1)\rho_2(\boldsymbol{s}_2)U(|\boldsymbol{r}+\boldsymbol{s}_2-\boldsymbol{s}_1|)d\boldsymbol{s}_1d\boldsymbol{s}_2\ . \tag{2.3}$$

Here $\boldsymbol{r}$ is the radius vector from the center of molecule 1 to that of molecule 2.

We define the standard deviation $\delta$ of the distribution by

$$\delta^2=\int s^2\rho(\boldsymbol{s})d\boldsymbol{s}\ ,\quad s\equiv|\boldsymbol{s}|\ , \tag{2.4}$$

and assume that $\delta$ be sufficiently small in comparison with the molecular size.

For this model of molecule the virial coefficients of a simple gas may be expanded into double series in $\hbar$ and $\delta$. Up to the terms proportional to $\hbar^2$ and to $\delta^2$ hold

$$B=B^{(0)}+\left(\frac{\hbar^2}{4mkT}+\delta^2\right)B^{(1)}\ , \tag{2.5}$$

$$C=C^{(0)}+\left(\frac{\hbar^2}{4mkT}+\delta^2\right)C^{(1)}\ , \tag{2.6}$$

and similar relations as regards higher virial coefficients. A proof of this formula will be given in the next section. This formula shows that $\hbar^2/4mkT$ and $\delta^2$ are equivalent so far as both quantum and polyatomic effects are small.

## § 3. Proof of the Formula

With respect to (2.3) we have, up to the term of $\delta^2$,

$$|\boldsymbol{r}+\boldsymbol{s}_2-\boldsymbol{s}_1|=[r^2+s_2{}^2+s_1{}^2+2\boldsymbol{r}\cdot\boldsymbol{s}_2-2\boldsymbol{r}\cdot\boldsymbol{s}_1-2\boldsymbol{s}_2\cdot\boldsymbol{s}_1]^{1/2}$$

$$=r+\frac{1}{2r}(s_2{}^2+s_1{}^2+2\boldsymbol{r}\cdot\boldsymbol{s}_2-2\boldsymbol{r}\cdot\boldsymbol{s}_1-2\boldsymbol{s}_2\cdot\boldsymbol{s}_1)-\frac{1}{2r^3}(\boldsymbol{r}\cdot\boldsymbol{s}_2-\boldsymbol{r}\cdot\boldsymbol{s}_1)^2\ ,$$

$$U(|\boldsymbol{r}+\boldsymbol{s}_2-\boldsymbol{s}_1|)=U(r)+\frac{U'(r)}{2r}(s_2{}^2+s_1{}^2+2\boldsymbol{r}\cdot\boldsymbol{s}_2-2\boldsymbol{r}\cdot\boldsymbol{s}_1-2\boldsymbol{s}_2\cdot\boldsymbol{s}_1)$$

$$+\left(\frac{U''(r)}{2}-\frac{U'(r)}{2r}\right)\frac{(\boldsymbol{r}\cdot\boldsymbol{s}_2-\boldsymbol{r}\cdot\boldsymbol{s}_1)^2}{r^2}\ ,\ r\equiv|\boldsymbol{r}|\ .$$

Zeroth approximation to $V$ is the basic potential $U(r)$, and the first correction is, by use of (2.1), (2.2) and (2.4),

$$V-U(r)=\frac{U'(r)}{r}\delta^2$$

$$+\left(\frac{U''(r)}{2}-\frac{U'(r)}{2r}\right)\left[\int\rho_1(\boldsymbol{s}_1)\left(\frac{\boldsymbol{r}}{r}\cdot\boldsymbol{s}_1\right)^2d\boldsymbol{s}_1+\int\rho_2(\boldsymbol{s}_2)\left(\frac{\boldsymbol{r}}{r}\cdot\boldsymbol{s}_2\right)^2d\boldsymbol{s}_2\right].$$

What we need is the average with respect to all orientations of the two molecules, $r$ being kept constant:

$$\langle V-U(r)\rangle_{\mathrm{Av}}=\frac{\delta^2}{3}\left[U''(r)+2\frac{U'(r)}{r}\right].$$

Here we have used the relationships as

$$\left\langle\int\rho(\boldsymbol{s})\left(\frac{\boldsymbol{r}}{r}\cdot\boldsymbol{s}\right)^2d\boldsymbol{s}\right\rangle_{\mathrm{Av}}=\frac{1}{3}\int\rho(\boldsymbol{s})s^2d\boldsymbol{s}=\frac{1}{3}\delta^2$$

(The average with respect to orientations of a molecule for a fixed $\boldsymbol{r}$ is equal to the average with respect to the direction of $\boldsymbol{r}$ for a fixed orientation of the molecule.)

Let us denote the distance and the potential between $i$th and $j$th molecules by $r_{ij}$ and $V_{ij}$ respectively so that

$$\langle V_{ij}-U(r_{ij})\rangle_{\mathrm{Av}}=\frac{\delta^2}{3}\left[U''(r_{ij})+2\frac{U'(r_{ij})}{r_{ij}}\right].$$

Hence the classical configurational partition function for a system of $N$ identical molecules,

$$\frac{1}{N!}\int\cdots\int\left\langle\exp\left(-\frac{1}{kT}\sum_{i<j}V_{ij}\right)\right\rangle_{\mathrm{Av}}d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N\ ,$$

is given, up to the term of $\delta^2$, by

$$Q^{(0)}+\delta^2Q^{(1)}$$

$$Q^{(0)}=\frac{1}{N!}\int\cdots\int\exp\left(-\frac{\Phi}{kT}\right)d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N\ ,$$

$$Q^{(1)}=-\frac{1}{3kT}\frac{1}{N!}\int\cdots\int\exp\left(-\frac{\Phi}{kT}\right)$$

$$\times\sum_{i<j}\left[U''(r_{ij})+2\frac{U'(r_{ij})}{r_{ij}}\right]d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N\ .$$

Here

Table I. Second and third virial coefficients of hydrogen.

| $T$°K | $B$ Å$^3$ | $C\times10^{-2}$ Å$^6$ |
|---|---|---|
| 65.1 | −30.3 | 13.9 |
| 90.0 | − 9.2 | 18.2 |
| 123 | 4.9 | 14.9 |
| 173 | 15.1 | 10.1 |
| 223 | 20.0 | 9.6 |

L. Holborn, J. Otto; Zeits. f. Phys. **23** (1925) 1.

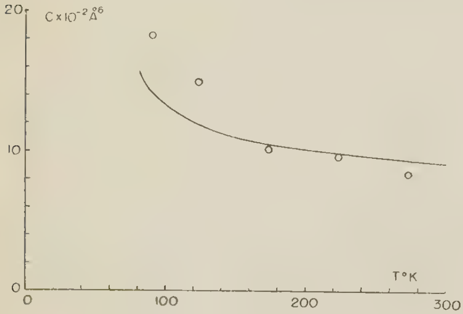

Fig. 1. The third virial coefficient of hydrogen compared with a curve for an intermolecular potential determined from the second virial coefficient.

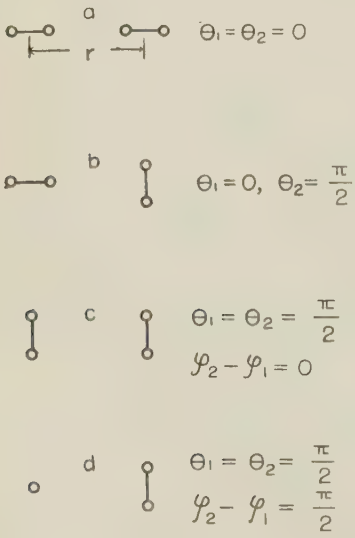

Fig. 2.

$$\Phi=\sum_{i<j}U(r_{ij})$$

is the zeroth approximation to the potential energy of the total system.

Since

$$U''(r_{ij})+\frac{2}{r_{ij}}U'(r_{ij})$$
$$=\frac{\partial}{\partial \boldsymbol{r}_i}\cdot\frac{\partial}{\partial \boldsymbol{r}_i}U(\boldsymbol{r}_{ij})$$
$$=\frac{1}{2}\left(\frac{\partial}{\partial_i}\cdot\frac{\partial}{\partial \boldsymbol{r}_i}+\frac{\partial}{\partial \boldsymbol{r}_j}\cdot\frac{\partial}{\partial \boldsymbol{r}_j}\right)U(r_{ij})$$
$$=\frac{1}{2}\sum_{k=1}^{N}\frac{\partial}{\partial \boldsymbol{r}_k}\cdot\frac{\partial}{\partial \boldsymbol{r}_k}U(r_{ij}),$$

$Q^{(1)}$ can be transformed into

$$Q^{(1)}=-\frac{1}{6kT}\frac{1}{N!}\int\cdots\int\exp\left(-\frac{\Phi}{kT}\right)\times\sum_{i=1}^{N}\frac{\partial}{\partial \boldsymbol{r}_i}\cdot\frac{\partial}{\partial \boldsymbol{r}_i}\Phi d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N$$

or

$$Q^{(1)}=-\frac{1}{6(kT)^2}\frac{1}{N!}\int\cdots\int\exp\left(-\frac{\Phi}{kT}\right)\times\sum_{i=1}^{N}\left(\frac{\partial}{\partial \boldsymbol{r}_i}\Phi\right)^2 d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N\,.$$

On the other hand the configurational partition function for spherical molecules with the intermolecular potential $U(r)$ is, up to the first quantum correction,

$$Q^{(0)}+\frac{\hbar^2}{4mkT}Q^{(1)}\,, \tag{3.2}$$

$Q^{(1)}$ being the same as above[4].

Combining (3.1) and (3.2) we finally obtain the partition function of the form

$$Q=Q^{(0)}+\left(\frac{\hbar^2}{4mkT}+\delta^2\right)Q^{(1)} \tag{3.3}$$

so far as terms of higher order can be neglected. The formula given in the preceding section can be derived from (3.3).

## § 4. Second and Third Virial Coefficients of Hydrogen at Moderate Temperatures

For hydrogen at moderate temperatures we may assume that both the quantum and the polyatomic effects can be treated as small perturbations.

Let the potential source of a hydrogen molecule be located at the two nuclei. Then the standard deviation $\delta$ is the one half of the internuclear distance, $\delta=0.37$Å. ($\hbar^2/4mkT=\delta^2$ at $T=44$°K). Let furthermore the basic potential function $U(r)$ in (2.3) be of the Lennard-Jones type (1.2) with $n=9$. Then $B^{(0)}$, $B^{(1)}$, $C^{(0)}$, $C^{(1)}$ in (2.5) and (2.6) are all known.

Using the formula (2.5) and the observed values of the second virial coefficient given in

Table I we can determine two parameters $U_0$ and $r_0$. The result is

$$U_0/k=39.8°\text{K}, \quad r_0=3.20\text{Å} . \tag{4.1}$$

Using these parameters and the formula (2.6) we can calculate the third virial coefficient. The calculated curve is compared in Fig. 1 with observed values given also in Table I. (The polyatomic correction is $\delta^2C^{(1)}/C^{(0)}=0.25$ at the Boyle temperature 109°K.)

We have been taking the electrostatic quadrupole of a hydrogen molecule not into account. The energy of quadrupole-quadrupole interaction is proportional to the square of the moment. When the virial coefficients are expanded into series with respect to the moment, however, the term of the square of the moment vanishes because of the orientational average. The first non-vanishing term is proportional to the 4th power of the moment and can consistently be neglected.

## § 5. Intermolecular Potential of Hydrogen

There are quantum-mechanical calculations of the intermolecular potential for hydrogen⁵⁾. The calculations are made for four mutual orientations *a*, *b*, *c*, and *d* as shown in Fig. 2. Here *r* is the distance between two centers, $(\theta_1, \varphi_1)$ and $(\theta_2, \varphi_2)$ are polar angles of both molecular axes in regard to the line connecting the centers. The potential curves are given in Fig. 3.

With these curves let us compare the result obtained in the preceding section. For this purpose we must take the quadrupole interaction into account.

Let us assume a point quadrupole at the molecular center along the axis in addition to the distribution of source of van der Waals' potential. As the moment of the quadrupole we adopt James and Coolidge's⁶⁾ value

$$q=0.124 \text{ electron charge Å}^2,$$

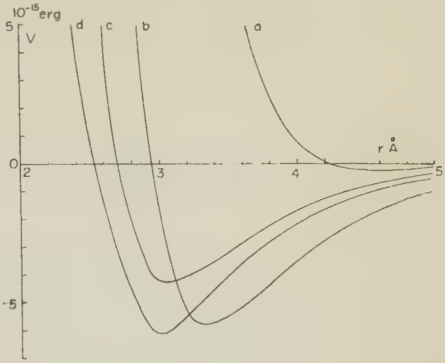

Fig. 3. Intermolecular potential of hydrogen calculated quantum-mechanically for several mutual orientations shown in Fig. 2. (From Hirschfelder, Curtiss and Bird: *Molecular Theory of Gases and Liquids* (Wiley, 1954) Fig. 14.4–1).

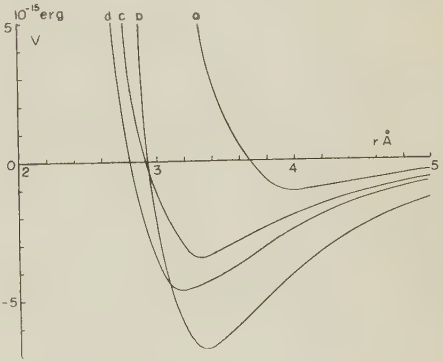

Fig. 4. Intermolecular potential of hydrogen determined from the virial coefficients. The four curves are for four orientations shown in Fig. 2. (Compare Fig. 3.)

with which the quadrupole-quadrupole interaction is given by the potential energy

$$\frac{3}{4}\frac{q^2}{r^5}[1-5\cos^2\theta_1-5\cos^2\theta_2-15\cos^2\theta_1\cos^2\theta_2$$
$$+2\{\sin\theta_1\sin\theta_2\cos(\varphi_2-\varphi_1)-4\cos\theta_1\cos\theta_2\}^2] .$$

Then the total intermolecular potential becomes

$$\frac{2}{4}U(r)+\frac{1}{4}U(r+2\delta)+\frac{1}{4}U(r-2\delta)+6\frac{q^2}{r^5} \qquad \text{for position } a,$$

$$\frac{2}{4}U(\sqrt{(r+\delta)^2+\delta^2})+\frac{2}{4}U(\sqrt{(r-\delta)^2+\delta^2})-3\frac{q^2}{r^5} \qquad \text{for position } b,$$

$$\frac{2}{4}U(r)+\frac{2}{4}U(\sqrt{r^2+(2\delta)^2})+\frac{9}{4}\frac{q^2}{r^5} \qquad \text{for position } c,$$

$$\frac{4}{4}U(\sqrt{r^2+(2\delta)^2})+\frac{3}{4}\frac{q^2}{r^5} \qquad \text{for position } d.$$

Table II. Second virial coefficient between argon and hydrogen.

| $T$°K | $B_{AB}$ Å$^3$ |
|---|---|
| 298 | 13.6 |
| 323 | 15.4 |
| 348 | 18.3 |
| 373 | 20.8 |
| 398 | 22.9 |

| 447 | 26.2 |

E. A. Guggenheim, Mixtures (University Press, Oxford, England, 1952) p. 160.

the four curves being shown in Fig. 4, which correspond to four curves in Fig. 3.

## § 6. Second Virial Coefficient between Unlike Molecules

The second virial coefficient for a binary mixture of species $A$ and $B$ is expressed by

$$B_{AA}\xi_A^2+2B_{AB}\xi_A\xi_B+B_{BB}\xi_B^2$$

Here $\xi_A$ and $\xi_B=1-\xi_A$ are mole fractions of the species $A$ and $B$, respectively; $B_{AA}$ is the virial coefficient for molecule $A$, $B_{BB}$ that for molecule $B$; $B_{AB}$ is the virial coefficient between $A$ and $B$, which we will treat in this section.

The potential $V_{AB}$ between $A$ and $B$ is assumed to be a superposition of the mutual potential function $U_{AB}$ between the source element $\rho_A$ of molecule $A$ and $\rho_B$ of molecule $B$:

$$V_{AB}=\iint\rho_A(\boldsymbol{s}_1)\rho_B(\boldsymbol{s})U_{AB}(|\boldsymbol{r}+\boldsymbol{s}_2-\boldsymbol{s}_1|)d\boldsymbol{s}_1d\boldsymbol{s}_2$$

compare (2.3)). Let the standard deviation be $\delta_A$ and $\delta_B$ respectively. Then mixed second irial coefficient is, up to the first corrections, f the form

$$B_{AB}=B_{AB}^{(0)}+\left(\frac{\hbar^2}{8m^*kT}+\frac{\delta_A^2+\delta_B^2}{2}\right)B_{AB}^{(1)}, \tag{6.1}$$

where $m^*$ is the reduced mass (compare (2.5)).

Let us treat, as an example, mixtures of rgon and hydrogen which we denote by species $A$ and $B$ respectively. We assume $\delta_A=0$, $\delta_B=0.37$Å. Using the data given in Table II and the basic potential

$$U_{AB}(r)=U_{0AB}\left[2\left(\frac{r_{0AB}}{r}\right)^9-3\left(\frac{r_{0AB}}{r}\right)^6\right],$$

we can determine the parameters $U_{0AB}$ and $r_{0AB}$. The result is

$$U_{0AB}/k=60.3°\text{K},\quad r_{0AB}=3.77\text{Å}.$$

Since the corresponding parameters for argon are[7)]

$$U_{0AA}/k=89.7°\text{K},\quad r_{0AA}=3.29\text{Å}$$

and those for hydrogen is given by (4.1), we obtain

$$\frac{2r_{0AB}}{r_{0AA}+r_{0BB}}-1=0.04$$

$$\frac{U_{0AB}}{(U_{0AA}U_{0BB})^{1/2}}-1=0.01\ .$$

Namely $r_{0AB}$ is approximately equal to the arithmetical mean of $r_{0AA}$ and $r_{0BB}$, $U_{0AB}$ to the geometrical mean of $U_{0AA}$ and $U_{0BB}$. These relations are similar to those verified by Kihara and Koba[8)] for the "core-model" of molecules.

# On the Two Schemes of Approximating the Transport Coefficients (Chapman – Cowling and Kihara)

By S. C. SAXENA

*Indian Association for the Cultivation of Science, Calcutta-32, India*

(Received January 14, 1956)

The three elementary transport coefficients and the isotopic thermal separation ratio have been evaluated over an extensive range of temperatures by utilizing the expressions derived on the approximation procedure due to Kihara, for the Lennard-Jones 12:6 model. These values have been compared with the corresponding and a still higher order approximation values calculated on an alternative approximation scheme of Chapman and Cowling. The comparison of the results obtained on the two schemes of approximation indicates that the simple expressions of Kihara are more accurate and preferable even to the corresponding higher approximation expressions of Chapman and Cowling.

## § 1. Introduction

Chapman and Cowling1) have expressed the transport coefficients as ratios of infinite determinants which they subsequently expand into an infinite series by applying the theory of determinants. The various orders of Chapman and Cowling approximation correspond to taking into account increasing number of terms of this infinite series. On the other hand Kihara2)3) noted that the off-diagonal elements of these determinants are small compared to the diagonal elements. His approximation scheme is based on expanding the infinite determinants in powers of the off-diagonal elements in which the second and higher order temperature derivatives of collision integrals and also the third and higher powers of the first derivative are neglected. Kihara's approximation scheme leads to the results which are considerably simpler than the corresponding Chapman and Cowling expressions and are easier for computational purposes as these involve fewer collision integrals. Kihara's expressions are known to be more accurate in the case of a Lorentzian gas with a simple intermolecular potential. The purpose of the present report is to critically examine the two approximation schemes for the more realistic molecular model of the Lennard-Jones 12:6 type and further to estimate the relative accuracy of Kihara's expressions over those of Chapman and Cowling which are known to a still higher degree of approximation. Mason4) has recently made such quantitative comparison of the isotopic thermal diffusion ratio for his modified Buckingham Exp-six model.

## § 2. Calculation and Discussion of Transport Coefficients

Kihara's expressions for the second approximation to the correction factors for viscosity, $f_\eta^{(2)}$, thermal conductivity, $f_\lambda^{(2)}$, and diffusion, $f_D^{(2)}$, of pure gases and the first approximation to the thermal separation ratio, $[K_T]^*_1$, for a mixture of heavy isotopes are given in the book by Hirschfelder, Curtiss and Bird5). Making use of these expressions we have computed the values of $f_\eta^{(2)}$, $f_\lambda^{(2)}$, $f_D^{(2)}$ and $[K_T]_1^*$ over an extensive range of temperatures and these are recorded in tables I and II. The symbol * means reduced quantities, compare reference 5.

On Chapman and Cowling scheme of approximation values of $f_\eta^{(3)}$ and $f_\lambda^{(3)}$ are given in reference 5, while that of $f_D^{(3)}$ have been recently reported by Saxena6), over an extensive range of temperatures and these values are almost identical with those given in table I.

Mason4) has derived the expression for the second approximation to $[K_T]^*$ according to the method of Chapman and Cowling and recently Saxena and Srivastava7) have developed expressions for the additional collision integrals occuring in $[K_T]_2^*$ for the Lennard-Jones 12:6 model. The values of these collision integrals have been reported by Saxena8) over a large temperature range and these values along with those given by

Hirschfelder, Bird and Spotz⁵⁾ have been utilized to calculated $[K_T]_2^*$. In table III are recorded the computed values of $[K_T]_2^*$ along with $[K_T]_1^*$ values on the two approximation schemes over a wide range of temperatures. It is interesting to note that first approximation expression of Kihara yields values which are in excellent agreement with those obtained from the tedious calculations of Chapman and Cowling second approximation formula. Thus the over-all accuracy of Kihara's expressions seems to be somewhat better and are definitely preferable to the complicated expressions of Chapman and Cowling. Mason⁴⁾ too has arrived at a similar conclusion for his Exp-Six model.

Similar computation have been performed for the thermal and interdiffusion coefficients of binary inert gas mixtures, and these again have established the supriority of Kihara's formulae.

## Acknowledgement

It is a great pleasure to thank Prof. B. N. Srivastava for helpful discussions and to Dr. T. Kihara of the University of Tokyo, Japan, for some useful suggestions. An award of a research scholarship from the Council of Scientific and Industrial Research, New Delhi, is also gratefully acknowledged.

# Adsorption and Surface Potential of Semi-conductors, Part II. Surface Vacancies and its Reaction with Oxygen on ZnS

By Akio KOBAYASHI and Shinji KAWAJI

*Research Institute for Catalysis, Hokkaido University, Sapporo*

(Received October 6, 1955)

The surface potential and its change with illumination for the (110) cleavage surface of zincblende have been measured. It was found that electron trap centers were created near the surface of the crystal, when the crystal was heat-treated in vacuum, and these traps were diminished by the reaction with oxygen. The traps are attributed to sulphur vacancies which are formed by evaporation of sulphur component by the following reasons; (1) the higher the temperature of heattreatment in vacuum, the number of traps becomes the larger and (2) after heat-treatment at 350°C for 4 hours in vacuum, the surface becomes charged positively. It is concluded that oxygen reacts with these traps making the surface to be charged negatively.

An overall change of surface potential in the range between the initial and saturated adsorption agrees fairly well with the initial heat of adsorption observed, as expected theoretically.

## § 1. Introduction

Chemisorbed molecules, which are adsorbed in an ionic form on the surface of semiconductors, induce the opposite charge in the crystal near the surface and thus a barrier layer due to space charge is formed next to the free surface. When the surface is illuminated with light to generate conduction electrons and free holes in the crystal, photo-currents induced in the barrier will produce a change of the surface potential. This is the recently developed method for studying the free surface after Brattain and Bardeen (1). They studied on silicon and germanium, Tanaka and Aoki (2) and Wlerick (3) studied on the surface of the single crystals of cadmium sulphide with this method and found that the surface of CdS was charged negatively either in air or in vacuum. The authors studied previously on ZnS phosphor with Brattain's method and observed enhanced adsorption of oxygen with illumination (4). It was found the change of the contact potential with illumination, $(\Delta\text{c.p.})_L$, increased with oxygen pressures and was always positive showing the work function of the crystal to be decreased with illumination. The results showed the surface of ZnS charged always negatively in oxygen ambient.

In the present paper the authors have studied on the cleavage surface of zincblende which might have more definit nature of the surface than that of the powder of the phosphor studied by the previous paper.

## § 2. Experiments

A natural zincblende crystal used was transparent and slightly straw-coloured. Contact potentials of the cleavage surface (110) of the crystal were measured by the Kelvin method. The geometry of the crystal was $8\times5\ \text{mm}^2$ in area and 0.7 mm thick. The back of the crystal was coated with aquadag to ensure good contact with the lead. Fig. 1 shows the absorption curve of the crystal and

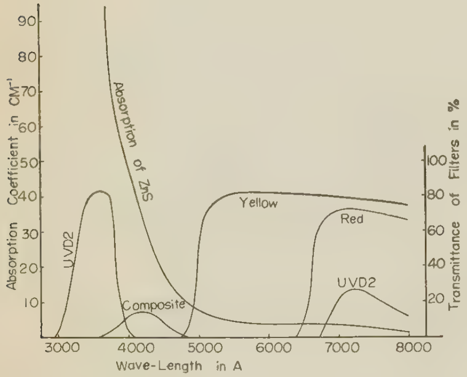

Fig. 2. The absorption curve of the sample of ZnS and spectral transmission of the filters.

the transmission curves of filters employed.

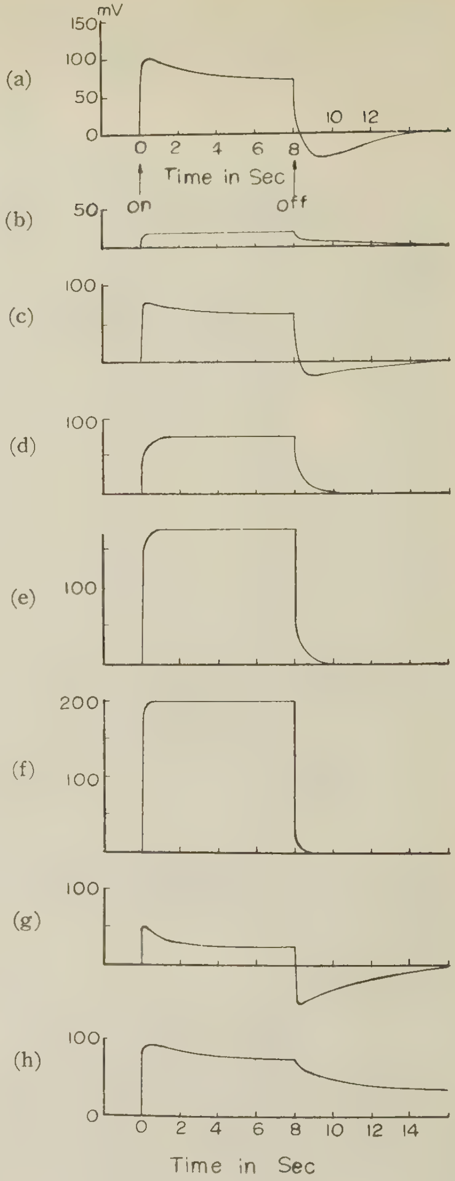

Fig. 3. Variation of rise and decay of the change of contact potential with illumination of 3650 A light for successive treatments.
(a) The fresh crystal evacuated for 2 hours at 180°C, then cooled to room temperature, (b) at 100°C, (c) then cooled to room temperature, (d) evacuated at 200°C for 2 hours, then cooled to room temperature, (e) at pressure of $9\times10^{-4}$ mmHg of oxygen, (f) at $5\times10^{-2}$ mmHg of oxygen, (g) after heattreatment in vacuum and (h) at $2.3\times10^{-3}$ mmHg of oxygen at 85°C.

The sample was first observed being mounted in a bulb of a kinetic vacuum system described in the previous paper, then mounted in a sealed-off-type bulb shown in Fig. 2. In this figure *H* is a sample holder made of a brass block having four filaments to serve for heater in it. Man can rotate the holder around a center rod *C* of 2 mm in dia. with a magnetic device. Temperatures of the holder is measured with a copper-constantan junction. The stem tube of the center rod serves for a small reservoir of liquid nitrogen. The surface is illuminated by light from an ultra high pressure mercury lamp of 500 watts in conjunction with filters through the grid of the reference electrode which is gold-plated and removes 15 per cent of the light. The distance between the reed and the sample is about 1 mm and amplitude of vibration of the reed is about 0.1 mm at resonance.

After carefully preheating and evacuating of the system, the getter is flashed, then the bulb is sealed off. Then gold is evaporated onto the reed from the filament *F*. During this procedure the window for light above the reed is covered by a screen *S* in order to prevent it from darkning. The vibrating reed is driven electromagnetically at its resonant frequency of 310 cps. A self-balancing circuit with phase detection is employed to record the changes of contact potential with ambient and with illumination on oscillograms.

The results obtained with the kinetic vacuum system are shown in Fig. 3 which represents that the time dependence of the change of contact potential with light, $(\Delta c.p.)_L$, depends remarkablly on whether the sample are heat-treated in vacuum or in oxygen atmosphere. When the crystal freshly cleaved was mounted in the bulb and evacuated for 2 hours at 180°C, then cooled to room temperature, the contact potential shown in Fig. 3 (a) overshoots on switching off the illumination of ultra-violet light having a peak of intensity at 3650 A. Fig. 3 (6) shows this overshooting vanishes at higher temperatures about 100°C. The overshooting appears again when the crystal is cooled in vacuum (Fig. 3 (c)).

After standing for six months in air, the crystal was heated in vacuum at 200°C for 2 hours and then cooled to room temperature ((d) in Fig. 3), then oxygen was introduced ((e) and (f)). After sequent heattreatment in vacuum for 2 hours, the overshooting of residual $(\Delta c.p.)_L$ again appeared at low temperature in vacuum and disappeared with introduction of oxygen at 85°C as shown in (g) and (h). It was found from the results of the above experiments that the overshooting of residual $(\Delta c.p.)_L$ disappeared with rising the temperatures of the crystal or with introduction of oxygen at somewhat higher temperatures, say 100°C, and appeared again with heattreatment in vacuum.

In succession of the above-mentioned experiments, the crystal was mounted in the bulb shown in Fig. 2 and evacuated thoroughly at 300°C for several hours, then sealed off from the pumping system. The temperature dependence of the residual $(\Delta c.p.)_L$ and the extinction effects with light with long wave-length were measured and then process of the change of contact potential and $(\Delta c.p.)_L$ resulted from abrupt introduction of oxygen has been observed. Fig. 4 shows oscillograms of $(\Delta c.p.)_L$'s for the sealed-off bulb. The lower curve in this figure shows the surface potential, which reaches an maximum abruptly with illumination of the U. V. light, decreases exponentially with time upto lower value than the initial. After the light is removed, it decreases rapidly furthermore by about 100 mV and then recovers slowly from negative residual $(\Delta c.p.)_L$ to the initial in few minutes. If the crystal be illuminated with the light

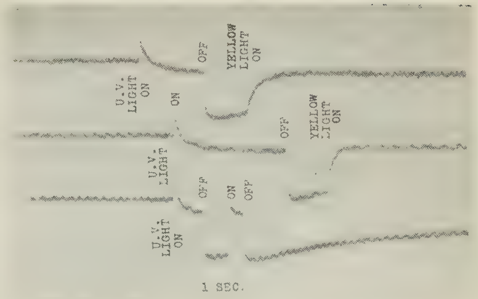

Fig. 4. Oscillograms of overshooting of residual $(\Delta c.p.)_L$ for the sealed-off bulb. The lower curve for switching on and off of the ultra-violet light, the middle curve showing extinction with the yellow light and the upper showing that with a half intensity of the yellow light.

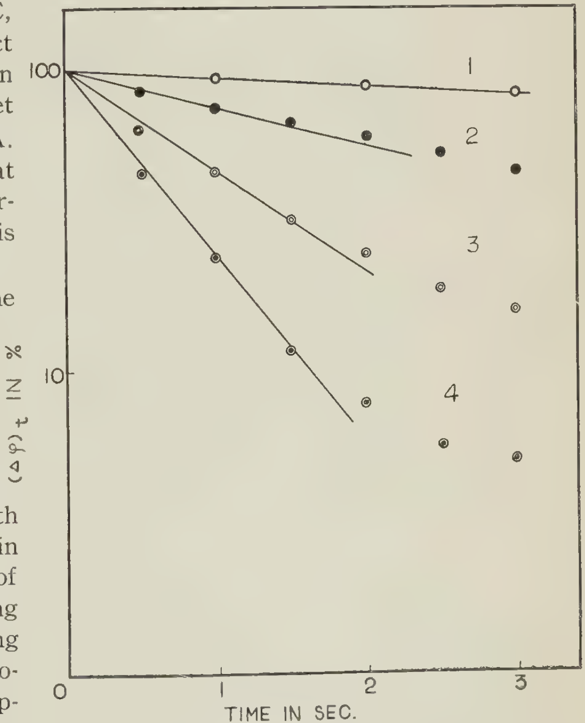

Fig. 5. The initial decays due to extinction of overshooting. Curve 1 for natural (thermal) decay, Curves 2, 3 and 4 for relative intensities of the yellow light 1/4, 1/2 and 1 respectively.

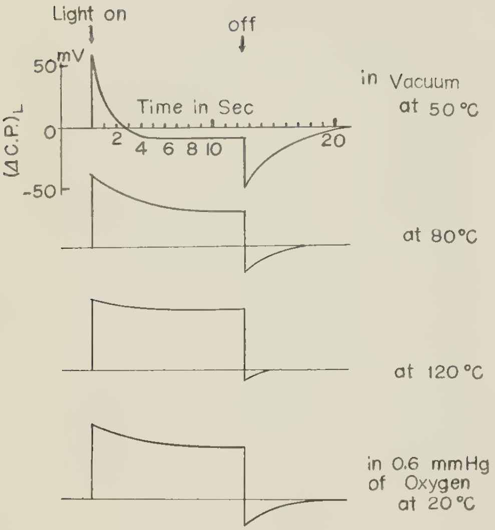

Fig. 6. Temperature dependence of overshooting.

passed through the yellow filter shown in Fig. 1 during this decay of the residual $(\Delta c.p.)_L$, extinction occurs as shown on upper curves of Fig. 4. This effect on the decay occurs also with infra-red light.

Since initial decays of extinction with the yellow light vary almost exponentially with time as shown in Fig. 5, one can obtain decay constants $\tau_L$ for illumination with the yellow light from the following equations denoting natural, i.e. thermal, decay constants as $\tau_0$ and apparent decay constants under illumination of yellow light as $\tau$,

$$(\Delta\varphi)_t=(\Delta\varphi)_0\exp(-t/\tau)$$

$$\frac{1}{\tau}=\frac{1}{\tau_0}+\frac{1}{\tau_L}$$

where $(\Delta\varphi)_0$ is the value of the residual $(\Delta$ c. p.$)_L$ at the beginning of illumination with the yellow light and $(\Delta\varphi)_t$ that after $t$ seconds.

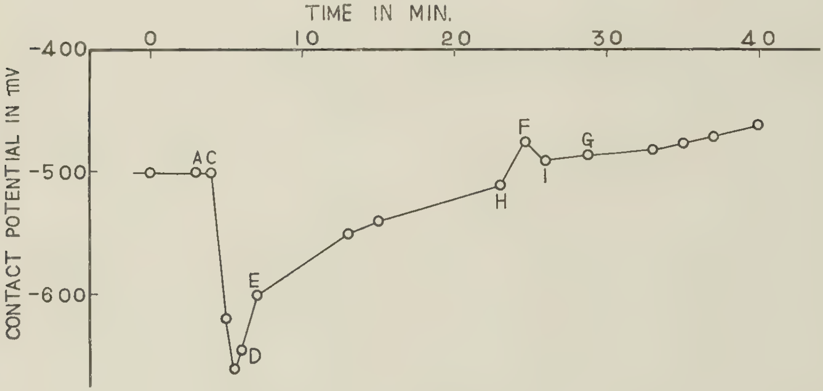

Fig. 7. The change of contact potential due to introduction of oxygen. Oxygen introduced at $C$.

Table I. Decay constants of extinction of the residual $(\Delta$ c.p.$)_L$ under illumination with the yellow light after the U.V. light is removed.

| Relative intensities of the yellow light | |
|---|---|
| 1 | 0.05 sec |
| 1/2 | 0.11 |
| 1/4 | 0.23 |

Using the value 1.1 sec. for $\tau_0$ at 18°C, one can obtain $\tau_L$'s for different intensities of the light as tabulated in Tab. I. It is found in this table $1/\tau_L$'s are propotional to intensity of light.

Since the yellow light also gives rise to the change of contact potential with illumination by an amount of 20 mV, there are some ambiguity in above values, but the rise time of this change is greater by one order of magnitude than the above-mentioned decay constants of extinction. One can, therefore, neglect $(\Delta$ c.p.$)_L$ for the yellow light at the beginning of extinction in the above-mentioned calculation. The overshooting of the residual $(\Delta$c. p.$)_L$ are diminished with rising the temperatures as shown in Fig. 6. From these results the activation of the decay are estimated at about 0.2 eV.

When oxygen was introduced in the bulb through the breakable joint and the sample was heattreated up to about 100°C, the overshooting of the residual $(\Delta$c.p.$)_L$ were vanished at room temperature as same as the above-described experiments with the bulb of the kinetic vacuum system. At the end of the experiments, the current of the heaters inserted into the sample holder was switched off after 2 hours standing at 350°C in vacuum, then oxygen was introduced. This procedure serves to prevent the contamination of the crystal surface by residual gases. The change of contact potential during introduction of the gas is shown in Fig. 7, where the heaters are switched off at the point *C* and at the same time oxygen is introduced. The surface potential decreases to *D* by an amount of 160 mV as soon as the gas is introduced and then turns upwards gradually. The $(\Delta \text{c.p.})_L$'s measured at points *A*, *D*, *E*, *F*, *G*, *H* and *I* during this process are shown in Fig. 8. The light used to measure the $(\Delta \text{c.p.})_L$'s at *A*, *D*, *E* and *F* is the violet light from the mercury lamp in conjunction with a composite filter having a peak of transmission at 4300 A wavelength and having no trace of infra-red light, and the U. V. light is used for *G*, the yellow light for *H* and the red light for *I*. The spectral transmission of these filters are shown in Fig. 1.

## § 3. Discussion of the Results

(A) The change of contact potential due to the introduction of oxygen gas.

It is a characteristic nature of ionic adsorption of gases on the surface of semi-conductors that heats of adsorption decrease rapidly with increase of covering factor, therefore, the adsorption of gases ends with small amounts of covering factor (5)*. For instance, Kwan and Kinuyama (6) have observed on the adsorption of $CO_2$ on ZnO that the differential heats of adsorption decreased from 48 to 35 kcal in the range between the covering factors $\Theta = 0$ and 0.03. The authors (7) also have found on the adsorption of oxygen on the powder of wurtzite type ZnS phosphor that heats of adsorption decrease from 7 kcal to almost zero in the range between $\Theta = 10^{-4}$ and $10^{-2}$.

The origin of such large changes of heats of adsorption can be attributed to rapid increase of electrostatic self-energy of the space charge near the surface due to increase of adsorbed ions. An illustration for this point of view is given in the electronic energy level diagram of Fig. 9, where *E* and $\zeta$ denote the electronic level of an initially adsorbed negative ion and the Fermi level respectively.

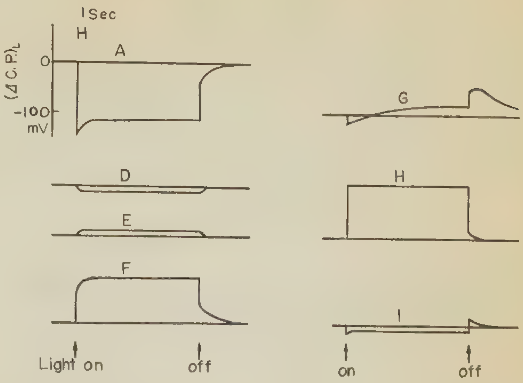

Fig. 8. The $(\Delta \text{c.p.})_L$'s measured at points *A*, *D*, *E*, *F*, *G*, *H* and *I* in Fig. 7. They change the sign after introduction of oxygen.

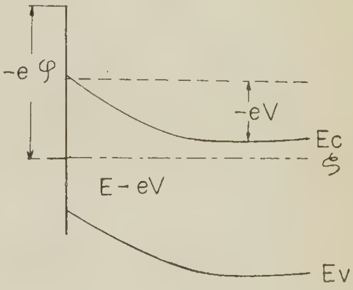

Fig. 9. The electronic energy level diagram near the surface.
$E_c$: the bottom of conduction band, $E_v$ the top of valence band, $\zeta$ the Fermi level, $-e\varphi$ the work function of the crystal, $-eV$ the barrier potential drop due to adsorbed ions and charged surface traps and *E* energy level of an initially adsorbed ion.

From this diagram one can obtain $\zeta - E$ as the initial heat of adsorption. Since with increase of coverage the work function $-e\varphi$ increases by an amount of $-eV$, which is the height of the potential barrier due to space charge and adsorbed ions, *E* becomes $E - eV$ and the heat of adsorption *q* becomes

$$q = \zeta - (E - eV)$$

One would, therefore, find that the adsorption terminates if the work function of the semi-conductor increases by an amount of $-eV = \zeta - E$ with increasing adsorptive ions. This change of the contact potential has been expected by Hauffe and Engel, Aigrain and

---

* One must multiply Airgain and Dugas's values for the maximum adsorption by $\sqrt{2}$, because they overestimate an electrostatic self-energy of surface polarization due to ionic adsorption by a factor of two.

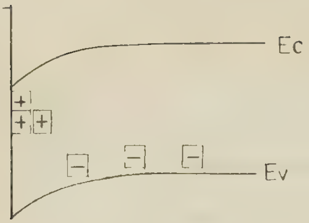

Fig. 10. The electronic energy level diagram near the surface after heavy heattreatment.
$\boxed{+}$ and $\boxed{-}$ denote electron traps of sulphur vacancies and acceptors respectively.

Dugas (5).

In Fig. 7 the change of the surface potential due to introduction of oxygen is 160 mV, i. e. 4 kcal, whereas the authors have found that the initial heat of adsorption of oxygen on the wurtzite ZnS powder is 7 kcal and the overall change of the contact potential due to adsorption is 200 mV, i. e. 5 kcal. Hence one can see qualitatively the expectation comes true. But in the case of Fig. 7 one must take into account both the chemisorption and migration of oxygen into the crystal since the surface is at high temperature at the beginning of introduction of oxygen. No explanation for the increase of c. p. from *D* to *F* can be given, but it seems to be attributed to contamination of grease.

(B) Anion vacancies and the overshooting of the residual $(\Delta \text{c.p.})_L$.

The change of contact potential with illumination, $(\Delta \text{c.p.})_L$, is composed of two photo-electromotive forces; the one part is induced at the potential barrier near the surface and the other induced in the bulk. When the barrier is illuminated with the light giving rise to the internal photo-conduction, photo-currents flow along the field at the barrier, hence a counter electromotive force, which is the former component of the $(\Delta \text{c.p.})_L$, is built up at the barrier. The other part of $(\Delta \text{c.p.})_L$ is due to a photo-voltaic effect caused by diffusion of charge carriers in the bulk. But the most part of the $(\Delta \text{c.p.})_L$ would have to be attributed to the effect at the barrier, since in the case of the present paper $(\Delta \text{c.p.})_L$'s depend remarkably upon the adsorption of oxygen as shown in Fig.'s 3, 6 and 8. One may, therefore, see that the sign of charge of the surface can be determined as positive or negative according to whether the sign of $(\Delta \text{c.p.})_L$ is negative or positive.

Overshooting of the residual $(\Delta \text{c.p.})_L$ is enhanced with heattreatment in vacuum and shows extinction by means of illumination of light with long wave-length and diminishes with rising temperatures. All the results lead us to a conclusion that the overshooting is attributed to trap-centers which are produced by the sublimation of the sulphur constituent near the surface and can trap photo-electrons. Kröger (8) has attributed the traps caused by sublimation of the sulphur constituent to sulphur vacancies. When the crystal be illuminated, electrons will begin to charge the traps of sulphur vacancies at the surface, on the cessation of illumination the photo-voltatic voltage due to photo-currents disappears, then the surface potential decreases by an amount of the contribution of the excess negative charge due to filled electron-traps. This is the reason for the overshooting of contact potential after the light is removed. Garret and Brattain (9) have ascribed the overshooting to photo-enhanced adsorption to which the authors also have done with wrong interpretation (4). But the time constants of $(\Delta \text{c.p.})_L$, both rise and decay, are of two order of magnitude smaller than that of photo-enhanced adsorption and moreover the overshootings appear even in very high vacuum. The effect must, therefore, associate with electronic process rather than ionic process.

If sulphur ions at lattice points near the surface leave the crystal for vacuum, electrons of the sulphur ions may be captured by internal impurity centers forming acceptor levels, e. g. interstitial zinc ions, and thus the surface may be charged positively by an amount of sublimated sulphur as shown in Fig. 10. This point of view is supported by the case of the heavy heattreatment of Fig. 8 where the surface is charged undoubtedly positively, since the $(\Delta \text{c.p.})_L$ in vacuum is negative. When oxygen is introduced into the bulb, the surface becomes charged negatively changing the sign of the slope of the barrier, since the $(\Delta \text{c.p.})_L$ at this time becomes positive with adsorption of oxygen.

Vanishing of overshooting means annihilation of such traps, thus one may conclude that adsorbed oxygen molecules bind with negative ion vacancies near the surface at higher temperatures charging them negatively and thus the function of trapping will be lost. Considering the convers of this conclusion as an extension of the problem, we will reach an important rule that ions should be able to be adsorbed only on the surface vacancies and defects, since only these points have enough large Madelung potential to attract and bind with them.

Usually the surface is charged negatively unless the crystal is heavily heattreated in vacuum, because oxygen in the atmosphere binds with sulphur vacancies and furthermore zinc vacancies, which is effectively negative, are also created at the surface during oxydation. This may be the reason that the $(\Delta \text{c.p.})_L$'s are always positive except the case of Fig. 8. (A), where it has been obtained at the highest heattreatment during this study.

## § 4. Conclusions

It has been studied that the contact potential and its change with illumination vary remarkably with the treatments wether the crystal is heattreated in vacuum or in oxygen. The overshootings of the surface potential on switching off the ultra-violet light and their extinctions with illumination of the yellow light lead us to a conclusion that there are electron traps of sulphur vacancies near the surface and these traps bind with oxygen. As an extension of this conclusion, we will reach an expectation that ions should be able to be adsorbed only on the surface vacancies and defects. An overall change of surface potential in the range between the initial and saturated adsorption agrees fairly well with the initial heat of adsorption as expected.

This study has been supported by the research grant from the Ministry of Education.

# On the Application of the Thomas-Fermi-Dirac Method to the Study of the Residual Resistance of Binary Alloys containing Foreign Atoms in small Concentrations

By Hiroshi FUJIWARA

*Department of Physics, Faculty of Science, University of Tokyo*

(Received November 15, 1955)

By taking the exchange interaction among electrons which was neglected in our previous work, into account, modified screened potential around the substitutional impurities of di- or trivalent metal in monovalent metal in dilute solid solution is exactly obtained from the Thomas-Fermi-Dirac type equation by numerical integration.

As one of the applications of our obtained potential, we took the residual resistance due to the foreign atoms. We use the method of partial waves together with the Born approximation for the calculation of the scattering cross section and the residual resistance is calculated. The disagreement of theoretical values with experiment has been greatly improved by introducing the exchange effects.

## §1. Introduction

In the previous paper, to be referred as I hereafter[1], we have treated the problem about the non-periodic charge distribution around the dissolved atoms in an alloy which contains such dissolved foreign atoms in the form of dilute solid solution.

As is well known, in such an alloy, the dissolved atoms form impurity centres around which the charge distribution of electrons deviates from the periodic one which is characteristic of the pure solvent metal. Therefore, it is important to find such non-periodic charge distribution as exactly as possible for the theoretical interpretation of several physical problems concerning alloys[2].

In I, we investigated the case where the di- or trivalent metal existed as a substitutional impurity in monovalent metals, and using thus obtained modified screened Coulomb potential around an impurity atom, we computed the increase of the electrical resistance due to those dissolved foreign atoms. In part I, we took the Thomas-Fermi type equation as the starting fundamental equation. We tried to find the much accurater solution of the problem than the usual one, that is, we solved the non-linear differential equation of the T. F. exactly by numerical integration*, instead of solving the equation approximately by linearization. And we used the method of partial waves as well as the Born approximation in order to obtain the scattering cross section. However, our model was still a simple one as far as we neglected the exchange interaction among electrons as in Mott's original work on this problem[3].

As the result of this calculation, we find that our modified screened potential reduces the disagreement between theoretical and experimental values of residual resistance, when we use the Born approximation at the same time. However, if we improve the calculation of the scattering cross section by employing the method of partial waves instead of the Born approximation, the theoretical values of residual resistance becomes too large.

In this paper, we shall take the exchange interaction among electrons into account, i.e., instead of the Thomas-Fermi type equation, we take the Thomas-Fermi-Dirac type equation[4] as the starting fundamental equation. Solving this equation by numerical integration, we obtain the new screened Coulomb potential and using this potential, the subsequent calculations of the residual resistance are carried out in the same way as in I.

And we find that the disagreement which has remained in the previous work between the theory and experiment can be diminished by introducing the exchange interaction.

---

* Recently, L. C. R. Alfred & N. H. March reported about this problem (Phil. Mag. **46** (1955) 759) and their results consist with our previous work (without exchange).

## A. Modified Screened Potential

### § 2. Fundamental Equation

In the dilute solid solution which consists of two metals with different valencies, the whole charge distribution is not uniform on account of the presence of the foreign atoms.

For example, if a small quantity of divalent metal Cd is dissolved in the monovalent metal Ag, $Cd^{++}$ ion has one excess positive charge compared with the body $Ag^{+}$ ion. So, the conduction electrons are attracted to the impurity centre so as to screen the excess charge.

We regard this excess positive charge which represents the difference between the atomic valency of the dissolved and that of the solvent metal as a point charge localized near the nucleus of the impurity atom. Although the nature of rest positive charge depends on the kind of the solvent and dissolved atoms, we assume, in the first approximation, that the rest positive charge is distributed with a uniform density $\rho_+$.

For treating our problem, we take the Thomas-Fermi-Dirac type equation as our starting equation.

Then the electrostatic potential $\Phi(r)$ around the dissolved atom is now determined from the following Poisson's equation:

$$\nabla^2\Phi=-4\pi\rho_+ +4\pi e n(r)\,, \tag{1}$$

where $n(r)$ is given by the formula:

$$\left(\frac{8\pi}{3h^3}\right)\left\{\frac{2e^2m}{h}+\left[\frac{4e^4m^2}{h^2}+2em\Phi(r)\right]^{1/2}\right\}^3. \tag{2}$$

We assume the radial symmetry and introduce the new dimensionless variables $\phi$, $x$ which are related to $\Phi$, $r$ by

$$\Phi(r)+\frac{2e^3m}{h^2}=\frac{e}{r}\phi \tag{3 a}$$

$$r=ax\,, \tag{3 b}$$

where $a$ is:

$$a=\frac{1}{2}\left(\frac{3\pi}{4}\right)^{2/3}\frac{h^2}{me^2}=0.885\,a_H\,.$$

$$(a_H\text{: Bohr radius}) \tag{4}$$

With these substitutions, the equation (1) takes the following dimensionless form:

$$\frac{d^2\phi}{dx^2}=x\left[B+\left(\frac{\phi}{x}\right)^{1/2}\right]^3-xA^{3/2}\,, \tag{5}$$

where

$$A^{3/2}=\left(\frac{3\pi}{4}\right)^3\left(\frac{Z_0}{2\pi}\right)\left(\frac{a_H}{r_0}\right)^3 \tag{6 a}$$

$$B=\left(\frac{3}{32\pi^2}\right)^{1/3}. \tag{6 b}$$

Here, $A$ is a new constant which has been introduced in I, and depends only on the kind of the solvent metal, $Z_0$ and $r_0$ being atomic valency and atomic radius in Å of the solvent atom respectively. Equation (5) reduces to the Thomas-Fermi equation in the former case, if we put $B=0$.

It we denote by $Z$ the difference between the atomic valency of the dissolved and that of the solvent metal, the boundary conditions of $\phi$ are given as follows:

$$x=0,\qquad \phi=Z \tag{7 a}$$

$$x\to\infty,\qquad \phi\to k^2x, \tag{7 b}$$

where $k=A^{1/2}-B$.

### § 3. The Solution of the Equation (5)

The following computation is performed by the same method as in the previous paper, i.e.,

We shall consider the form of solution $\phi$ of (5) by dividing the whole range $0<x<\infty$ in the following two regions: (i) in the neighbourhood of $x=0$, (ii) in the region of large $x$, and finally, to simplify our subsequent analysis, we shall try to put these two solutions in one expression over the whole region of $x$.

(i) Near the origin, we cannot use the Taylor expansion[5], because $\phi''$ is infinite at the origin. Instead of that, we use the follwing expansion for small $x$, which satisfies the boundary condition (7 a):

$$\begin{aligned}\phi=&Z+c_2x+\frac{4}{3}Z\sqrt{Z}\,x^{3/2}\\&+\frac{3}{2}BZx^2+\frac{4}{15}\left[3B^2\sqrt{Z}+\frac{3}{2}\sqrt{Z}\,c_2\right]x^{5/2}\\&+\frac{1}{6}[2Z^2-A^{3/2}+B^3+3Bc_2]x^3+\cdots\,,\end{aligned} \tag{8}$$

where $c_2$ is an adjustable parameter, which gives the starting slope at the origin.

We perform the numerical integration from the origin to large $x$ for several different numerical values of $c_2$ and try to find the numerical value of $c_2$ corresponding to the correct solution of equation (5), which satisfies the boundary condition (7 b) as well as (7 a).

The behaviors of variation of $\phi$ with $c_2$ thus obtained are shown in Fig. 1.

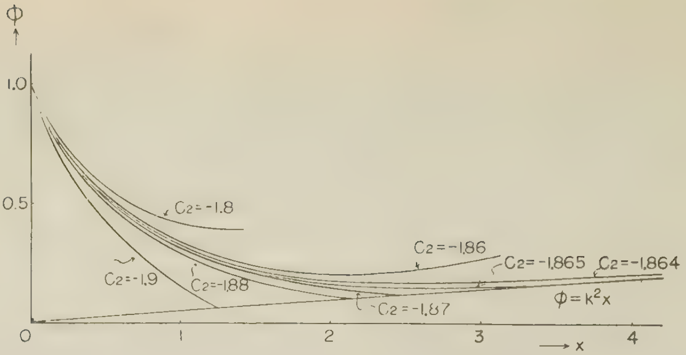

Fig. 1. The behaviors of variation $\phi$ with $c_2$. Solvent metal is Ag and $Z=1$.

(ii) When $x$ is large, $\phi$ can be written asymptotically in the form:

$$\phi=k^2x+y\,, \tag{9}$$

$y$ being small.

$y$ can be expressed with two integration constants $B_1$ and $B_2$ as:

$$y=B_1\exp(-\beta_1'x)+B_2\exp(+\beta_1'x)\,, \tag{10}$$

where $\beta_1'=\sqrt{\frac{3}{2}\frac{A}{k}}$.

As stated in I, $B_1$ and $B_2$ are determined by joining smoothly the numerical solution obtained in (8) with (9) for each assumed value of $c_2$. For the correct solution, $B_2$ must be zero. In this way, $c_2$ and $B_1$ corresponding to the correct solution can be determined. Hereafter, we denote them by $m_0$ and $\alpha_1$ respectively.

Thus $\phi$ can be expressed by the following formula:

(a) when $x$ is small:

$$\phi=Z+m_0x+\frac{4}{3}Z\sqrt{Z}\,x^{3/2}+\frac{3}{2}BZx^2+\frac{4}{15}\left[3B^2\sqrt{Z}+\frac{3}{2}\sqrt{Z}\,m_0\right]x^{5/2}+\frac{1}{6}[2Z^2-A^{3/2}+B^3+3Bm_0]x^3+\cdots\,. \tag{11}$$

(b) when $x$ is large:

$$\phi=k^2x+\alpha_1\exp(-\beta_1'x)\,. \tag{12}$$

For the convenience of our further calculations, it is desirable to express these two formulas (11) and (12) by one analytical form which is valid over the whole region of $x$.

Thus, we find the following expression of $\phi$, which represents (11) and (12) with sufficient accuracy.

$$\phi=k^2x+\alpha_1\exp(-\beta_1'x)+(Z-\alpha_1)\times\exp(-\beta_2'x)+\alpha_2'x\exp(-\beta_3'x)\,. \tag{13}$$

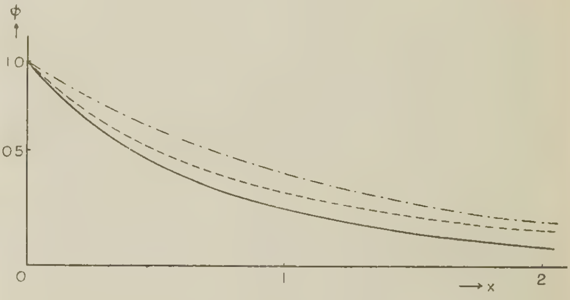

Fig. 2. Curves of $\phi$ for several cases.
(Solvent metal is Ag and $Z=1$)
—— with exchange
– – – – without exchange
–·–·– $Z\exp(-qax)$

Our modified screened Coulomb potential is therefore expressed as follows:

$$V(r)=-\frac{e^2}{r}[\alpha_1\exp(-\beta_1r)+(Z-\alpha_1)\times\exp(-\beta_2r)+\alpha_2r\exp(-\beta_3r)]\,, \tag{14}$$

where

$$\alpha_2=\frac{\alpha_2'}{a},\quad \beta_1=\frac{\beta_1'}{a},\quad \beta_2=\frac{\beta_2'}{a}\ \text{and}\ \beta_3=\frac{\beta_3'}{a}.$$

To compare our modified screened potential with that of the previous one and the usual one $\left(V(r)=-\frac{Ze^2}{r}\exp(-qr)\right)$, these three curves are shown in Fig. 2.

For convenience, we plott in the dimensionless coordinates $(\phi, x)$. We find that the curve of $\phi(x)$ obtained in I (without exchange) is further lowered by taking the exchange effect into acount.

Our obtained values of $A^{3/2}$, $m_0$, $k^2$, $\alpha_1$ etc. are tabulated in Table I and Table II. In these tables, those values obtained in I are also retabulated in parenthesis. The solvent metals are Ag and Cu and $Z=1$.

Table I. The values of $A^{3/2}$, $m_0$, $k^2$ and $\sqrt{\frac{3}{2}\frac{A}{k}}$.

| Z | Solvent | $A^{3/2}$ | $m_0$ | $k^2$ | $\sqrt{\frac{3}{2}\frac{A}{k}}$ |
|---|---|---|---|---|---|
| 1 | Ag | 0.0762 | −1.8647<br>(−1.4939) | 0.0405<br>(0.1798) | 1.1272<br>(0.7975) |
|  | Cu | 0.1093 | −1.8453<br>(−1.4615) | 0.0709<br>(0.2286) | 1.1347<br>(0.8469) |

Table II. The values of the coefficients $\alpha_l$ and $\beta_l$.

| Solvent | $\alpha_1$ | $\alpha_2$ | $\beta_1$ | $\beta_2$ | $\beta_3$ |
|---|---|---|---|---|---|
| Ag | 0.8384<br>(0.7476) | −0.427<br>(−0.491) | 2.41<br>(1.71) | 7.05<br>(4.70) | 10.7<br>( 7.9) |
| Cu | 0.8333<br>(0.7724) | −0.427<br>(−0.448) | 2.42<br>(1.81) | 7.37<br>(4.80) | 14.9<br>( 7.5) |

The values in parenthesis are those obtained in our previous work (without exchange).

## B. Residual Resistance due to the Foreign Atoms

### § 4. Scattering Cross Section by the Foreign Atoms

In the course of considering the elastic scattering of electrons by a foreign atom which is represented by our screened Coulomb potential $V(r)$, the calculation of the differential cross section $I(\theta)$ is carried out by the method of partial waves as well as the Born approximation.

The total cross section $\sigma$ which is effective for our case is:

$$\sigma=2\pi\int_0^\pi I(\theta)(1-\cos\theta)\cdot\sin\theta\,d\theta\ , \qquad (15)$$

where the differential cross section $I(\theta)$ is given as $|f(\theta)|^2$ by the scattering amplitude $f(\theta)$.

(i) The Born approximation

The scattering amplitude $f_B(\theta)$ for the Born approximation is given by:

$$f_B(\theta)=-\frac{2m}{\hbar^2}\int_0^\infty V(r)\frac{\sin Kr}{K}rdr\ , \qquad (16)$$

where $K=2k\sin\frac{1}{2}\theta$ and $k=2\pi mv/h$. Here, $V(r)$ is (14), but hereafter we shall neglect the third term in (14) for its small magnitude. For our purpose of calculation, the scattering of electrons at the Fermi surface is important, so we have $k=1.92/r_0$ after introducing the numerical values, $r_0$ being the atomic radius of the solvent metal in Å.

(ii) The method of partial waves

Since the de Broglie wavelength for electrons $\lambda=2\pi/k$ near the Fermi surface is fairly large in comparison with the force range due to impurity centre, the legitimacy of the Born approximation is doubtful, so we have calculated the cross section also by the method of partial waves.

The exact expression for the scattering amplitude is given by:

$$f(\theta)=\frac{1}{2ik}\sum_{l=0}^{\infty}(2l+1)\{\exp(2i\eta_l)-1\}P_l(\cos\theta)\ , \qquad (17)$$

where $\eta_l$ is the phase shift of the $l$ th order. The direct use of this formula would require rather tedious numerical evaluation of a fairly large number of the phase shifts $\eta_l$, but since the higher phase shifts are small, they can be replaced by the corresponding quantities given by the Born approximation. In fact, the scattering amplitude $f_B(\theta)$ in the Born approximation can be written in terms of partial amplitude of different orders as follows

$$f_B(\theta)=\frac{1}{2ik}\sum_{l=0}^{\infty}(2l+1)(2i\zeta_l)P_l(\cos\theta) \qquad (18)$$

$$\zeta_l=-\frac{\pi m}{\hbar^2}\int_0^\infty V(r)[J_{l+1/2}(kr)]^2r\cdot dr\ . \qquad (19)$$

and, for partial waves of higher order, $\exp(2i\eta_l)-1$ are closely approximated by $2i\zeta_l$. Hence $f(\theta)$ in (17) can be obtained from $f_B(\theta)$ by correcting only lower order phase shifts:

$$f(\theta)=f_B(\theta)+\frac{1}{2ik}\sum_{l=0}^{l'}(2l+1)$$
$$\times[\{\exp(2i\eta_l)-1\}-2i\zeta_l]P_l(\cos\theta)\ , \qquad (20)$$

where the series converge very rapidly. It has been found sufficient to take only two terms $l=0$ and 1.

$\zeta_l$ is obtained by the following formula by the use of the formulas about the Bessel functions:

$$\zeta_l=\frac{1}{a_H\cdot k}\left\{\alpha_1Q_l\left(1+\frac{\beta_1^2}{2k^2}\right)+(Z-\alpha_1)Q_l\left(1+\frac{\beta_2^2}{2k^2}\right)\right.$$
$$\left.+\frac{\alpha_2\beta_3}{k^2}\frac{d}{dX}Q_l(X)\right\};\quad X=1+\frac{\beta_3^2}{2k^2}\ . \qquad (21)$$

$\eta_l$ can be obtained by numerical calculation in the usual way and for full information, the readers are referred to the previous paper I.

(iii) Total cross section

The total cross section $\sigma$ can be expressed by the sum of three terms $\sigma_1$, $\sigma_2$ and $\sigma_3$ as follows;

Table III. The values of $\eta_l$ and $\zeta_l$.

| Solvent | $\zeta_0$ | $\zeta_1$ | $\zeta_2$ | $\eta_0$ | $\eta_1$ | $\eta_2$ | Fridel sum $\frac{2}{\pi}\sum(2l+1)\eta_l$ |
|---|---|---|---|---|---|---|---|
| Ag | 0.4742<br>(0.6995) | 0.0531<br>(0.1181) | 0.0075<br>(0.0250) | 0.8538<br>(1.1374) | 0.0599<br>(0.1349) | 0.0079<br>(0.0262) | 0.676<br>(1.064) |
| Cu | 0.4895<br>(0.6885) | 0.0637<br>(0.1249) | 0.0080<br>(0.0284) | 0.8232<br>(1.0705) | 0.0736<br>(0.1420) | 0.0082<br>(0.0276) | 0.691<br>(1.041) |

Table IV. The values of $\sigma_l$ and $\sigma$ ($10^{-16}\text{cm}^2$)

| Solvent | $\sigma_1$ | $\sigma_2$ | $\sigma_3$ | $\sum\sigma_l$ | $\sigma$ |
|---|---|---|---|---|---|
| Ag | 0.246<br>(0.474) | −0.021<br>(−0.521) | 0.429<br>(1.052) | 0.654<br>(1.005) | 4.11<br>(6.31) |
| Cu | 0.194<br>(0.353) | −0.030<br>(−0.332) | 0.310<br>(0.690) | 0.474<br>(0.711) | 2.98<br>(4.47) |

Table V. Tables for $\Delta\rho$ (microohm·cm)

| Used screened potential | | Calculated values: Born approximation, Solvent Ag | Born approximation, Solvent Cu | Partial waves, Solvent Ag | Partial waves, Solvent Cu |
|---|---|---|---|---|---|
| Our modified | with exchange (this time) | 0.75 | 0.67 | 2.01 | 1.67 |
| | without exchange (previons work) | 1.45 | 1.14 | 3.09 | 2.50 |
| Usual type without exchange $V(r)=-\frac{Ze^2}{r}\exp(-qr)$ | | 2.20 | 1.88 | 4.34 | 3.28 |

Experimental values
Cd in Ag 0.38 Zn in Ag 0.62
Cd in Cu 0.21 Zn in Cu 0.34

$$\sigma=2\pi\{\sigma_1+\sigma_2+\sigma_3\}, \qquad (22)$$

where $\sigma_1$ is the term due to the Born approximation and $\sigma_2$ and $\sigma_3$ are the terms which are introduced by using the formula (20). Terms $\sigma_i$ correspond to $I_i$ in the previous paper I. The full information about the calculation and the explicit expression for $\sigma_i$ are given in I.

Thus we obtained $\eta_l$, $\zeta_l$ and $\sigma_i$ in the same way as in I. Our calculated values of $\eta_l$, $\zeta_l$ and $\sigma_i$ are tabulated in Table III and IV. For the sake of comparison, we retabulated those corresponding values which were obtained in the previous work.

## § 5. Residual Resistance due to the Foreign Atoms

If we denote by $p$ the atomic ratio of dissolved metal to the solvent one, the increase $\Delta\rho$ of the electrical resistance due to the substitutional impurity is given by:

$$\Delta\rho=\left(\frac{mv}{e^2}\right)p\cdot\sigma=78\cdot p\left(\frac{\sigma}{r_0}\right)\text{microohm. cm.} \qquad (23)$$

where $\sigma$ is to be expressed in the unit of $10^{-16}$ cm². As the standard concentration, we take $p=1/100$.

Calculated values of $\Delta\rho$ are tabulated in Table V together with those values which have been obtained for other two screened potentials: the one is our previous one without exchange and the other is the one which was obtained from the linearized equation, i.e., $V(r)=-\frac{Ze^2}{r}\exp(-qr)$.

## § 6. Results and Discussions

In this paper, the exchange interaction among electrons which was neglected in the previous paper I, is taken into account, i.e., we take the Thomas-Fermi-Dirac equation as the starting equation.

Considering our results together with the previous ones, the following conclusions are obtained.

At first, a fairly remarkable improvement has been made by introducing the exchange effect in comparison with the previous case in which this effect was neglected. And we find that our results are improved step by step in accordance with the procedures for solving our problem, i.e., solving (i) analytically from the linearized equation without exchange, (ii) exactly by numerical integration, (iii) from the equation in which the exchange effect has been taken into account and in the same way as (ii).

It is true that our calculated values have been much improved both for the cases of using the Born approximation and the method of partial waves, but, as was the case in I, the values obtained by the latter method are still greater than those obtained by the former one. But, from the purely theoretical viewpoints, we can not find any reason for which the Born approximation should yield more reliable results than the method of partial waves. In fact, the validity condition $k/q \gg 1$ ($q$ is the screening constant in the potential $V(r) = -\frac{Ze^2}{r}\exp(-qr)$) is hardly satisfied in our case, so that the method of partial waves would be preferable.

As stated in the previous paper, our starting model is an approximated one for the actual case, i.e., we have neglected the details of the charge distribution due to the difference of the values $\rho_+$ due to the kind of the dissolved atoms of the same valency. Therefore, when we improve the above-mentioned shortcoming of our model in our further study, we expect that the agreement between the experimental values and theoretical values which are obtained by the method of partial waves will be much better than the one between experiment and theoretical values which are calculated by the Born approximation.

The considerations about these points are still to be taken into account in our further study on this kind of problem.

As Cd–Ag and Zn–Cu are neighbouring elements in the periodic table and the valence electrons are in 4s in Zn, Cu and in 5s in in Cd, Ag, the behaviors of ion cores of both solvent and dissolved metals will be similar in the solid solution Cd–Ag and Zn–Cu. But conversely, for the case of Cd in Cu and Zn in Ag, the behaviors of ion cores do not resemble. Taking these circumstances into account, we may be allowed to expect that the theoretical values which would be obtained in our further study will agree with the experimental ones more closely in the case of Cd in Ag and Zn in Cu than in the case of Zn in Ag and Cd in Cu.

Finally we shall discuss about the Friedel sum*. Friedel$^{6)}$ has proved that the sum $(2/\pi)\Sigma(2l+1)\eta_l$, where $\eta_l$ is the phase shift of the $l$ th order partial wave for electrons at the Fermi surface, is equal to the extra number of electrons attracted by the impurity centre, provided that the exchange interaction is negligible. Since in metals, the screening must be complete, Friedel-sum must be equal to the excess charge $Z$ of the impurity centre

$$\frac{2}{\pi}\Sigma(2l+1)\eta_l = Z$$

neglecting the exchange interaction. In the rightest column of Table III in parenthesis, we have tabulated this sum using the phase shifts obtained in our previous work (without exchange), which shows that Friedel sum is actually close to one. Small deviation from 1, of the order of a few %, may be due to the fact that we did not use the band-theoretical procedures of costructing the wave-function for individual electron, but employed the method of Thomas-Fermi to find the form of the potential function. The fact that the deviation is very small may be interpreted as indicating the self-consistency of this procedure. However, when the exchange interaction is introduced, there is no reason that the relation $Z$=Friedel-sum must be true. And our results show that the deviation from this rule is actually fairly remarkable.

## § 7. Acknowledgment

The author wishes to express his sincere thanks to Prof. M. Kotani for his continued guidance and encouragement throughout this work and also to Prof. Blatt who kindly discussed about this work and many thanks are also due to Drs. D.K.C. MacDonald and G.K. White of National Research Council, Ottawa, Canada for their kind discussions.

# Deformation of Thin Copper Crystals

By Hideji SUZUKI, Susumu IKEDA and Sakae TAKEUCHI

*The Research Institute for Iron, Steel and Other Metals,*
*Tohoku University, Sendai*

(Read October 15, 1955; Received December 2, 1955)

Stress/strain curves of many number of copper crystals having various radii from 0.06 to 1 mm were measured. The range of easy glide increases considerably when the radius of crystal decreases. In the case of suitably oriented crystal the range of easy glide reaches to 50 per cent in shear, when the radius of crystal decreases less than 0.1 mm. The extrapolation of the range of easy glide to the infinitesimal radius gives a value between 40 to 80 per cent in shear irrespectively to the initial crystal orientation. The hardening rate in the easy glide region considerably decreases with the decreasing crystal radius. Meanwhile, the critical shear stress, the stress required for the transition from the easy glide to the rapid hardening region, the hardening rate in rapid hardening region reveal only slight dependence on the crystal radii, i.e. the former two slightly increase and the last slightly decreases with the decreasing crystal radii. These results are discussed qualitatively by introducing a concept 'mean free path of dislocations' in a crystal.

## § 1. Introduction

Dislocation loops multiplied from a Frank-Read source[1] proceed in a usual crystal over finite area of the slip plane on account of the increasing resistance caused by the formation and migration of jogs[2][3]. Those multiplied dislocations exert back stress on the swept area of the slip plane, and the source ceases its action. One of the authors[4] has pointed out that the large slip as first observed by Heidenreich and Shockley[5] takes place through the co-operative action of Frank-Read sources situated in a thin zone parallel to the slip plane. This idea for the explanation of large slip has been appeared in many papers[2][6][7][8] independently, and implied that the dimension of crystal in a direction along the active slip plane must have large effects on the work-hardening of the crystal. Measurements made hitherto, however, have paid little attention to the role of specimen size, and have been carried out on crystals having certain dimension determined by the technique of the preparation of single crystals.

The experiments on single crystals of copper described in the following pages were carried out with the object throwing light on the mechanism of deformation in easy glide and rapid hardening regions, by systematic investigation of the effect of crystal radius on work-hardening.

## § 2. Preparation of Crystals

The single crystals of copper were grown from electrolytic copper about 99.98 per cent pure. Those copper wires of 1.7 mm diameter were inserted into porcelain tubes which were 2 mm in inner diameter, 10 or 30 cm in length and closed in the one end by alumina including some amount of clay. The crucible containing the copper wire was doubly protected from atmosphere by two silica tubes and made pass through an electric furnace. In order to avoid the reaction between the porcelain tube and molten copper, the porcelain tubes were previously dipped in aqueous solution of suger and were dried in air for a few days. The crucibles containing the copper wires were lowered at a rate of 3 cm $\text{min}^{-1}$. The porcelain tubes were then cracked gently by a pinchers, and were removed from the copper crystals. When sufficiently porous tubes were used, the yield of perfect crystals exceeded 80 per cent and the remainder contained small angle boundaries in the direction of growth.

The crystal orientations were determined by optical figure method extensively developed by Yamamoto and Watanabe[9]. Using their method it is not difficult to determine the orientations of several tens crystals in a day. The observed crystal orientations are plotted stereographically in Fig. 1.

The crystals were annealed in vacuum (about $10^{-4}$ mm Hg) at 1000°C for three hours after orientation determination. The crystals with radii of about 1 mm were electro-polished using 30 per cent ortho-phosphoric acid in water before deformation.

The thin crystals less than 0.5 mm in radii were produced from those annealed 1 mm crystals by etching in dilute nitric acid, after cutting the long crystal into pieces having suitable lengths by a pinchers. By means of careful etch, thin crystals with uniform cross sections as small as 0.01 $\text{mm}^2$ were obtained. The cross section of an etched crystal was usually of an elliptic shape, eccentricity of which depended on crystal orientation. Those thin crystals were then polished electrolytically using 30 per cent ortho-phosphoric acid in water, putting on a hook made of the same purity copper wire, which was connected to positive electric source. The crystals were then washed by water, dried in air and then set on the testing machine, which will be described in the next section, by 'De Khotinsky cement' the paste for high vacuum. The examined crystals, therefore, were not subjected to high temperature annealing after the etching.

The term 'radius of crystal' will be used in the following to denote the radius of a circle having the same area with the cross section of the crystal. The part of a crystal between guage markings was clipped by a nail-scissors after deformation and then measured the weight by a chemical balance. The cross section is obtained from the weight of the crystal assuming a uniform cross section over the guage length.

## § 3. Stress/strain Measurement

Two tensile machines were used according

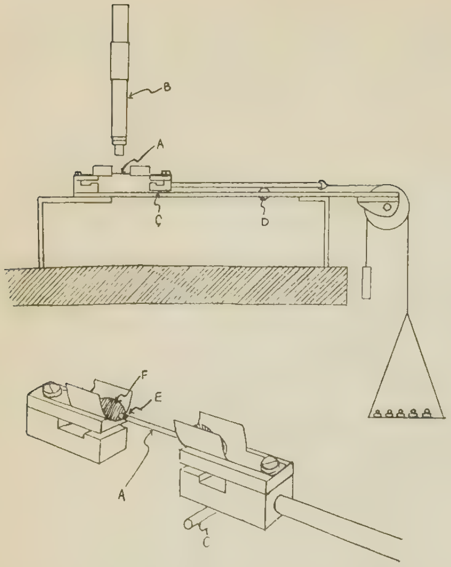

Fig. 3. Schematic representation of the tensile machine used for thin crystals less than 0.5 mm in radius.
A: Specimen. B: Travelling microscope to measure the elongation of crystal. C and D: Roller. E: Gauge marking. F: De Khotinski cement.

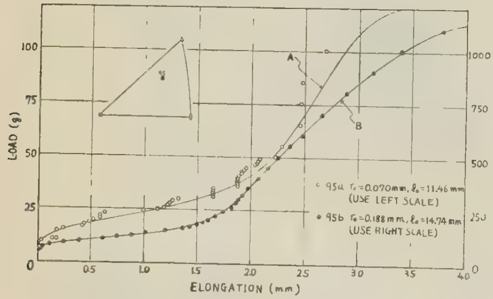

Fig. 4. Load/elongation curves obtained by the testing machine for thin crystals.

to the required stress range. The machine shown in Fig. 2 can be loaded up to 50 Kg by decreasing the buoyoncy of the counter balance A. The load is proportional to the relative displacement of the counter balance to the water level. The loading rate is propotional to the rate of flow from the water tank, which is controlled by the degree of turning the cock B. The loading is thus continuous in the machine shown in Fig. 2. The elongation was read by the dial-guage C attatched at the pulling rod D.

The machine shown in Fig. 3 was used for thin crystals less than 0.5 mm in radii. The maximum load applicable to this machine is about 10 Kg. The tension was applied on the crystal through adding wire pieces, each of which is of 1 g in weight, in the initial region of deformation. The elongation was measured on the guage length between two markings drawn by ink on the crystal A, using a travelling microscope B. The accuracy of the load was 1 g in the best condition, but in many cases there was greater error than this on account of friction by dusts attatched to the roller, ball bearing, etc. during the measurement.

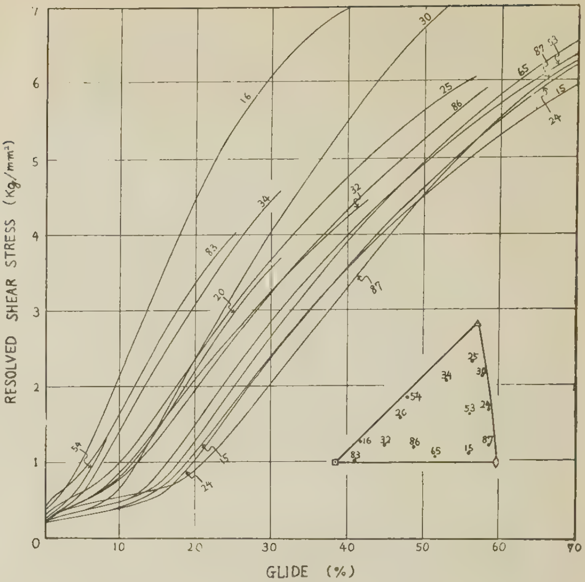

Fig. 5. Shear stress/glide relations of some crystals of about 1 mm in radii.

Fig. 4 shows a few examples of load/elongation curves, by which the accuracy of loading can be seen. If there is random solid friction in the tensile machine, the full curve *A* in the figure may be regarded as a reasonable approximation to the true load/elongation curve. Such scattering of each observed value from a smooth curve was hardly observed in a crystal greater than 0.15 mm in radius as shown by curve *B*.

The computations of the shear stress and the shear strain were performed in the usual manner[10]. It was assumed that duplex slip occurs when the specimen is in the dodecahedral plane or has rotated into the plane. It is also assumed that the tensile axis remains in the dedecahedral plane and rotates towards the [112] direction during the duplex slip.

## § 4. Deformation of Crystals of 1 mm in Radii

Some of the shear stress/glide curves of crystals of about 1 mm in radii are shown in Fig. 5. The curves reveal considerable scattering between those crystals according to the crystal orientations of the tensile axes as was observed first in aluminium by Masing and Raffelsieper[11] and investigated in detail by Lücke and Lange[12]. The orientation dependence of shear stress / glide curves is now generally established in some face-centred cubic metals[13][14][15][16].

The stress/strain curves can be approximated by two linear segment if the stress is not too large as shown in Fig. 5. The stress/strain curves may then be characterized by four quantities[14], i.e. the critical shear stress $S_1$, the shear stress for the initiation of the rapid hardening $S_2$, the hardening rate in the easy glide region $(dS/da)_1$ and the hardening rate in the rapid hardening region $(dS/da)_2$. The glide amount in the easy glide region $a$ is also very important quantity representing the feature of work-hardening, though this quantity can be derived from the above-mentioned four quantities. The definition of these five quantities will be seen in Fig. 6.

The observed values of five quantities, $S_1$, $S_2$, $(dS/da)_1$, $(dS/da)_2$ and $a$, are summarized in Table I. Here $l_0$ is the initial guage length of a sample, $r_0$ the initial radius of the crystal, $\chi_0$ the original angle between the slip plane and tensile axis, $\lambda_0$ the original angle between the tensile axis and the slip direction. The crystal orientations of these crystals were already shown in Fig. 1.

The orientation dependence of $S_1$, $S_2$, $(dS/da)_1$, $(dS/da)_2$ and $a$ for the crystals of 1 mm in radius are shown in Fig. 7a, b, c, d and e, respectively. The critical shear stress, $S_1$, which is extrapolated from easy glide region, increases in the crystals oriented near the three corners of the triangle. The amount of increase in each corner seems to be proportional to the number of slip systems on which nearly equal shear stresses are applied.

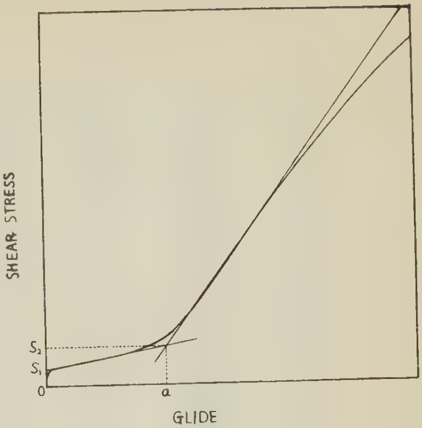

Fig. 6. Schematic representation of shear stress /glide relation.

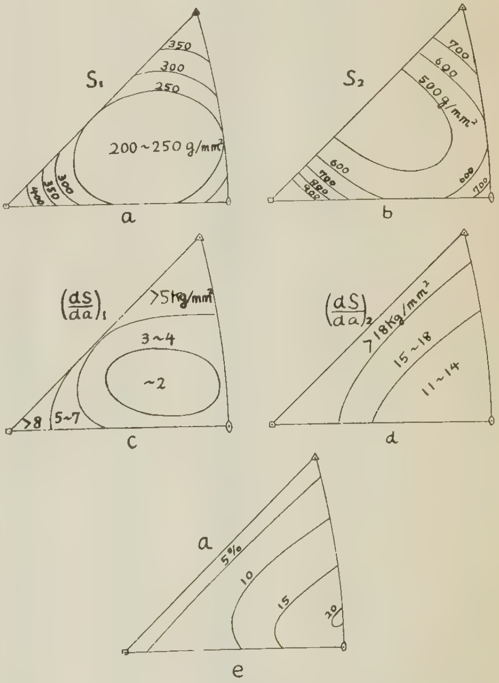

Fig. 7. Orientation dependence of $S_1$, $S_2$, $(dS/da)_1$, $(dS/da)_2$ and $a$ of crystals of about 1 mm in radii.

Following Fujita, T. Suzuki and Yamamoto[17], let us represent a slip system by the triangle in the sterographic projection of the imaginary tension axis, in which the slip system might be subjected to the maximum resolved shear stress. The real wire axis is always in the triangle $a$ in Fig. 8, then other triangles represent latent slip systems.

The orientation dependence of $S_2$ is very similar to that of $S_1$, but it seems to be not affected by the conjugate slip system, $e$.

The hardening rate $(dS/da)_1$ shows stronger dependence on the orientation than $S_1$, but the contours of equi-hardening resembles with those of $S_1$.

The hardening rate $(dS/da)_2$ seems to be

Table I. Observed values of five constants characterizing the shear stress/glide curves.

| Sample No. | $l_0$ in mm | $r_0$ in mm | $\chi_0$ in degree | $\lambda_0$ in degree | $S_1$ in Kg/mm² | $S_2$ in Kg/mm² | $a$ in mm/mm | $(dS/da)_1$ in Kg/mm² | $(dS/da)_2$ in Kg/mm² |

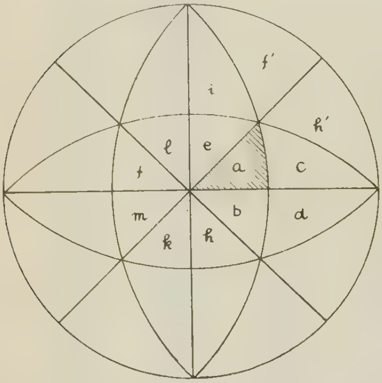

Fig. 8. Slip systems in a face-centred cubic crystal.

increased only by the influence of the conjugate slip system, $e$, as already pointed out by Rosi[14] in the case of thicker crystals than in this investigation.

The range of easy glide seems also to depend strongly on the action of the conjugate slip system, $e$, and slightly on $b$ and $d$ systems, but not on $c$-system.

## § 5. Effects of Radii of Crystal on Work-Hardening

Figs. 9, 10 and 11 show stress/strain curves of crystals with various radii. The crystal orientations of the tensile axes are in the vicinity of [011] in Fig. 9, in the vicinity of [001] in Fig. 10, and in a direction far from any of [001], [011] and [111] in Fig. 11.

In the case of the crystals oriented in the vicinity of [011] direction, the range of easy glide $a$ increases and the corresponding hardening rate in this region $(dS/da)_1$ seems to be irrespective to the radius of crystal as shown in Fig. 12. $S_1$ and $S_2$ increase slightly with the decreasing radius.

The situation is not so simple in the case of the crystals oriented near [001]. The crystals 136 and 96, which make angles of about 1 and 3 degrees with [001] respectively, reveal more rapid hardening in thinner crystals than in thicker crystals. Meanwhile, in crystals making with [001] an angle about 6 degrees the hardening rate decreases with the decreasing radius. The increase in the range of easy glide is very significant in crystals 16, 78, 106 and 120, which make with [001] angles from 10 to 16 degrees. These results indicate that there are strong orientation dependence of size effect especially in the vicinity of [001]. The effects of radii of crystals on $S_1$, $S_2$, $(dS/da)_1$ and $(dS/da)_2$ are represented in Fig. 13. There are only slight orientation dependence of $S_1$, $S_2$, $(dS/da)_2$, while $(dS/da)_1$ considerably decreases with the decreasing radius. The extrapolated value of $(dS/da)_1$ to the infinitensimal radius, however, seems to reach about 1.2 Kg/mm$^2$, which is equal to the corresponding value of the crystals oriented near [011]. The orientation dependence of $(dS/da)_1$ may be, therefore, recognized more rationally as the orientation dependence of the size effect of $(dS/da)_1$.

Fig. 11 shows the stress/strain curves of some crystals making a large angle with any

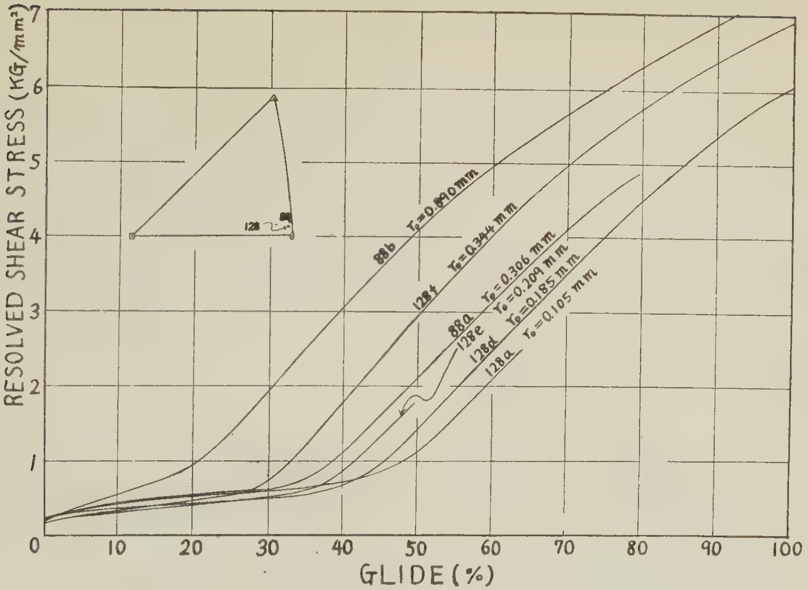

Fig. 9. Shear stress/glide curves of crystals having various radii; in the vicinity of [011].

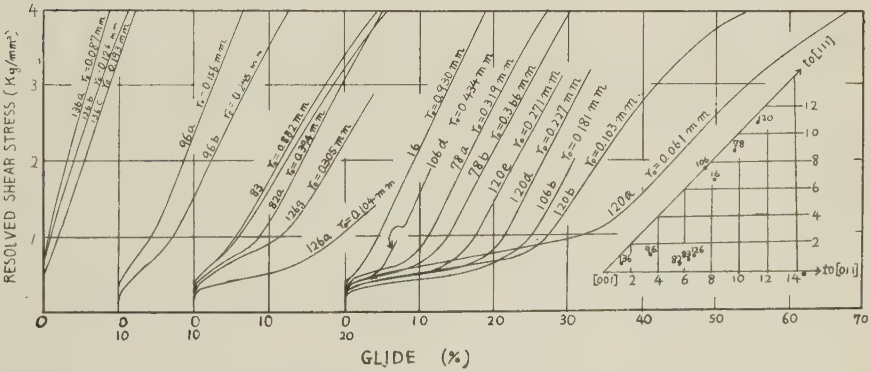

Fig. 10. Shear stress/glide curves of crystals having various radii; in the vicinity of [001].

one of [001], [011], [111]. The hardening rate is not a unique function of the crystal radius, but these irregular effects seem to be caused by difficulty in the measurements, especially, in handling of crystals before mounting it. It is, however, distinctly shown that the decrease of radius results in the increase of range of easy glide.

The range of easy glide has a relation with the radius of crystal. In Fig. 14 the range of easy glide in logarithmic scale is plotted against the radius of crystal for two groups of crystals having the orientations shown in Figs. 12b and 13a, respectively. Though the observed values reveal considerable scattering, there is a linear relation between the loga-

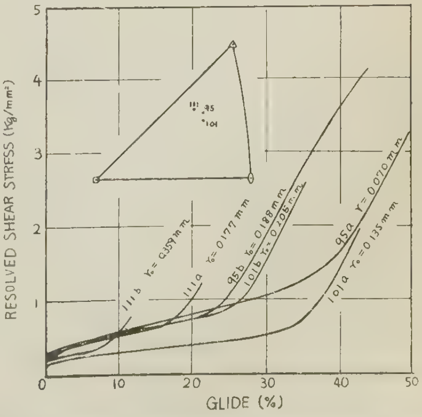

Fig. 11. Shear stress/glide curves of crystals having various radii; in the vicinity of [459].

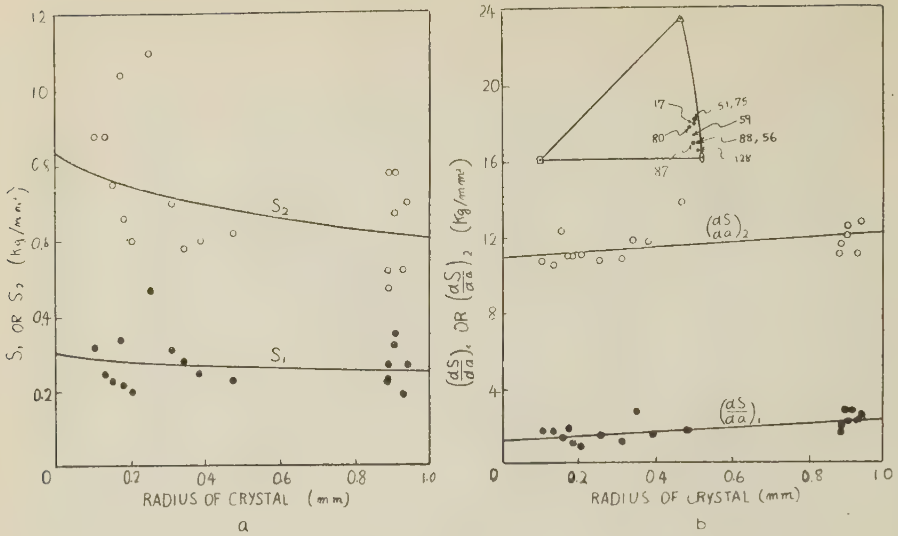

Fig. 12. Dependence of $S_1$, $S_2$, $(dS/da)_1$ and $(dS/da)_2$ on radius of crystal; in the vicinity of [011].

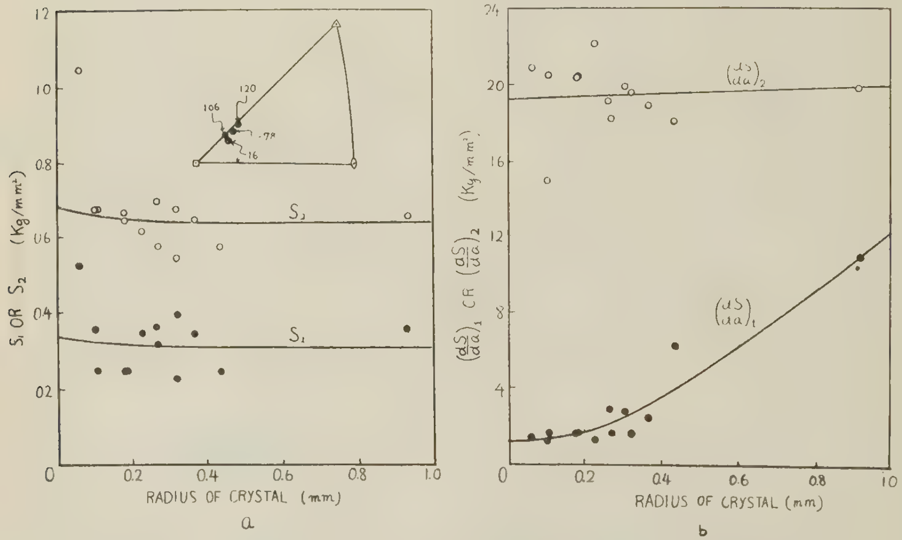

Fig. 13. Dependence of $S_1$, $S_2$, $(dS/da)_1$ and $(dS/da)_2$ on radius of crystal; in the vicinity of [001].

rithms of range of easy glide and radii of crystals at least when the radii of crystals are less than a certain value depending on the crystal orientation. There are, of course, some other empirical formulae, which fit in the observed values at the same degree of scattering with this. This relation, however, seems to be the most reasonable according to the dislocation theory of deformation.

Fig. 14 indicates very important fact, that is, the range of easy glide reaches to a value between 0.4 and 0.8 irrespectively to the crystal orientation when the radius of crystal decreases to a sufficiently small value.

## § 6. Discussion of the Results

The results described in the forgoing sections may be explained from the theory of dislocation. The precise treatment of the size effect in the deformation of crystals, however, requires extensive considerations on the deformation process of crystals, so only a preliminary consideration will be given in this section.

The relation shown in Fig. 14 may be derived as follows. The easy glide may correspond to the exhaustion hardening process of Frank-Read sources[18], which have existed in annealed state. Let us suppose that a dislocation can proceed in the crystal freely by the distance $l$ in average, namely, it meets with any obstacle $P$ times during the dislocation sweeps unit area. The shear deformation performed by dislocations, which pass through the whole cross sections of the crystal, is then given by the expression

$$S = ns \exp(-Pr) \qquad (1)$$

where $n$ is the number of operated Frank-Read sources which have existed at the annealed state, and $S$ the shear produced by the operation of a Frank-Read source. If a Frank-Read source multiplies a dislocation in every atomic plane[4][19][20], and the radius of crystal is not too large compared with the mean free path of dislocations, Frank-Read sources existed at the annealed state must consumed when $ns$ reaches to the value $b/h$. Here $b$ is the strength of a dislocation, $h$ is the spacing of the two neighbouring atomic planes parallel to the slip plane. The shear shown in (1), then may be equal to the range of easy glide. There is thus a linear relationship between the logarithm of range of easy glide and the radius of crystal. The range of easy glide extrapolated to the infinitesimal radius will be about 1.2 irrespectively to the orientation of the crystal, if Eq. (1) is valid. Meanwhile, the corresponding value in Fig. 14 is 0.4~0.8. This difference may be caused from two sources: in the first place the hardening in the vicinity of a slip zone is neglected, which will forbid the formation of another slip zone in contact with the former one. In the second place, the easy glide is apt to be disturbed by any heterogeneity in the crystal, so we have measured rather low values than in the ideal case.

The explanation described above seems to be adequate to understand the various kinds of stress/strain curves of face-centred cubic metals and alloys[21][22][23][24]. The wide range of easy glide in high alloy crystals, especially well known in $\alpha$-brass crystals, may be attributed to longer mean free path of dislocations in these alloy crystals than in pure metals. Then the situations appeared in thin metal crystals take place in rather thick alloy crystals. Actually there are slight size effect on the range of easy glide in $\alpha$–brass crystals[25].

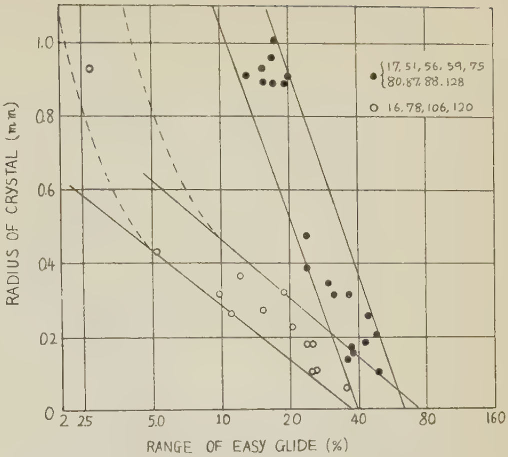

Fig. 14. The relation between the range of easy glide and radius of crystal.

The term, mean free path of dislocations, is of course a rude concept, but it may be very useful to understand the phenomena of work-hardening. The mean free path of dislocations may be determined by some factors such as the frequency of sessile reaction proposed by Lomer(26) and Cottrell(27), the density of intersecting dislocations etc. as already discussed by Mott[2], and Seeger[8]

The effect of surface film on the range of easy glide seems to be exaggerated, for example, in the investigation by Andrade and Henderson[28] on silver crystals. They ignored the orientation dependence of work-hardening as generally believed at the time of their investigation, and compared the work-hardening of two crystals, the one was annealed in argon and immediately examined in argon gas without exposing to atmosphere and the other was exposed to the air for about two hours. The range of easy glide was about 30 per cent in the former crystal, while it was about 8 per cent in the latter crystal. The difference of the range of easy glide between these two crystals was attributed to the existence of oxide layer formed by the action of the atmosphere at room temperature by Andrade and Henderson, and this interpretation was accepted in Cottrell's famous book[29]. This difference, however, can also be explained by the orientation effect on work-

hardening as already shown in Fig. 5.

It is interest to compare the results obtained here with those by previous investigators. Fig. 15 represents stress / strain curves of crystals having nearly the same orientation by these investigators[13][14][30][31]. There are considerable scattering in the vicinity of small amount of deformation, but the range of easy glide changes systematically with the change of crystal radii. It must be noted, especially, the hardening rate in simple shear experiment by Edwards, Washburn and Parker is considerably greater than the hardening rate in tensile test of thin crystals. Edwards et al obtained the hardening rate of the order of 4 Kg/mm², which is about three times greater than the extrapolated hardening rate to the infinitesimal radius. The discrepancy indicates that the simple shear experiment is also governed by some complex process of dislocation reaction in face-centred cubic crystals.

## § 7. Summary

Using many number of copper crystals, the orientation dependence of work-hardening and the effects of crystal radii on the work-hardening are observed. The main results are summarized as follows.

(1) The stress / strain curves of copper crystals are usually composed of linear parts, providing the stress is not too large, corresponding to the easy glide and rapid hardening region, respectively.

(2) In the case of 1 mm radius of crystals, there are strong orientation dependence of stress/strain curves especially in the range of easy glide. The critical shear stress, work-hardening rate in the rapid hardening region reveals a weak but systematic orientation dependence.

(3) When the radius of crystal decreases, the range of easy glide increases considerably. The dependence of the range on the radius differs between crystals of different orientations, but the limitting value extrapolated to the infinitesimal radius is identically about 50 per cent in shear for any crystal orientation.

(4) Hardening rate in rapid hardening region depends weakly on the radius but the hardening rate in easy glide region depends strongly on the crystal radius, and reaches to 1.2 Kg/mm² when the radius decreased to the infininitesimal, irrespectively to the crystal orientation.

(5) The size effect of work-hardening depends strongly on the crystal orientation in the vicinity of [001], but moderately in the vicinity of [011]. The behaviour in the vicinity of [111] might be similar to [001], but the measurement was not performed on account of the difficulty to produce crystals having such an orientation.

The authors wish to express their thanks to Professor M. Yamamoto and Mr. J. Watanabe for their help in determining crystal orientation.

# On the Metastable Transition and the Crystal Structure of Ammonium Nitrate (Tetragonal Modification)

By Yasuhiro SHINNAKA

*Faculty of Literature and Science, Yamaguchi University*

(Received November 28, 1955)

Conditions for the appearance of the metastable transition (IV)⇄(II) were studied by X-ray method and dilatometer method and it was found that when the single crystals of the phase (IV) were formed from the aqueous solution at room temperature the metastable transition was always observed and that in dry ones it often proceeded as a single crystal transformation without any noticeable change in orientation. The crystal structure of the phase (II) was determined by using a single crystal obtained by the single crystal transformation. It was found that tetragonal modification (II) has also CsCl-like structure, and a hindered rotation of the nitrate groups was proposed.

## §1. Introduction

It is known that ammonium nitrate has five stable transitions and in some cases a metastable transition occurs at ordinary pressure.[1][2][3] They are shown in the following table. (Table I, and Table II.)

Among five modifications, information about the tetragonal modification (II) was particularly incomplete: nothing has been determined concerning atomic positions along the *c* axis. The reason is that it was very difficult to obtain reliable intensity measurements since the particle size increased rapidly during powder photographing. The author studied the metastable transition (IV)⇄(II) and determined the structure of this modification (II) by using

Table I. Stable Transition

| Phase | Liquid | | (I) | | (II) | | (III) | | (IV) | | (V) |

Table II. Metastable Transition.

| Phase | (II) $\rightleftarrows$ (IV) |
|---|---|
| Trans. Temp. (°C) | ~50 |

a single crystal obtained by the process of this metastable transition (IV)→(II) under certain conditions.

## § 2. Metastable Transition

The conditions for the appearance of the metastable transition were studied by the method of dilatometer; they are related to the maximum temperature reached, the time of heat treatment and the water content of the specimen.

On the metastable transition (II)→(IV), conditions for the appearance of it were recently studied also by K. Tanaka and his co-worker[4] and the same results were obtained by this experiment.

On the other hand, on the metastable transition (IV)→(II), it was found that conditions for the appearance of it have the same tendency as that of the metastable transition (II)→(IV). When the phase (IV) was originally formed from the phase (III), it was required for the appearance of this metastable transition that the samples were to be left untouched more than one week at room temperature (20°C) in wet samples, but in dry ones the samples were to be left untouched for several months at the same temperature. And when the phase (IV) was originally formed directly either from the phase (II) by the process of metastable transition (II)→(IV), or from the aqueous solution at room temperature, the metastable transition was always observed.

The character of the metastable transition was investigated by the X-ray method using the single crystal of the phase (IV) prepared from the aqueous solution at room temperature. The metastable transition often proceeded in dry samples as a single crystal transformation without any noticeable change in orientation, and the single crystal was sometimes found to be broken even in dry samples by distinct recrystallization after the above transformation; also in wet samples, it was broken by the transformation to stable modification (III) after the metastable transition.

These phenomena might be explained as K. Tanaka[4] did on the metastable transition (II)→(IV): Nuclei of the phase (III) in the phase (IV), still remaining after the transformation (III)→(IV), were completely destructed by leaving untouched at room temperature in a long period, and so the phase (IV) changes directly to the phase (II) without nucleation of the phase (III) in the course of heating. The phase (II) has similar structure (CsCl-like structure) to the phase (IV) as will be described in the next paragraph. But the phase (III) has NiAs-like structure and a larger specific volume than those of the phases (IV) and (II). Wet specimens are easier to get in and out of metastable conditions than dry ones are. The action of moisture is now under investigation.

## § 3. Crystal Structure of the Phase (II)

Thus the single crystal (II) was obtained by the single crystal transfomation (IV)→(II) from the single crystal (IV), and it had mosaic structure with slight diffuse Laue spots. As the needle axis of the crystal is $a$ axis, photographs were taken with a crystal rotating about $a$ axis with CuK$\alpha$ and MoK$\alpha$ radiations at 60°C and 100°C. At both temperatures the noticeable change was not observed in the photographs. In this experiment it was observed that several reflection planes have different values of intensity from those given by S. B. Hendricks and his co-workers[2].

The data require a tetragonal unit of structure with $a = 5.74$ Å, $c = 4.95$ Å at 60°C, containing two molecules. Among possible six space groups ($P_4$, $P_{\bar{4}}$, $P_{4mm}$, $P_{4bm}$, $P_{\bar{4}2_1m}$ and $C_{\bar{4}2m}$) $P_{4bm}$ and $P_{\bar{4}2_1m}$ seem to be selected by the fact that planes of the type $(0\,k\,l)$ with odd values of $k$ and $(h\,0\,0)$ with odd values of $h$ are absent.

The intensities were calculated on the basis of the assumed $f$-curves.[5][6][7] From the reflections of $(h\,k\,0)$ it was determined that the atomic arrangement on (001) corresponds to positions $x$, $\frac{1}{2}+x$, $w$; etc., with $x = 0.12$ for space groups $P_{4bm}$, and $P_{\bar{4}2_1m}$ (see Fig. 1). But the atomic arrangements derived from these space groups lead to calculated intensities entirely out of agreement with the observed intensities of planes of type either $(0\,0\,l)$ or $(0\,k\,l)$.

Possible escape from this contradiction might be achieved by rotation of nitrate groups, as it was considered in cubic modification (I). Several modes of randomness in orientations of the nitrate groups were tried. When nitrate groups are assumed to be rotating in a plane of each nitrate group determined from the atomic arrangement on (001) mentioned above, the calculated intensities were in good agreement with the observed intensities. However, the rotation of the nitrate group in the plane is required to be not free, but is almost bound in two orientations (in opposite directions) considered from the atomic arrangement on (001).

Atomic positions are approximately as follows.

$$2NH_4 : 0, 0, 0;\ \tfrac{1}{2}, \tfrac{1}{2}, 0$$

Two orientations of nitrate group:

| $2NO_3$ | One nitrate group | | | Other nitrate group | | |
|---|---|---|---|---|---|---|
| N | $\frac{1}{2}, 0, u$ | or | $\frac{1}{2}, 0, \bar{u}$ | $0, \frac{1}{2}, u$ | or | $0, \frac{1}{2}, \bar{u}$ |
| O (1) | $\frac{1}{2}, 0, v$ | | $\frac{1}{2}, 0, \bar{v}$ | $0, \frac{1}{2}, v$ | | $0, \frac{1}{2}, \bar{v}$ |
| (2) | $\frac{1}{2}+x, x, w$ | | $\frac{1}{2}+x, x, \bar{w}$ | $\bar{x}, \frac{1}{2}+x, w$ | | $\bar{x}, \frac{1}{2}+x, \bar{w}$ |
| | $\frac{1}{2}-x, \bar{x}, w$ | | $\frac{1}{2}-x, \bar{x}, \bar{w}$ | $x, \frac{1}{2}-x, w$ | | $x, \frac{1}{2}-x, \bar{w}$ |

with $x=0.12$, $u=0.53$, $v=0.75$, and $w=0.42$.

The agreement of observed and calculated intensities from the atomic positions is shown in Table III.

The results mentioned above show that the phase (II) has also the CsCl-like structure. The unimolecular pseudocell resembling CsCl has the same value of $c$ axis as the true unit, and each of the $a'$ axes is half the face diagonal of the latter (see Fig. 2). Each nitrate ion has eight nearest ammonium ions and all the nearest $NH_4-O$ distances are approximately the same (about 3.1 Å). From this structure it is natural to consider that the nitrate groups are in hindered rotation in the phase (II) before the free rotation sets in at higher temperatures (the phase (I)).

In conclusion the author wishes to express his hearty thanks to Dr. K. Tanaka of Kyoto University for many valuable suggestions and discussions. He is also grateful to Prof. T.

# Electron-Diffraction Study of the Structure of Supercooled Liquid Bismuth

By Mieko TAKAGI

*Physics Department, Tokyo Institute of Technology,*
*Oh-Okayama, Meguro, Tokyo*

(Received December 3, 1955)

Thin bismuth films were prepared on crystal surfaces by evaporation and the liquid state of the films at temperatures above and below the ordinary melting point (271°C) has been studied by means of the reflexion method of electron diffraction. The marked supercooling of the films (M. Takagi: J. Phys. Soc. Japan **9** (1954) 359) has been utilized for the study below the melting point. A method to eliminate difficulties inherent to the intensity measurement by reflexion method and a method to refine the observed intensity values were developed.

The radial distribution curves at 400°C, 271°C (the melting point), 175°C, 130°C and 110°C (a little above the solidification temperature) were computed from experimental data. The curves showed a systematic change with temperature. It was revealed that the atomic arrangement at 110°C resembles closely that of solid bismuth. Above the melting point a tendency towards close-packed structure was noted.

## § 1. Introduction

The radial distribution function is an important characteristic of liquid substances, metals and non-metals. From this function, direct information on the degree of the short range regularity present in atomic arrangement of liquids can be derived. For instance, it has been revealed by the temperature dependence of the function that the regularity increases as temperature lowers, tending to manifest a quasi-crystalline structure.

There have been reported many studies on structure of the liquid phase of metals not only by $X$-ray but recently even by neutron diffraction method. Of the studies which treated the temperature dependence of the distribution function, we can mention the work of Boyd and Wakeham1) on liquid mercury at the temperature ranging from −36°C (just above the melting point) to 250°C. That the melting point of mercury is fairly low (−38.9°C) is especially favorable to observe a characteristic change in the radial distribution function with temperature. However, it has been reported that the similar change is not appreciable for metals having higher melting point. For instance, the structures of liquid tin studied by Hendus2) by means of $X$-rays, and of liquid lead and bismuth studied by Chamberlain3) and by Scharrah and Smith4) by means of neutron diffraction showed no remarkable difference with temperature. If we can maintain the supercooled state of these metals at temperatures far below the melting point so that the variation of radial distribution curves is studied over much wider temperature range including the melting point, the temperature effect will appear more distinctly. However such a study is very difficult by *X*-ray or neutron diffraction method because in these methods a mass of metal must be used as a sample and the supercooled state is hardly maintained for a long period.

On the other hand, as has been shown by the electron diffraction studies by Sayama⁵⁾ on tin and the present author⁶⁾ on lead, bismuth and tin, thin metal films prepared in vacuum by evaporation on crystal surfaces show a quite marked nature of supercooling. For example, the observed solidification temperature of *Bi* films, *Pb* films and *Sn* films with thickness of about 50 Å were 124°C, 170°C and 40°C respectively, while the ordinary melting points of these metals are 271°C, 327°C and 232°C respectively. In my previous paper⁶⁾ the phenomenon was explained, with reference to Turnbull's⁷⁾ experiment and his theory, as that the evaporated films are made of droplets whose diameters are so small that each of them contains scarcely any accidental inclusion which acts as a nucleus of crystallization.

The fact that the supercooled liquid state is maintained during the period of observation means that the electron diffraction method is very suitable for the study of liquid states of metals over an extended temperature range. There are, however, some experimental difficulties inherent to the reflexion method of electron diffraction. In the present paper a method to analyse the liquid pattern in reflexion photographs of electron diffraction is developed, and the change of the radial distribution function of liquid bismuth is studied over the temperature range from 400°C to 110°C. Since the crystal structure of solid bismuth is not of a close-packed type, we expected the radial distribution function at lower temperatures to show some interesting behaviors.

## § 2. Experimental

Bismuth films of about 50 Å in mean thickness were prepared by evaporation in an evacuated electron diffraction camera⁸⁾. The base crystals employed were either fresh cleavage surfaces of zincblende single crystals or flat natural surfaces of silicon carbide single crystals. Oxide films formed on the surfaces of silicon carbide were removed beforehand by the following treatment: the crystals were boiled in conc. aqueous caustic soda, dipped in dilute nitric acid, washed in water, dipped in absolute alchol and then dried.

While evaporating bismuth, the base crystal was kept at about 400°C so that a bismuth film in liquid state was formed on its surface. The temperature of the crystal is measured by a thermocouple⁶⁾. After the formation of the film, the temperature of the crystal was lowered gradually. The solidification temperature of the film was easily determined by observing the diffraction pattern on a fluorescent screen because at this temperature the pattern changed abruptly from halos to Debye-Scherrer rings. The film thus solidified was reheated through the melting point up to 400°C, and then cooled again gradually. The diffraction patterns from the liquid film were taken at various temperatures during the second course of cooling. The cooling rate near the solidification temperature was kept at about 1°C per minute. As the exposure time needed was 1∼2 seconds, it was possible to observe the state at a temperature within 0.2°C of the solidification temperature.

completely free from rings due to oxides of *Bi*. The photographs obtained at 400°C and 110° (just above the solidification temperature) are shown in Fig. 1.

All the photometry of the halo patterns from liquid bismuth was performed along radius nearly perpendicular to the shadow edge. The obtained microphotometer curves were converted into the intensity curves in accordance with the method of Karle and Karle⁹⁾. In their method, a pair of diffraction photographs with different exposure time were taken at each temperature concerned. The blackness-intensity curve of the photographic film used was determined by the photometry of the pair of photographs assuming the linearity of this curve in the range of weak electron intensity.

An example of the obtained intensity curve, $I_{obs}$ is shown in Fig. 2. In this curve which corresponds to the film of liquid bismuth at 110°C, intensity maxima are observed at about 2.0 $\text{Å}^{-1}$, 4.0 $\text{Å}^{-1}$ and 6.1 $\text{Å}^{-1}$ in $s$ value, where $s=4\pi\sin\theta/\lambda$, $2\theta$ being the scattering angle and $\lambda$, the wave length. In addition a subsidiary maximum is noted at about 2.9 $\text{Å}^{-1}$. This subsidiary maximum is more conspicuous at lower temperatures than at higher temperatures. Positions of maxima in the observed liquid patterns are summarized in Table I.

The decrease of $I_{obs}$ is approximately inversely proportional to the scattering angle, and is not so rapid as expected from the law of the inverse fourth power of scattering angle. This is because the background in $I_{obs}$ includes components which depend only a little on the scattering angle. The nature of the background is discussed in more detail in the following section.

## § 3. Method of Calculation of Radial Distribution Function from Observed Intensity

Similarly to the well known procedure in X-ray diffraction¹⁰⁾, the radial distribution function $4\pi r^2\rho(r)$ for a monatomic liquid is obtained by the following formula:

$$4\pi r^2\rho(r)$$

$$=4\pi r^2\rho_0+\left(\frac{2\pi}{\pi}\right)\int_0^\infty si(s)\sin sr\,ds,$$

$$i(s)=\frac{I_{co}-NI_e|f|^2}{NI_e|f|^2},$$

$$f=Z-F,\quad s=4\pi\sin\theta/\lambda\,, \qquad (1)$$

where $\rho_0$ is the mean density of atoms in the liquid, $I_{co}$ is the intensity of coherent electron scattering from the liquid, $N$ is the total number of scattering atoms, $I_e$ is the intensity of the electron wave scattered by a point charge $+e$, $Z$ is the atomic number, $F$ is the atom form factor for X-rays and $f$ is the atom form factor for electrons.

We are required to deduce $I_{co}$ from the observed total intensity, $I_{obs}$, which is written as

$$I_{obs}=I_{co(obs)}+I_{back} \qquad (2)$$

where $I_{co(obs)}$ is the coherent single scattering from the liquid film and $I_{back}$, the general background. Since the interference pattern proper to the base crystal is mostly covered by the liquid pattern, the scattering from the base crystal contributes only to the general background. Besides, $I_{back}$ contains the stray scattering from slits and residual gases, the incoherent scattering from the liquid film, and the secondary or multiple scatterings of the coherent part from the liquid film.

It should be noted that $I_{co(obs)}$ is not the same as $I_{co}$ in (1) because the scatterings from the liquid suffer a intensity modulation due to the presence of the surface of the base crystal, the circumstance which is peculiar to the reflexion method in the present study. This modulation is due to the absorption of the scattered electrons due to the surface, and depends upon the topography of the surface, the thickness of the film, as well as the kind of substance of the base crystal and that of the evaporated metal. Let us define for each photograph the modulation function $\Phi$ as follows:

$$\Phi = \frac{I_{co(obs)}}{I_{co}} . \qquad (3)$$

From (3), (2) is rewritten as

$$I_{obs} = \Phi \cdot I_{co} + I_{back} . \qquad (4)$$

$I_{co}$ can be obtained provided the function $\Phi$ is available and the background term $I_{back}$ is separable from (4).

$\Phi$ is, of course, an angle dependent function; it depends not only on the scattering angle but also on the direction of radius along which photometry is performed. It also depends on the glancing angle of the incident electrons to the base crystal. The method employed to obtain the function $\Phi$ and the procedure of separation of the $I_{co}$ term were as follows.

### a) Experimental Determination of the Modulation Function

To determine the function $\Phi$, we assume that this function remains unchanged whether the film concerned is in liquid state or in solid state. This assumption will be reasonable provided that the submicroscopic structure of the film undergoes no marked change at the time of melting or solidification. This can be considered to be the case for evaporated metal films as thin as 50 Å, for the films are composed of almost independent colonies. Then the function $\Phi$ for a liquid film is given by the ratio of observed to theoretical values of the integrated intensities of the Debye-Scherrer rings from crystallized state. In order to apply this method, it is required that the crystalline texture of the solidefied film is free from preferred orientation.

Though the function $\Phi$ should be obtained for the same sample which was used in the study of liquid, it was impossible unfortunately for evaporated *Bi* film because of a preferred orientation of crystallites. We were therefore obliged to apply an approximate procedure in the following way.

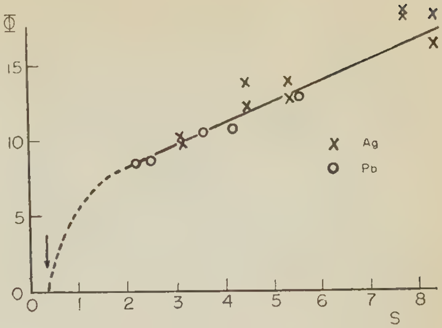

Fig. 3. Modulation function $\Phi$ obtained from two Ag films and a lead film in arbitrary scale. An arrow in the fig. indicates the position of shadow edge in diffraction patterns.

We prepared orientationless films of silver or lead metal, instead of bismuth, on base crystals of zincblende or silicon carbide, which were similar in size and in nature of the surface to the base crystals used for the study of liquid. The orientationless silver films were prepared by evaporating AgI on the base kept at about 450°C (Silver is formed as the result of decomposition of AgI.). The orientationless lead film was prepared by evaporating lead on the base crystal at room temperature. The diffraction patterns from these films were taken with glancing angles of incident beams approximately equal to the angles adopted in the study of the liquid bismuth. The modulation functions for these samples were obtained as the ratios of the observed values to the theoretical ones of the integrated intensities of the diffraction rings.

Some of the earlier experiments have shown that the intensities of the Debye-Scherrer rings from certain metal films of about 50 Å in mean thickness or in grain size can be estimated in accordance with the kinematical theory11)12), while other experiments have shown that the intensity of (111) and (200) rings from similar metal films deviates about 10%* from the kinematical value13)14). Since both the grain size estimated from the half

---

* The value 10% was estimated making allowance for different values of the mean thickness, grain size and energy of electrons in different experiments.

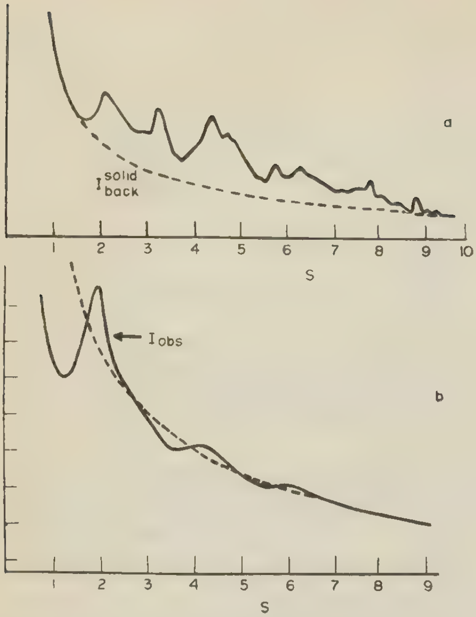

Fig. 4. The experimental procedure to deduce $I_{co}$ and $NI_e|f|^2$.

b. Full line shows the total intensity of liquid halo $I_{obs}$, and the broken line shows $b|f|^2+a\cdot I^{solid}_{back}$. $a$ and $b$ were determined so as to make the broken line agrees with the full line at large value of $s$.

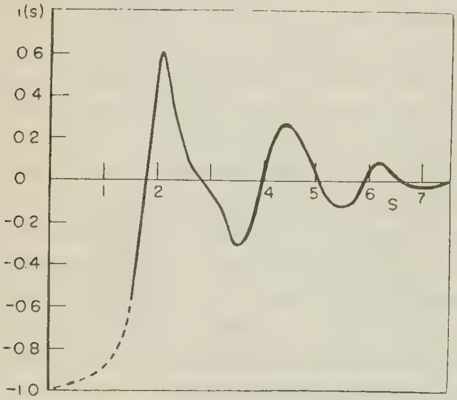

Fig. 5. $i(s)$ curve at 110°C.

breadth of the diffraction rings and the mean thickness of silver and lead films used in the present study were about 50 Å, there is a possibility that the Debye-Scherrer rings from these films contain the dynamical effect. However, for simplicity, we have neglected the dynamical effect. Also, the Debye temperature factor was neglected. The influence of the approximate estimation of ring intensities on the final result of the present study will be discussed in § 5.

Similarly to the case of the halo patterns from liquid bismuth, the photometry of the ring patterns to determine the function $\Phi$ was performed along radius nearly perpendicular to the shadow edge. Fig. 3 shows the function $\Phi$ obtained from two Ag films made on zinc-blende and a *Pb* film made on silicon carbide. We can see in Fig. 3 that the observational points in the three cases lie approximately on a commom curve irrespective of the kinds of evaporated metals and of base crystals. Considering this fact together with the fact that the size of colonies in the films of silver, lead and bismuth are similar (about 50 Å), and that the atomic numbers of lead ($Z=84$) and bismuth ($Z=83$) are near, it is most probable that the modulation function for bismuth films will not be so different from the average curve given in Fig. 3. We, therefore, adopted this curve for the modulation function for the bismuth films.

### b) Separation of $I_{co}$

Though the theoretical estimation of background $I_{back}$ in (4) is most difficult, $I_{back}$ can be separated from $I_{obs}$ when we assume:

(i) For one sample the dependence of $I_{back}$ on scattering angle is the same independent of the state of the film, liquid and solid.

(ii) $I_{co}$ is proportional to the square of the atomic scattering factor $f$ for sufficiently large value of $s$.

Let us denote the background intensity in the Debye-Scherrer ring pattern from a solidified film as $I^{solid}_{back}$. Then, from the assumption (**i**) the background in the liquid halo pattern is.

$$I_{back}=a\cdot I^{solid}_{back}\,, \tag{5}$$

where $a$ is a certain constant which depends on the ratio of the effective exposure time for the photograph from the liquid state to that for the photograph from the solid state. Then, we have

$$I_{obs}=\Phi\cdot I_{co}+a\cdot I^{solid}_{back}\,. \tag{6}$$

Next, by the assumption (**ii**) and from (6) we have

$$I_{obs}=\Phi\cdot b|f|^2+a\cdot I^{solid}_{back}\,, \tag{7}$$

in the range where $s$ is sufficiently large. $b$

is again a certain proportional constant. $NI_e|f|^2$ in (1) is given by

$$b|f|^2 = NI_e|f|^2 \,. \qquad (8)$$

The experimental procedure to deduce $I_{co}$ and $NI_e|f|^2$ in (1) is as follows. The constant $a$ and $b$ are determined so that the experimental curves $I_{obs}$ and $I_{back}^{solid}$ (Fig. 4a), both of which are given in arbitrary scale, fulfil the relation (7) in the range where $s$ is large (Fig. 4b). Then from (6) and (8), $I_{co}$ and $NI_e|f|^2$ can be determined, from which $i(s)$ in (1) is obtained. An example of $i(s)$ curve is showed in Fig. 5.

## § 4. Refinement of the Radial Distribution Curve

The errors of the radial distribution function calculated by the relation (1) may be mainly due to the error of $I_{co}$, hence of $i(s)$, and to the termination effect.

**a) Refinement of the Intensity Curve $I_{co}$.** The inaccuracy of $I_{co}$ may be mainly caused by the inaccurate determination of the curve $I_{back}$ and that of the modulation function $\Phi$. As described in the previous section, we have utilized $I_{back}^{solid}$ to deduce $I_{back}$. Actually, however, the Debye-Scherrer rings from solid *Bi* films were so broad that determination of the curve $I_{back}^{solid}$ is not free from arbitrariness. As $I_{back}$ amounts to a relatively large part in the total intensity $I_{obs}$, the error of $I_{back}$ due to the error of $I_{back}^{solid}$ influence sensitively the final values of the radial distribution function. In order to minimize the above error, the $I_{back}$ curve was corrected in the following way.

In electron diffraction studies of structure of gas molecules, the background intensity curve has been refined to conform to the criterion that there should be no negative value of the atomic density for all value of the distance $r$[15]. In the case of liquid, the same criterion is not effective to make refinement of the result because the atomic distribution density of liquid fluctuates around the mean density $4\pi r^2 \rho_0$ which possesses an appreciable positive value except for a range of small $r$. In the present study, therefore, the refinement of the curve $I_{back}$, or that of the curve $I_{co}$ was made by imposing a more severe condition as follows: *the atomic distribution function must be zero for* $r$ *which is smaller than the atomic diameter* $d$. From (1) the condition requires,

$$u(r) \equiv \int_0^\infty s i(s) \sin rs \, ds = -2\pi^2 r \rho_0 \quad \text{for} \quad r < d. \qquad (9)$$

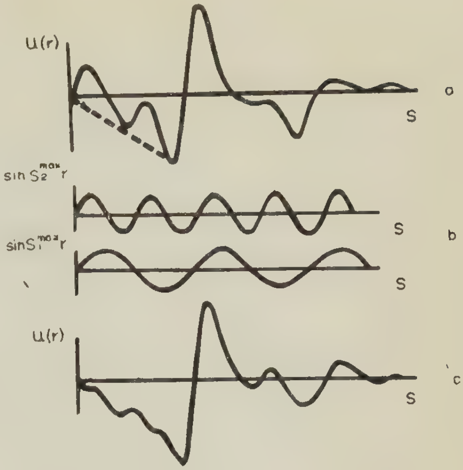

Fig. 6. Experimental method of refining the intensity curve.
a. Uncorrected $u(r)$ curve at 271°C. Broken line shows the theoretical value $-2\pi^2 r \rho_0$.
b. Value of $\sin s_2^{\max} r$ and of $\sin s_1^{\max} r$.
c. The $u(r)$ curve calculated with improved $i(s)$.

The experimental method of refining the intensity curve is explained below with an example.

Fig. 6a shows the function $u(r)$ calculated by using an uncorrected intensity curve measured on a pattern from a liquid *Bi* film at 271°C. The broken line drawn in the range of small $r$ represents the theoretical value $-2\pi^2 r \rho_0$. A ripple having two prominent peaks in this range is gohst peaks which should be extinguished by the appropriate correction of the intensity curves $I_{co}$ or $I_{back}$. The method of correction is generally trial and error guided by the following principle.

Let us denote the $s$-values at maxima and at minima of a $i(s)$ curve by $s_1^{max}, s_2^{max}, \cdots$ and $s_1^{min}, s_2^{min}, \cdots$. Since the contribution of these values amounts to a large value in the integral (9), errors of maximum and minimum values have an important influence on the results. If, for instance, one of maxima say at $s = s_i^{max}$, is too low or too high compared with the correct value of $i(s)$, a ripple with the period $2\pi/s_i^{max}$ may appear in the calculated $u(r)$ curve. This may be noticed most distinctly in the range $r < d$. The same is true of $s_i^{miu}$. Therefore, it may be said that the ripple appearing in Fig. 6a was caused by a too low estimation of the value of the second maximum at $s_2^{max}$ in the $I_{co}$ or $i(s)$ curves. This circumstance is seen clearly from the comparison of Fig. 6a with Fig. 6b showing $\sin s_2^{max}r$ and $\sin s_1^{max}r$ respectively. In order to approach the condition (9) more, the second peak of $I_{co}$ must be lowered and accordingly the background $I_{back}$ must be corrected to a little higher value in the range near $s=s_2^{max}$. By repeating this process we can obtain the $i(s)$ curve improved throughout the whole range of $s$. The $u(r)$ curve calculated with the improved $i(s)$ is showh in Fig. 6c, in which we can see that the ripple has almost disappeared.

The radial distribution function shown in Fig. 7 (§ 5) are calculated with the intensity curves refined by the above procedure.

We have no systematic method to elliminate the error which might come from inaccuracy of the modulation function, in particular when liquid bismuth is dealt with. Also the influence of the error accompanying the photometry may not be negligible. However, we can say that the above procedure of refining the intensity curve simultaneously mitigates effect of the errors due to these sources to some extent, though not satisfactorily.

**b) Termination effect**

The upper limit of the $s$-value adopted in the present study is $s=8$, as the magnitude of $i(s)$ falls to the order of experimental error for larger values of $s$. For the purpose of testing whether or not the termination of the integral in (1) at $s=8$ gives rise to spurious maxima or minima in the calculated distribution curves, we computed the integral by using $i(s)$ multiplied by a damping factor[15] exp $(-as^2)$. By means of the convolution theorem such an integral is related to $\rho(r)$ as follows:

$$\int_0^{s_{max}} si(s)\exp(-as^2)ds=[1/2(\pi a)^{1/2}]$$
$$\times\int_{-\infty}^{\infty} 2\pi^2 t[\rho(t)-\rho_0]\exp[-(r-t)^2/4a]dt. \tag{10}$$

In order to keep the half breadth[15] of $\exp[-(r-t)^2/4a]$ small enough compared with those of peaks present in the radial distribution function, the value adopted for the constant $a$ was $a=0.0145$ Å$^2$, thence $\exp(-as^2)\approx 1/2.5$ at $s=8$.

The calculations carried out on a few selected examples showed that the radial distribution curves remain almost unchanged. From this evidence we can conclude that the termination effect is small and does not give rise to any extra peaks.

That the effect of the termination is negligible can be endorsed also from the following consideration. Since the density function $\rho(r)$ for monatomic liquid distributes over a wider range of $r$ and since it contains broader peaks compared with the density function of gas molecules, the intensity function $i(s)$ of liquid (being the Fourier transform of $\rho(r)-\rho_0$) must damp with $s$ more rapidly than the intensity function of gas molecules. This explains why the termination effect is less important for monatomic liquid than for gas molecules.

## § 5. Result and Discussion

By using improved values of $i(s)$, the integral in (1) up to $s=8$ was calculated with the aid of punched cards and a Remington Band machine. For $i(s)$ in the range from $s=0$ to $s=1.3$ the extrapolated value was used. Fig. 7 shows the obtained radial distribution functions $4\pi r^2\rho(r)$ for bismuth films of about 50 Å in mean thickness at 400°C, 271°C (the ordinary melting point), 175°C, 130°C and 110°C (a little above the solidification temperature of the film).

In Fig. 8 our distribution curve at 271°C is compared with the curve at 310°C obtained by neutron diffraction by Chamberlain[3]. Though the temperatures are different, the change in atomic distribution in liquid above the melting point is negligible for such a small temperature difference. The similarity in both curves and the systematic change of the radial distribution curves with temperatures support the validity of our result in spite of difficulties accompanying the electron diffraction method as mentioned in § 3.

Moreover, we can show that the influence of systematic errors of the modulation function (§ 3a) on the final result is not so important. Let us denote the correct modulation function for the film concerned by $\Phi'$. $\Phi'$ will be related to $\Phi$ used in the present calculation as $\Phi'=m(s)\cdot\Phi$, where $m(s)$ is a monotoneus function. The difference between $\Phi$ and $\Phi'$ mainly results from the neglect of the dyna-

mical effect which is negligible at large $s$-values and is conspicuous at small $s$-values. The deviation of intensity at the position of (111) rings from films of metals such as silver or lead is at most about 10% as was described in § 3 a. Therefore $m(s)$ is approximately equal to unity but increases slightly as $s$-value decreases and may attain to a value∼1.1 at $s=2$ (the position of (111) ring). The correct value of $i(s)$ for the film, which we denote here by $i'(s)$, is related to $i(s)$ as $i'(s) \sim i(s)/m(s)$. Thus the integral in (1) for the film should be $\int si'(s)\sin rs\,ds$, while in the present calculation the integral $\int si(s)\sin rs\,ds$, or $\int si'(s)m(s)\sin rs\,ds$, has been used instead. According to the convolution theorem, this integral can be written as the convolution of the Fourier inversion of $si'(s)$ and of $m(s)$. Because of the monotonous nature of $m(s)$ as mentioned above, the Fourier inversion of $m(s)$ will have a dominant peak only at the

Table II. Position of peaks in the radial distribution curves and the number of atoms (shown in parenthesis) under each peak.

| | position of peaks and the number of atoms | | | |

| 110°C | 3.3 Å (6) | 4.5 Å (10) | 5.6 Å (8) | 6.5 Å |

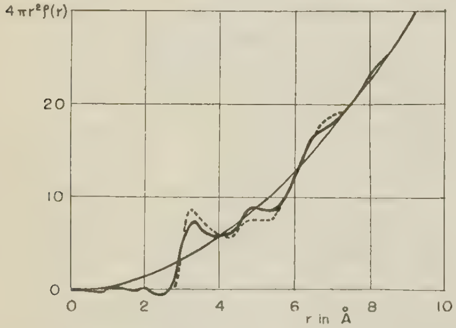

Fig. 8. Comparison of a obtained distribution function with that from other experiment. Full line shows the distribution curve at 271°C in this experiment, and broken line shows that at 310°C with neutrons by Chamberlain.

origin and no other serious ripples at larger distances[16], thus the integral $\int si'(s)m(s)\sin rs ds$ will differ not greatly from the integral $\int si'(s) \sin rs\, ds$.

The distribution curves can be divided into peaks as are shown by broken lines in Fig. 7. Numerals inscribed are the number of atoms under the peak concerned. The positions of the peaks and the number of atoms under each peak are summarised in Table II.

Solid bismuth has the rhombohedral structure with the cell dimension $a_0=4.736$ Å, $\alpha=57°14.5'$, containing two atoms in the position $uuu$; $\bar{u}\bar{u}\bar{u}$, where $u=0.237$. This structure is a sort of distorted simple cubic structure; when $\alpha=60°$ and $u=0.25$, it is a simple cubic structure. The distribution of atomic shells in solid bismuth and that in a fictitious structure which is a simple cubic arrangement of atoms with the same atomic volume as bismuth are shown in Fig. 7f and 7g, respectively. The distribution of the fictitious close-packed structure of atoms with the same atomic volume is also shown in Fig. 7h. The feature of the radial distribution curves at each temperature are described below in detail.

### Supercooled state

**i) 110°C** (0.2°C above the solidification temperature) (Fig. 7e). Four peaks are observed at 3.3 Å, 4.5 Å, 5.5 Å and 6.5 Å. The number of atoms under the first, second and third peaks are 6, 10 and 8, respectively. At this temperature, both the position and the number of atoms under each peak are almost the same as those in the structure of solid bismuth (Fig. 7f) or in the above mentioned simple cubic structure (Fig. 7g).

**ii) 130°C and 175°C** (Fig. 7d and 7c). The positions of peaks are at about 3.3 Å, 4.4 Å, 5.2 Å and 6.5 Å. The number of atoms under the first, second and third peaks are 6, 6 and 8 respectively. The second and the third peaks at 130°C and 175°C are nearer the origin than the corresponding peaks at 110°C. The three curves at 110°C, 130°C and 175°C show that the sharpness of the peaks, hence the deviation from the mean atomic distribution $4\pi r^2\rho_0$ is more conspicuous at lower temperatures.

### Above the melting point

271°C and 400°C (Fig. 7b and 7a). The position of peaks at 271°C are 3.3 Å, 4.8 Å and 6.5 Å, and those at 400°C are 3.6 Å, 5.0 Å and 7 Å. The number of atoms under the first peak at these temperatures is about 8. The second peak corresponds to the unified peak of the second and the third peaks observed at 110°C, 130°C and 175°C.

From the above result we can see that the nature of homopolar binding persists in the liquid state of bismuth. The fact that the number of atoms under the first peak is 6 in the supercooled state indicates that the shell structure in this state is almost the same as that of solid. At 110°C, not only the first but the second and the third peaks are also related to the corresponding atomic shells in the solid structure. At the melting point the number of atoms under the first peak increases from 6 to 8 and the position of the peak shifts outwards slightly. The positions of the first and the second peaks above the melting point tend to the positions for the fictitious close-packed structure (Fig. 7h), suggesting a tendency towards the close-packed structure.

For mercury, Harasima[17] showed as an application of his theory that the peak value of the first maximum is inversely proportional to $\sqrt{T}$, where $T$ is absolute temperature. The same trend is observed in the present experiment in the supercooled state. In Table III the maximum value of the first peak $4\pi r^2 \rho(r)_{max}$ and also $4\pi r^2\rho(r)_{max}\cdot\sqrt{T}$ are tabulated. We can see in it that the latter value remains almost unchanged for the supercooled state.

Table III.

| | $4\pi r^2\rho(r)_{\max}$ | $4\pi r^2\rho(r)_{\max}\cdot\sqrt{T}$ |
|---|---|---|
| 175°C | 7.4 | 16×10 |
| 130°C | 8.0 | 16×10 |
| 110°C | 8.7 | 17×10 |

The result of the present study shows that the application of the electron diffraction method is quite useful for study of the liquid state of metals. The merits exclusive to this method are the feasibility of treating the supercooled state over a wide temperature range. On the other hand, the most important weakpoint of this method is found in inevitable limit in the accuracy of the intensity measurement. The accuracy of the photometric or Geiger counter determination of the intensity of X-ray pattern is superior to the photometric determination of the intensity of electron diffraction pattern, mainly because of higher background and of larger intensity range in the electron diffraction pattern compared with those in the X-ray patterns. This defect in electron diffraction method can be lessened to some extent with the use of rotating sectors which have been applied in the study of gas molecules. It will be interesting to extend the present study to other kind of metals with such an improved method of intensity measurement.

In concluding the present article the author wished to express her sincere thanks to Prof. S. Miyake for his kind advices throughout this work and also to Prof. A. Harasima and to Mr. S. Takagi for discussing this paper with me. The author's thanks are also due to Prof. Y. Morino for allowing me to use punched cards and to Mr. K. Kuchizu and Mr. E. Hirota for their advices and for laborious work in computing integral in the formula (1) with punched cards and machines.

# Application de la Méthode de Décapage Ionique en Diffraction Electronique:

## Etude de la Structure de Dépôts Thermiques d'Or sur des Supports Cristallisés ou Amorphes

Par Jean Jacques TRILLAT, Nobuzo TERAO, Léa TERTIAN
et Henri GERVAIS

*Laboratoire de Rayons X du Centre National de la Recherche
Scientifique á Bellevue (S. & O.), France*

(Received December 17, 1955)

We have done a new arrangement which allows us to bomb a sample with ions and at the same time examine its structure. In these conditions we obtain a progressive scouring of the superficial coats; electron diffraction gives information about the structure so laid bare.

In this paper we first describe the experimental method and give an example referring to the study of the gold coats laid down on different props. So it's possible to study continuously the relations of epitaxy between the prop and the metal laid down in various conditions. Then we point out the limits of that method and the causes of error.

## §1. Introduction

On sait que l'impact d'un faisceau d'ions positifs sur une cible métallique peut provoquer l'arrachement de particules du métal; c'est le principe même de la pulvérisation cathodique, qui a été utilisé par divers auteurs pour l'attaque ou l'amincissement des préparations destinées à la Microscopie électronique (HEINDENREICH1), CASTAING et LABORIE2)). Récemment FERT3) a montré qu'en utilisant un "canon à ions" approprié, il était possible de bombarder un échantillon en cours d'observation en microscopie ou diffraction électronique, et d'explorer ainsi la structure de l'échantillon en fonction de la profondeur, par arrachement des couches successives de la surface.

Les observations de FERT laissent entrevoir un champ d'applications considérable pour l'étude des structures superficielles et des phénomènes d'épitaxie, sous la condition formelle que l'action du faisceau d'ions ne donne pas lieu à des phénomènes parasites (contamination, action chimique, échauffement etc.). Or, nous avons montré que ces actions pouvaient parfois être importantes et qu'il était donc nécessaire de bien préciser les limites et les possibilités de la méthode de bombardment ionique associée à la diffraction électronique (J. J. TRILLAT)4).

Le but du présent travail est précisément d'étudier en détail une application du décapage ionique dans un cas caractéristique, celui d'un dépôt métallique orienté par son support. Pour cela, nous avons choisi un métal non oxydable et chimiquement inerte, l'or, et des supports variés, cristallisés ou amorphes. De plus, nous avons cherché, à cette occasion, à perfectionner la technique et à l'appliquer non seulement aux examens par réflexion, mais aussi aux examens par transmission.

## §2. Méthode Expérimentale

Le schéma du canon à ions que nous avons utilisé est représenté sur la figure I; cet appareil, construit dans notre laboratoire par H. GERVAIS, permet de réaliser l'ionisation d'une petite quantité d'air ou de gaz raréfié (argon, azote, etc.) entre une anode pouvant être portée jusqu'à 27 Kilovolts et une cathode mise au sol et servant de diaphragme.

L'isolement électrique est assuré par un double manchon en verre Pyrex. Les parties métalliques sont en lation recouvert d'une couche de nickel; le diaphragme de sortie (cathode) est constitué d'une pastille d'aluminium ou de molybdène percée d'un trou. (Fig. 2)

L'alimentation haute tension continue est fournie par un générateur du type employé en

Télévision, mais modifié pour permettre de disposer à la sortie d'une tension variable à volonté entre 2 et 27 Kilovolts; le débit total dans le circuit est de l'ordre de 200 $\mu$A; il est fonction de la quantité de gaz admise dans le canon, qui est elle-même réglée au moyen d'une soupape du type Induni, utilisée dans le diffractographe électronique Trüb-Tauber. Dans les conditions usuelles, en employant pour le vide la pompe moléculaire Holweck qui équipe ce diffractographe, (4 à 5 litres/sec), on obtient un vide de l'ordre de $10^{-3}$ m/m Hg, qui peut être abaissé à $3.10^{-4}$ m/m Hg par l'emploi d'une pompe à débit plus élevé (120 litres/sec.).

La mise au point et les perfectionnements apportés au canon ont eu pour but essentiel d'éviter ou d'atténuer un certain nombre d'inconvénients, portant en particulier1), sur la stabilité de fonctionnement2), sur la contamination des échantillons sous l'action des ions, 3) sur la formation d'un cratère au point d'impact du faisceau ionique, 4) sur l'échauffement de la préparation.

1) *La stabilité de fonctionnement* est avant tout fonction des caractéristiques géométriques des diverses pièces constituant le canon à ions, et en particulier des dimensions du diaphragme de sortie. Ces dimensions ont dû être déterminées par des tâtonnements successifs; pour le diaphragme, les meilleurs résultats ont été obtenus avec un canal de sortie de 1 m/m de diamètre et 1 m/m, 5 de longueur. Le fonctionnement de l'appareil est très stable entre 2 et 27 Kilovolts.

2) *La contamination* des échantillons apportée par le faisceau ionique est bien connue et a été signalée par CASTAING et DESCAMPS5) à propos du microanalyseur à sonde électronique. L'un de nous a montré antérieurement qu'elle se produit également sous l'action d'un faisceau d'électrons rapides (TRILLAT et MERIGOUX)6) et qu'elle est dûe alors à un dépôt de carbone provenant de la décomposition des traces de vapeurs hydrocarbonées présentes dans le diffractographe. Dans le cas du canon à ions, nous avons été amenés à remplacer les parties en plexiglass par du verre et à supprimer les joints de caoutchouc susceptibles de s'échauffer; la contamination est ainsi fortement diminuée et devient même négligeable grâce au perfectionnement indiqué dans le paragraphe suivant.

réflexion, est sensiblement parallèle à la surface de l'échantillon et perpendiculaire à la direction des ions, cesse donc bientôt d'y pénétrer, et toute observation par diffraction devient impossible. Si en outre il s'est formé un dépôt de contamination tout autour du cratère, la faisceau électronique rencontre ces parties contaminées et le diagramme de diffraction devient celui de l'impureté. Pour remédier à cet inconvénient, nous avons réalisé un système de balayage de la surface suivant une direction qui coïncide avec celle du faisceau (Fig. 3); ce balayage est réalisé mécaniquement, avec l'amplitude et la vitesse désirées, par l'emploi d'une came en coeur venant déformer un tube flexible étanche au vide et portant à son intérieur le dispositif de production d'ions. Le décapage ionique creuse dans ces conditions un fin canal dans lequel le faisceau d'électrons peut toujours pénétrer et se diffracter (Fig. 3). Le tube flexible est muni de vis de réglage qui permettent de pointer le canon et d'amener exactement la trajectoire des ions à rencontrer le faisceau d'électrons.

La figure 4 montre la trace du décapage ionique obtenu avec ce dispositif oscillant pour un dépôt d'or sur une lame de verre; l'échantillon est décapé sur toute sa hauteur (5 mm), sur une largeur d'environ 1 mm.

Les principaux avantages de ce systéme de balayage sont la suppression du cratère et donc la possibilité d'examiner la surface d'une préparation sur une profondeur notable (quelques microns au moins), la suppression du dépôt de contamination le long du trajet des électrons et enfin la réduction de l'échauffement superficiel.

4) *L'échauffement* de la préparation, si le faisceau ionique est immobile, est en effet notable, surtout si l'énergie des ions est grande (au-dessus de 20 KV). En recevant un faisceau d'ions de 20 KV (débit total $200\,\mu$A) sur la soudure d'un couple thermoélectrique disposé au foyer d'un paraboloïde en platine, nous avons trouvé, à l'équilibre, une température de l'ordre de 200°C. Cette température varie naturellement avec le débit des ions, la tension d'accélération, la nature et les dimensions de la cible; elle peut être localement encore plus élevée. Or, à une telle température, des métaux oxydables comme le fer, le nickel, le cobalt, etc. peuvent déjà subir une légère oxydation superficielle grâce à la présence de l'oxygène résiduel, comme nous l'avons montré antérieurement (J. J. TRILLAT)[4]. C'est d'ailleurs la raison qui nous a fait choisir l'or dans cette étude, de façon à éliminer cette cause d'erreur.

Le dispositif de balayage provoquant un changement incessant du point d'impact, permet de réduire considérablement l'effet thermique, comme on peut le vérifier au thermocouple.

*Méthode par transmission.*

Nous avons pu également adapter la technique du bombardement ionique aux examens par transmission. Pour cela, la préparation, d'une épaisseur de l'ordre de 100 à 500 Å, est disposée à 45° du faisceau d'électrons et du faisceau d'ions (Fig. 5); le faisceau d'ions la traverse au même point que le faisceau d'électrons et s'y diffracte. Les préparations résistent bien en général à l'action du faisceau ionique et, malgré la diminution progressive d'épaisseur, permettent un examen prolongé; cette technique est à rapprocher par certains côtés de celle décrite par CASTAING et LABORIE[2] pour l'examen des métaux au microscape électronique.

La méthode du bombardement ionique ainsi améliorée nous a donné des résultats intéressants dans de nombreux cas et elle peut être généralisée pour l'étude d'un grand nombre de problèmes de structures superficielles. Nous l'avons appliquée ici à l'examen de la structure des couches d'or déposées par évaporation thermique sur différents supports.

## § 3. Etude des Couches d'Or Déposées sur Différents Supports

Des couches d'or d'une épaisseur de 2.000 Å sont déposées, par évaporation thermique dans un vide de $10^{-4}$ mm Hg, soit sur des supports amorphes (lames de verre ou de plexiglass), soit sur des supports parfaitement cristallisés (plan de clivage (001) d'un cristal de NaCl).

Le dépôt est effectué de deux façons différentes suivant que les supports sont maintenus à la température de 20°C ou au contraire chauffés à une température de 400° à 450°C. Selon les cas, la méthode du décapage ionique conduit comme nous verrons, à des résultats différents. (J. J. TRILLAT, N. TERAO, L. TERTIAN et H. GERVAIS)[7].

Nous donnerons d'abord les résultats expérimentaux que nous discuterons ensuite.

*Dépots sur supports froids* (20°C).

Si l'on examine des couches d'or de 2000 Å d'épaisseur, le diagramme initial obtenu avant bombardement ionique est toujours un diagramme de Debye-Scherrer (Fig. 6), indiquant une structure microcristalline désordonnée de la surface métallique.

En bombardant le dépôt par le faisceau d'ions, avec le dispositif de balayage, on constate l'apparition rapide d'une structure fibreuse (Fig. 7) qui se précise après quelques minutes d'attaque. La disposition des arcs, dont les indices sont donnés sur la figure 8, correspond à une orientation privilégiée des microcristaux d'or autour d'un axe [110] perpendiculaire à la surface et à son support. Cette orientation est la même sur support amorphe (verre) ou unicristallin (NaCl). En continuant l'attaque ionique, le diagramme d'or fibreux s'affaiblit progressivement à mesure que l'épaisseur du métal diminue et finit par disparaître.

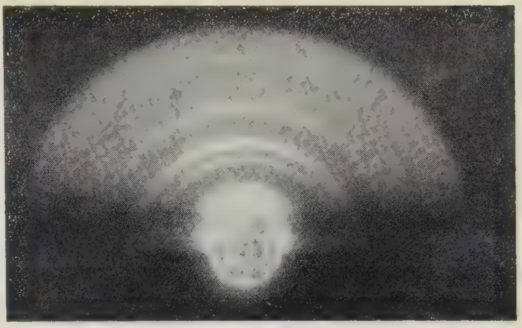

Fig. 6. Couche d'or de 2000 Å déposée sur NaCl froid, examinée par réflexion avant le bombardement ionique.

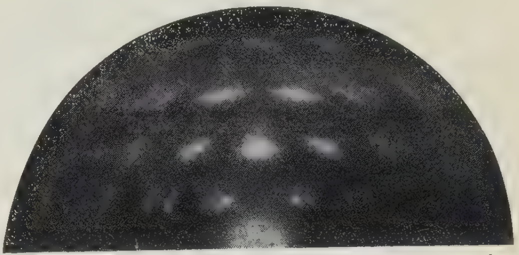

Fig. 7. Même préparation que sur figure 6, aprés quelques minutes de bombardement ionique (Au orienté).

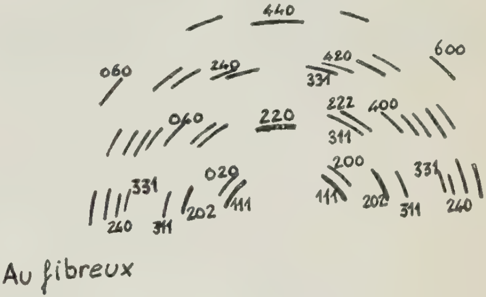

Fig. 8. Schéma correspondant à la figure 7.

Si le support est amorphe (verre), on observe alors quelques halos diffus dûs au verre. La figure 4 montre l'aspect macroscopique de la préparation, sur laquelle le faisceau d'ions a marqué sa trace après avoir arraché tout le

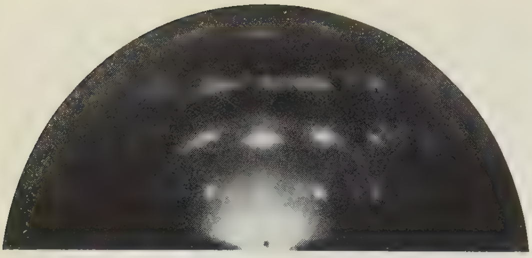

Fig. 9. Même préparation que sur figure 6, après décapage ionique plus long (Au+NaCl).

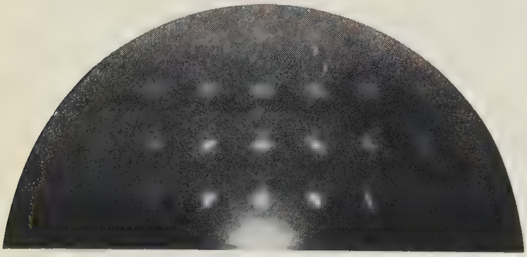

Fig. 10. Même préparation que sur figure 6, après décapage ionique prolongé (NaCl).

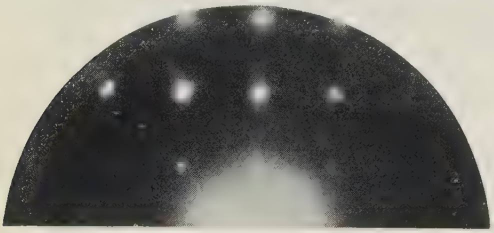

Fig. 11. Couche déposée sur NaCl chaud, après quelques minutes de bombardement ionique-structure monocristalline Au.

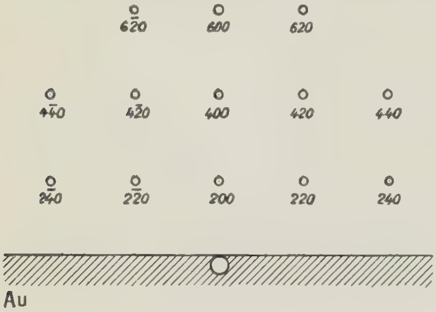

Fig. 12. Schéma correspondant à la figure 11.

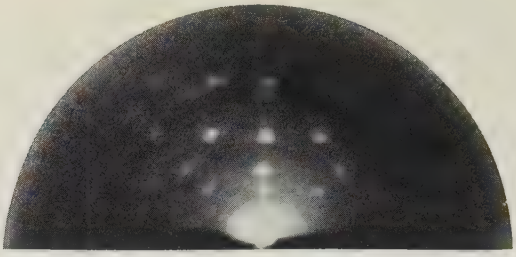

Fig. 13. Même préparation que sur figure 11, mais après bombardement ionique plus long. (Au+NaCl).

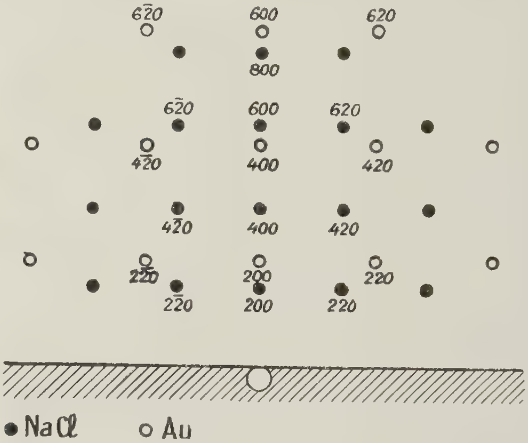

Fig. 14. Schéma correspondant à la figure 13.

métal déposé.

Si le support est unicristallin (NaCl), il arrive un moment où la couche d'or étant fortement amincie laisse pénétrer les électrons jusqu'à la surface du cristal de NaCl. Le diagramme de taches de ce dernier commence alors à apparaître et se superpose aux arcs de l'or (Fig. 9), pour bientôt subsister seul lorsque tout l'or a été enlevé par le décapage ionique (Fig. 10).

*Depots sur supports chauds* (400°C).

Dans ces expériences, le dépôt thermique est effectué sur les mêmes supports amorphes ou cristallins que précédemment, mais portés à une température de 400–450°C. L'examen de la structure de ces dépôts est faite de la meme manière en employant le décapage ionique avec balayage.

a) *Sur support verre*, les phénomènes observés sont exactement les mêmes que lorsque la condensation de la vapeur métallique a lieu à froid. D'abord apparaissent des anneaux de Debye-Scherrer dûs à l'or, puis une structure fibreuse [110] et enfin les halos du verre amorphe.

b) *Sur support constitué par un plan de clivage* (100) *de NaCl*, les résultats sont au contraire très différents. Au départ, et avant décapage ionique, la structure est encore celle de microcristaux d'or disposés au hasard (anneaux D. S.) (Fig. 6); par contre, le bombardement ionique fait apparaître très rapidement des taches de diffraction très nettes, (et non des arcs), localisées sur certains anneaux et qui bientôt subsistent seules en donnant un diagramme typique de monocristal (Fig. 11) correspondant à un plan (100) du réseau c.f.c. de l'or ($a$=4,07 Å), (voir figure 12 obtenue à partir du diagramme de la figure 11); une direction [001] est parallèle au faisceau d'électrons.

Le balayage ionique continuant, le diagramme se transforme progressivement, et de nouvelles taches de diffraction apparaissent. La figure 13 montre l'aspect observé, qui est la superposition du diagramme d'or monocristallin (figures 11 et 12) et du diagramme de NaCl monocristallin (Fig. 10), les réseaux de l'or et du sel étant disposés parallèlement. La figure 14 représente schématiquement la disposition des taches de diffraction avec leurs indices.

*Interprétation et discussion des résultats*

Les résultats expérimentaux que nous venons d'indiquer s'interprètent aisément dans le cas des dépôts d'or obtenus sur une *face de clivage de NaCl chauffé à* 400°C–450°C. Différents auteurs (BRUCK-OGAWA et WATANABE-SHIRAI) (8) (9) (10) ont en effet déja étudié l'orientation des couches métalliques vaporisées thermiquement et déposées sur une face (100) de NaCl fraîchement clivé; BRUCK (8) en particulier a montré en examinant *par transmission* des films métalliques minces, qu'au delà d'une température critique (400°C pour l'or), le support imposait au métal une orientation privilégiée, donnant lieu à la formation d'une mosaïque de petits cristaux tous orientés de la même façon, ce qui, au point de vue de la diffraction électronique, est analogue à une structure unicristalline. Cette température critique varie pour un support donné, avec la nature du métal vaporisé.

Selon BRUCK8), pour les métaux cubiques à faces centrées comme l'or, les cubes ont la même orientation que le cube support (NaCl); pour les métaux cubiques centrés (Fe $\alpha$), la face de contact est tournée de 45° par rapport au cube de NaCl. Sans préciser aussi nettement l'orientation relative de l'or et du sel, OGAWA et WATANABE9) ont signalé qu'ils obtenaient la structure pseudo-unicristalline de de l'or, quand le NaCl est chauffé à 400°C au moins. C'est la raison pour laquelle nous avons adopté la température de 400°C pour le support, dans la seconde série de nos expériences.

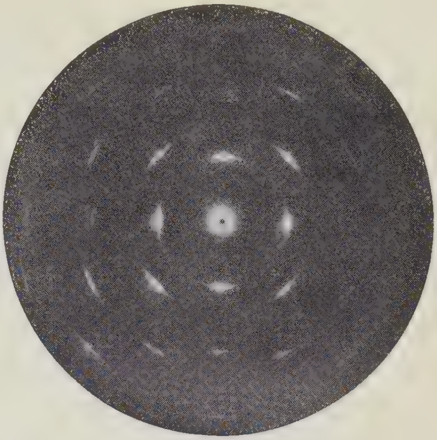

Figure 15. Couche d'or mince (~200 Å) sur NaCl chaud (par transmission).

La méthode du décapage ionique montre en outre que l'orientation imposée par le support ne se produit que jusqu'à une certaine distance de celui-ci, et qu'elle se détruit progressivement à mesure que l'épaisseur du dépôt métallique augmente, ce qui se traduit dans nos expériences (épaisseurs Au=2.000 Å) par l'apparition des anneaux D. S. de l'or *avant* l'attaque ionique. En utilisant des dépôts plus minces, nous avons en effet obtenu, dans les mêmes conditions de température du support, des couches d'or qui, par réflexion comme par transmission (après enlèvement du film d'or par dissolution de NaCl dans l'eau), présentent la structure orientée ou pseudounicristalline, imposée par le support. La figure 15 représente un diagramme par transmission d'une couche d'or de 150 Å condensée sur NaCl chauffé à 450°C; on peut y vérifier facilement que les arêtes des deux réseaux Au et NaCl sont parallèles en prenant soin de repérer la disposition de la couche d'or détachée par rapport aux directions [010] et [001] du support. Par réflexion, sur des couches d'or de 150 Å, on obtient directement et sans attaque ionique, un diagramme tel que celui de la figure 13 qui consiste en la superposition des diagrammes unicristallins de l'or et du NaCl.

Dans le cas des couches d'or déposées sur NaCl froid, il semble au contraire assez difficile de conclure à une action orientante du support; on sait en effet qu'une température suffisamment élevée est nécessaire pour permettre aux atomes du métal la mobilité

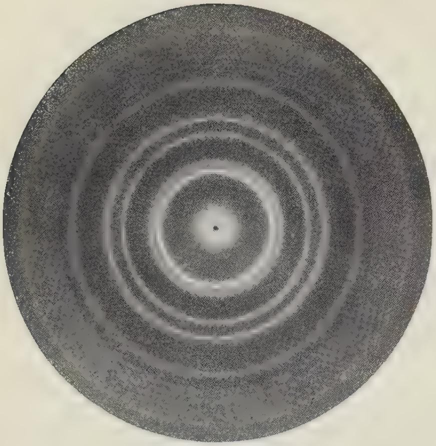

Fig. 16. Couche d'or mince (~200 Å) sur NaCl froid (par transmission).

indispensable à l'apparition de plages unicristallines.

Comment expliquer dès lors l'apparition de la structure fibreuse telle que celle de la figure 7? Tout d'abord, il faut noter qu'une telle structure n'a pu être observée dans des couches plus minces (150 Å) évaporées sur NaCl *froid* et examinées par transmission (Fig. 16); de même, elle n'apparaît pas lorsqu'on amincit par attaque chimique un dépôt épais (2000 Å) d'or. On serait donc amené à penser que cette structure fibreuse est due à un effet secondaire du bombardement ionique; l'effet thermique seul ne suffit pas, car si l'on chauffe à 400–450°C, dans le diffractographe même, des couches d'or obtenues à froid sur NaCl et qu'on les examine par réflexion, *sans bombardement ionique*, aucune orientation n'apparaît. On peut alors provisoirement faire l'hypothèse que l'orientation est produite par une action mécanique des ions, dont la direction est toujours perpendiculaire (ou presque perpendiculaire) à la surface de la couche étudiée.

Enfin, dans le cas d'un support amorphe (verre), nous avons vu que les résultats sont les mêmes si le support est chaud ou froid et qu'on obtient les mêmes diagrammes qu'avec NaCl froid. De plus, quelle que soit l'épaisseur de la couche d'or déposée, le diagramme, observé par réflexion avant attaque ionique, ne montre aucune orientation mais seulement une structure microcristalline confuse.

Là encore, ces expériences semblent montrer que l'effet d'orientation est dû à une action mécanique du faisceau d'ions, l'arrachement du métal s'accompagnant peut être d'effets mécaniques susceptibles d'orienter les cristaux sous-jacents; nous rappellerons à ce sujet les expériences faites dans notre Laboratoire par COURTEL[11] qui a montré que par abrasion dans le vide, les cristaux sont fortement orientés à chaque passage de la meule. Mais bien entendu notre hypothèse demande encore à être confirmée.

## § 4. Conclusion

Ces résultats et leur discussion indiquent qu'il est parfois nécessaire d'interpréter avec prudence les diagrammes qui apparaissent pendant le décapage ionique, et qu'il est toujours indispensable de contrôler avec soin toute action possible (chimique, thermique, mécanique) dûe aux ions. Ces causes d'erreurs étant connues, la méthode du décapage ionique combiné à la diffraction électronique est susceptible d'apporter des renseignements extrêmement intéressants pour de nombreux problèmes relatifs aux structures superficielles.

# The Visco-elastic Properties of Network Structure
## I. General Formalism

By Misazo YAMAMOTO

*Department of Chemistry, Faculty of Science, University of Kyoto*

(Received October 25, 1955)

Many kinds of amorphous high polymer substances show the non-ideal rheological behaviours even in the "static" observations. In this paper, the general stress-strain-time relation and energy of dissipation of these systems are treated by adopting the modified rubber-like network model in which the junctions connecting the polymer chains break up and reform continually. The probability of the breakage of the junction, namely the breakage of the chain, per unit time is not a constant but a functions of both the number of segments which construct the chain and the end-to-end distance of the chain. It is assumed that the velocities of deformation of the system and of the change of the situation of network structure are extremely slower than those of the micro-Brownian movements of polymer segments. Therefore the statistical mechanical considerations of equilibrium states may be used to derive the stress-strain-time ($S$–$S$–$T$) relation at each "instance" of macroscopic observations. From our general expression of $S$–$S$–$T$ relation it is pointed out that, in the case of small deformation, the $S$–$S$–$T$ relation is essentially similar to that of the phenomenological generalized Maxwell model and the reciprocal of the probability of chain-breakage corresponds to the relaxation time of each Maxwell element.

### § 1. Introduction

Remarkable progress has been made in the field of the statistical mechanics of the high polymer systems, particularly in the problems of rubber-like elasticity and of dilute polymer solutions. The basic molecular model used in these investigations is the so-called "random flight chain", i.e., the chain constructed from the volumeless "statistical chain-segments" which can rotate freely around each of their bonds, and the statistical properties of which are generally characterized by the mean length and the total number of segments in the chain. In the case of the rubber-like elasticity, the chains involved in the system are permanently connected with each other at their end points, "junctions", by primary chemical bonds, such as –S–S– bonds, to form a three dimensional network structure. It is usually assumed that, besides the liquid-like isotropic interactions, these chains mutually interact only at their junction points and that the effects of the external force upon any part of the system instantaneously spread over all parts of the network through these junctions. In this respect, these systems may be considered to have an infinite value of the coupling parameter. On the other hand, in the case of dilute polymer solutions, each chain molecule seems to be almost independent of others, so the value of the coupling parameter may be zero. In the latter case, many authors have had interests in the mean extension and shape of a chain molecule, and the coefficient of the osmotic pressure, the intrinsic viscosity coefficient, etc. have been calculated in various ways.

Contrary to the above cases, fairly concentrated high polymer solutions and melts show various anomalous rheological properties which cannot be seen in the dilute solutions or bulk rubbers: for instance, visco-elasticity, structural viscosity (which depends upon the rate of deformation), spinnability (formation of liquid thread), Weissenberg effect (anomalous pressure distribution in the system), etc. From the rheological point of view, these properties are very interesting, but their molecular theoretical explanations have been seldom given because of the difficulties due to the existence of the complicated mutual interactions between the chain molecules. Here, it is necessary to consider these systems having the finite value of the coupling parameter in the above sense. They are too complicated to be attacked by any direct method. However, there seems to be two different ways of approaching this problem. One is that, starting from the dilute solution, the mutual interactions between two or more chain molecules are taken into account successively in just the same manner as those in Mayer's imperfect gas theory.

The other approach is that of Green and Tobolsky[1]. They start from the rubber-like system, and assume that in these substances the rubber-like network structure is formed not by the primary chemical bonds but by the entanglements in the physical sense or by the secondary bonds, such as the hydrogen bonds, between the chain molecules. The connection between the chains at these junctions is rather weak and supposed to break up and reform continually. Consequently, the system can deform and flow in the liquid-like manner. Green and Tobolsky derived the phenomenological Maxwell equation of visco-elasticity by considering the shearing deformation of the system and also obtained the viscosity coefficient; but, owing to the assumptions used in their theory, they failed to derive the structural viscosity. Recently, Scott and Stein[2] have examined this model, treating the breakage and reformation processes of junctions in more detail, and found that the stress relaxation phenomenon has the relaxation time, which is slightly different from that of molecular mechanism.

In this paper, we shall formulate the statistical mechanical theory of the same system in a more general form. The chains involved in our system are permitted to have the arbitrary free energy function depending on the degree of their elongations. It is assumed that the probability of the chain-breakage is the function of the tension caused by the chain itself. We shall derive the stress-deformation-time relation and the energy of dissipation in the case of the arbitrary deformation tensor. It will become clear that our model corresponds phenomenologically to the "generalized" Maxwell model.

On the basis of our results, the anomalous rheological properties of such system will be discussed in a next paper.

## § 2. Rubber-like Network Model

In this paper we shall treat the rubber-like network as the model of concentrated polymer solutions or melts. The following assumptions will be used in our calculations to be developed here:

(i) Although the processes considered here are neither stationary nor reversible, but are irreversible, we shall assume that the velocities of the change of macroscopic condition (for example, the rate of deformation) are sufficiently slower than those of the micro-Brownian movements of the segments and also of the breakage and reformation processes, so that the equilibrium statistical mechanical theory can be applied at each instant of macroscopic measurements.

(ii) The free energy of single chain-molecule in the system is a function of the total number of segments of the chain and of its end-to-end distance.

(iii) The free energy of the whole network consists of two parts; the sum of the free energies of individual chains involved and the liquid-like internal energy caused by the interactions between the segments. The latter is assumed to depend solely upon the density of the segments.

(iv) Brownian movements of the junctions are here neglected. The junctions are assumed to be always at their most probable positions. Furthermore, their distribution is assumed to obey the "requirement of proportionality". In other words, when the whole system is deformed, the displacements of the junctions are proportional to the bulk deformation of the system.

(v) The origin of the dissipative mechanism is ascribed to the breakage and reformation of the junctions. The probability of breakage of a chain at a junction is dependent on the number of segments and on its end-to-end distance, but independent of the time.

The assumption (i) is introduced as the first approximation to the problem of the present irreversible phenomena. It should be noted that the assumption (ii) does not necessarily mean the Gaussian chain-network. The requirement of proportionality in the assumption (iv) has never been proved in general cases except in the Gaussian networks. Without this requirement the calculations would become very complicated and one could not gain an insight into our problem because of the lack of the detailed informations concerning the situation of network structure as a whole. With this requirement, however, one needs no longer any knowledge other than that of the distribution of chain length.

Finally, some comments must be made about the assumption (v). In the actual network, the breakage of the chain is caused by that of the junction. For example, in Fig. 1, if the breakage of the junction P occurs, the chains AP, BP, CP and DP disappear, and the new chains AB and CD are reformed. Therefore, the probability of the breakage of a chain may be influenced by the situation of the surrounding chain. However, owing to the same reason as that in the assumption (iv), it is necessary to adopt this assumption on the average. This assumption does make difference between the Green-Tobolsky's theory and ours. They assumed the constant probability of breakage of the chains. As will be shown in the next paper, their assumption of the constant probability is the main reason why they could not succeed to derive any non-linear rheological behaviour. Our more general assumption (v) is just sufficient to explain the essential feature of anomalous rheological properties of the systems.

## § 3. Free Energy of Network, Stress Tensor

Under the assumption (ii), the free energy of a chain $\phi(|\boldsymbol{h}|, N, T)$ is a function of the end-to-end distance $\boldsymbol{h}=(\xi, \eta, \zeta)$, number of segments $N$ and the temperature $T$. If the chain is assumed to be a Gaussian chain with $N$ segments of the length $a$, this energy becomes

$$\phi(|\boldsymbol{h}|, N, T)=(3kT/2)(|\boldsymbol{h}|^2/a^2N)\ . \qquad (1)$$

Owing to the assumption (iii), the free energy of the network per unit volume can be written in the form

$$\begin{aligned}\Phi(T, v)&=\sum_{\text{chain}}\phi(|\boldsymbol{h}|, N, T)+E(\rho)\\ &=\Sigma_N\iiint\phi(|\boldsymbol{h}|, N, T)F(\boldsymbol{h}, N, t)d\boldsymbol{h}+E(\rho),\end{aligned} \qquad (2)$$

where $E(\rho)$ is the internal energy depending on the density $\rho$ of the segments in the network, and $F(\boldsymbol{h}, N, t)$ is the number of the chains per unit volume which consist of $N$ segments with end-to-end distance $\boldsymbol{h}$ and which actually construct the network at the time $t$. Hereafter we shall call $F(\boldsymbol{h}, N, t)$ "chain-distribution function".

In order to obtain the stress tensor, we consider the change of the free energy due to the (small) virtual deformation $\boldsymbol{e}'_v$ of the sample, assuming that there are no breakage and reformation of junctions although in the actual deformation some of the junctions may break and reform. Namely, differentiating the free energy, which depends on $\boldsymbol{e}'_v$ through $F(\boldsymbol{h}, N, t)$, with respect to each component of $\boldsymbol{e}'_v$ and taking the limit $\boldsymbol{e}'_v\rightarrow\mathbf{1}$, we have the stress tensor at the time $t$:

$$\boldsymbol{s}=\Sigma_N\iiint(\boldsymbol{hh})\left(\frac{1}{r}\ \frac{d\phi(r, N, T)}{dr}\right)_{r=|\boldsymbol{h}|}\times F(\boldsymbol{h}, N, t)d\boldsymbol{h}+P\mathbf{1}\ , \qquad (3)$$

where $(\boldsymbol{hh})$ is a tensor:

$$(\boldsymbol{hh})=\begin{pmatrix}\xi^2 & \xi\eta & \xi\zeta\\ \eta\xi & \eta^2 & \eta\zeta\\ \zeta\xi & \zeta\eta & \zeta^2\end{pmatrix} \qquad (4)$$

and the "inner pressure" $P$ comes from the internal energy $E(\rho)$. This inner pressure should be determined by the suitable boundary conditions as in the case of the theory of rubber-like elasticity. In our formalism, the stress tensor is always accompanied with the inner pressure, but we are interested only in the term which essentially depends upon the network structure. Therefore, in this paper, we shall consider the quantity:

$$\boldsymbol{s}_n=\boldsymbol{s}-P\mathbf{1} \qquad (5)$$

where subscript $n$ indicates the "network". As is easily seen, the factor $d\phi(r, N, T)/dr$ in the integrand of $\boldsymbol{s}_n$ is the tension of the chain in the direction from one end to another, and when multiplied by the factor $(1/r)(\boldsymbol{hh})$ it is the contribution of this tension to the total stress $\boldsymbol{s}_n$ of the network.

In order to obtain the stress-deformation-time relation in the concrete form, it is necessary to know the explicit form of chain-distribution function in terms of the (actual) deformation tensor $\boldsymbol{e}(t)$ and the time $t$.

## § 4. Chain-distribution Function

Let us consider a volume element of the sample, the shape of which at the initial time $t=0$ is the rectangular parallelepiped whose edges $\Delta x_0$, $\Delta y_0$ and $\Delta z_0$ are parallel to the external coordinate axes $x$, $y$ and $z$, respectively. In this volume element, the chain-distribution

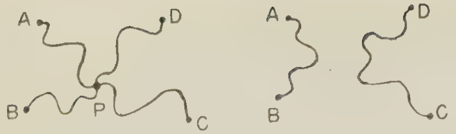

Fig. 1.

function at $t=0$ is expressed by $F_0(\boldsymbol{h}, N) \equiv F(\boldsymbol{h}, N, 0)$. This volume element changes in general not only its shape but also the volume with the time. This change is characterized by the deformation tensor $\boldsymbol{e}(t)$, which is the unit tensor at $t=0$: $\boldsymbol{e}(0)=\mathbf{1}$. The relative coordinate $d\boldsymbol{r}=(dx, dy, dz)$ of the two points in this volume element at the time $t$ is given by

$$d\boldsymbol{r}=\boldsymbol{e}(t)d\boldsymbol{r}_0 \qquad (6)$$

where $d\boldsymbol{r}_0$ is the initial relative coordinate, and the volume of this volume element is $|\boldsymbol{e}(t)|\Delta x_0 \Delta y_0 \Delta z_0$. It is to be noted that this deformation $\boldsymbol{e}(t)$ is rather large, and the classical procedure of symmetrization cannot in general be applied.

In this section we derive the equation of motion of the chain-distribution function in both the integral and differential forms. Let us begin with the expression of the former.

Suppose that a chain has $N$ segments and its end-to-end distance is $\boldsymbol{h}$ at $t$. If the junctions do not break, according to Eq. (6), one has $\boldsymbol{h}_0=\boldsymbol{e}^{-1}(t)\boldsymbol{h}$ where $\boldsymbol{h}_0=(\boldsymbol{h})_{t=0}$. More generally,

$$(\boldsymbol{h})_{t=t'} \equiv \boldsymbol{h}'=\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h} \,. \qquad (7)$$

Actually, the chain has a chance to break during the time interval from $t'$ to $t$. If $F'(\boldsymbol{h}, N, t)$ is the number of the chains at $t$ with $\boldsymbol{h}$ and $N$ per unit volume which constructed the network at the initial time $t=0$ and which have not broken until $t$, the number of such chains in our volume element is $f'(\boldsymbol{h}, N, t) =F'(\boldsymbol{h}, N, t)|\boldsymbol{e}(t)|\Delta x_0 \Delta y_0 \Delta z_0$. The number of such chains which break in the time interval $t \sim t+\Delta t$ can be written by the assumption (V). as $\beta(\boldsymbol{h}, N)f'(\boldsymbol{h}, N, t)\Delta t$. $\beta(\boldsymbol{h}, N)$, the "chain-breakage coefficient", is the probability of chain-breakage in unit time interval and is considered as the function of $\boldsymbol{h}$ and $N$. It will become clear afterwards that $\beta(\boldsymbol{h}, N)$ has the meaning of the reciprocal of the relaxation time. Comparing the values of $f'$-function at $t'$ and $t''=t'+\Delta t'$, one has the following equation:

$$f'(\boldsymbol{h}'', N, t'')=[1-\beta(\boldsymbol{h}', N)\Delta t']f'(\boldsymbol{h}', N, t').$$
$$\boldsymbol{h}' \equiv \boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h} \,, \quad \boldsymbol{h}'' \equiv \boldsymbol{e}(t'')\boldsymbol{e}^{-1}(t)\boldsymbol{h}. \qquad (8)$$

Taking the successive products of such equations from $t'=0$ to $t''=t$, and carrying out the limit process $\Delta t' \to 0$, we obtain

$$\begin{aligned} f'(\boldsymbol{h}, N, t) &= \lim_{\Delta t' \to 0} \prod_{\substack{\Delta t' \\ (t'=0)}}^{(t''=t)} [1-\beta(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)\Delta t'] \\ &\qquad \times f_0(\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N) \\ &= \exp\left[-\int_0^t \beta(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)dt'\right] \\ &\qquad \times f_0(\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N) \,, \qquad (9) \end{aligned}$$

$$f_0(\boldsymbol{h}, N)=F_0(\boldsymbol{h}, N)\Delta x_0 \Delta y_0 \Delta z_0 \,.$$

This is the number of chains that construct the network with $\boldsymbol{h}$ and $N$ at $t$, which were certainly involved in the network at $t=0$.

In order to obtain the total number of the chains at $t$, we must consider the effect of the reformation of the junctions. Let

$$g(\boldsymbol{h}', N, t')\Delta t'=G(\boldsymbol{h}', N, t')|\boldsymbol{e}(t')|\Delta x_0 \Delta y_0 \Delta z_0 \Delta t'$$

be the number of chains $\boldsymbol{h}', N$ in our volume element reformed in the time interval $t' \sim t'+\Delta t'$. It contributes

$$g(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N, t') \times \exp\left[-\int_{t'}^t \beta(\boldsymbol{e}(t'')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)\,dt''\right]\Delta t' \qquad (10)$$

to the real distribution function $f(\boldsymbol{h}, N, t)$. Summing up these quantities from $t'=0$ to $t'=t$ and adding it to Eq. (9), we obtain the actual number of chains at $t$:

$$\begin{aligned} f(\boldsymbol{h}, N, t) &= f_0(\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N) \\ &\quad \times \exp\left[-\int_0^t \beta(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)dt'\right] \\ &\quad + \int_0^t g(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N, t') \\ &\quad \times \exp\left[-\int_{t'}^t \beta(\boldsymbol{e}(t'')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)\,dt''\right]dt' \,. \qquad (11) \end{aligned}$$

Or, in terms of the chain-distribution function $F$ and the chain-reformation function $G$,

$$\begin{aligned} |\boldsymbol{e}(t)|F(\boldsymbol{h}, N, t) &= F_0(\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N) \\ &\quad \times \exp\left[-\int_0^t (\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)dt'\right] \\ &\quad + \int_0^t |\boldsymbol{e}(t')|G(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N, t') \\ &\quad \times \exp\left[-\int_{t'}^t \beta(\boldsymbol{e}(t'')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)\,dt''\right]dt' \,. \qquad (12) \end{aligned}$$

This is the integral form of the equation satisfied by the chain-distribution function.

In order to obtain the differential form, we may differentiate Eq. (12) with respect to $t$. After some elementary tensor calculations, we have

$$\frac{\partial F(\boldsymbol{h}, N, t)}{\partial t} = -\nabla F(\boldsymbol{h}, N, t) \frac{d\boldsymbol{e}}{dt} \boldsymbol{e}^{-1}\boldsymbol{h} - \frac{1}{|\boldsymbol{e}|}\frac{d|\boldsymbol{e}|}{dt} F(\boldsymbol{h}, N, t) + G(\boldsymbol{h}, N, t) - \beta(\boldsymbol{h}, N)F(\boldsymbol{h}, N, t) \,. \tag{13}$$

The meaning of the right-hand-side of the above equation is easily seen as follows: The first term gives the change of distribution function due to the change of the shape of the sample. The second term corresponds to the volume change. These two terms are the same as that appeared in the general theory of rubber-like elasticity. The third and fourth terms are due to the chain-reformation and the chain-breakage, respectively. They are new, and, as will become clear afterwards, it is these two terms that are responsible for the dissipative processes in our system.

## § 5. Stress-Deformation-Time Relation

Now, we have a chain-distribution function-deformation-time relation in both the differential and the integral forms. Substituting these relations into Eq. (3) or into its time derivative, we can obtain the stress-deformation-time relation in both forms.

We shall consider at first the differential form. If Eq. (12) is substituted into the time derivative of Eq. (3):

$$\frac{d\boldsymbol{s}_n}{dt} = \Sigma_N \iiint (\boldsymbol{h}\boldsymbol{h}) \left(\frac{1}{r}\frac{d\phi}{dr}\right)_{r=|\boldsymbol{h}|} \frac{\partial F(\boldsymbol{h}, N, t)}{\partial t} d\boldsymbol{h} \,, \tag{14}$$

and after some tensor calculations, we find

$$\frac{d\boldsymbol{s}_n}{dt} = \frac{d\boldsymbol{e}}{dt}\boldsymbol{e}^{-1}\boldsymbol{s}_n - \boldsymbol{s}_n\boldsymbol{e}^{+-1}\frac{d\boldsymbol{e}^+}{dt} + \Sigma_N \iiint (\boldsymbol{h}\boldsymbol{h}) \left( \boldsymbol{h} \left( \frac{d\boldsymbol{e}}{dt}\boldsymbol{e}^{-1} \right) \boldsymbol{h} \right) \times \left[ \frac{1}{r}\frac{d}{dr}\left(\frac{1}{r}\frac{d\phi}{dr}\right) \right]_{r=|\boldsymbol{h}|} F(\boldsymbol{h}, N, t) d\boldsymbol{h} + \left(\frac{d\boldsymbol{s}_n}{dt}\right)^{b,r} \tag{15}$$

$$\left(\frac{d\boldsymbol{s}_n}{dt}\right)^{b,r} = \Sigma_N \iiint (\boldsymbol{h}\boldsymbol{h}) \left(\frac{1}{r}\frac{d\phi}{dr}\right)_{r=|\boldsymbol{h}|} \times [G(\boldsymbol{h}, N, t) - \beta(\boldsymbol{h}, N)F(\boldsymbol{h}, N, t)] d\boldsymbol{h} \,. \tag{16}$$

where $\boldsymbol{e}^+$ is the transpose of $\boldsymbol{e}$. In this expression, the first three terms on the right-hand side express the change of stress due to the deformation only, and the last term $(d\boldsymbol{s}_n/dt)^{b,r}$ gives the effect due to the change of the situation of the chains in the network. If the chains are the Gaussian, $(d/dr)(d\phi/rdr)$ vanishes and the third term does not appear. In this case, the tension-stretching relation of a chain is exactly the Hookeian and this characteristic will be kept even in the network. Actually, in the first two terms on the right-hand side of Eq. (15), the factors $\boldsymbol{e}^{-1}\boldsymbol{s}_n$ or $\boldsymbol{s}_n\boldsymbol{e}^{+1}$ have the meaning of the elastic modulus. Thus these terms express the Hookeian law and the third term gives the deviation from the " linearity ". It should be noted that the effect of volume-change does not appear explicitly, but it is involved implicitly through both the chain-distribution and the reformation functions. Indeed, in the case of ideal rubber-like elasticity, in which

$$G(\boldsymbol{h}, N, t) = 0, \quad \beta(\boldsymbol{h}, N) = 0$$

and the chains are the Gaussian, the isotropic volume-change does not at all affect the stress tensor. This fact is understood as follows: On the one hand, the increase in volume decreases the number of chains per unit volume and, on the other hand, this change produces the increase of the tension of each chain, and these two tendencies balance each other.

Next, the integral form is obtained by substituting Eq. (12) into Eq. (3). After exchanging the order of integration, we have the integral stress-deformation-time relation:

$$\boldsymbol{s}_n = \boldsymbol{e}(t)\boldsymbol{S}(t)\boldsymbol{e}^+(t) \,, \tag{17}$$

$$\boldsymbol{S}(t) = \boldsymbol{S}_0(t) + \int_0^t \boldsymbol{e}^{-1}(t')\boldsymbol{T}(t, t')\boldsymbol{e}^{+-1}(t')dt' \,, \tag{18}$$

$$\boldsymbol{S}_0(t) = \Sigma_N \iiint (\boldsymbol{h}\boldsymbol{h}) \left(\frac{1}{r}\frac{d\phi}{dr}\right)_{r=|\boldsymbol{e}(t)\boldsymbol{h}|} F_0(\boldsymbol{h}, N) \times \exp\left[ -\int_0^t \beta(\boldsymbol{e}(t')\boldsymbol{h}, N) dt' \right] d\boldsymbol{h} \,, \tag{19}$$

$$\boldsymbol{T}(t, t') = \Sigma_N \iiint (\boldsymbol{h}\boldsymbol{h}) \left(\frac{1}{r}\frac{d\phi}{dr}\right)_{r=|\boldsymbol{e}(t)\boldsymbol{e}^{-1}(t')\boldsymbol{h}|} \times G(\boldsymbol{h}, N, t') \exp\left[ -\int_{t'}^t \beta(\boldsymbol{e}(t'')\boldsymbol{e}^{-1}(t')\boldsymbol{h}, N) dt' \right] d\boldsymbol{h} \,. \tag{20}$$

$\boldsymbol{S}(t)$ is nothing but the stress at $t$ when the deformation is suddenly removed at that instant. If the chain-breakage and the chain reformation had not occurred, and the chains are Gaussian, it would be proportional to the unit tensor. In the actual case, however, because of the above effect, $\boldsymbol{S}(t)$ becomes a complicated tensor, and consists of two terms: One is the contribution from the chains which constructed initially the network, and the other that from the newly formed chains during the course of the deformation. It should be noted that, unlike the case of the differential form, the deviation from the "linearity" does not appear explicitly.

## § 6. Energy of Dissipation

In a similar manner to the integral stress-deformation-time relation, it is possible to obtain the free energy of the network per unit volume as the function of the time. Substituting Eq. (12) into Eq. (2), we have

$$\Phi_n = \Phi - E(\rho) = \Psi_0(t) + \int_0^t \Psi(t, t')dt' \ . \tag{21}$$

$$\Psi_0(t) = \Sigma_N \iiint \phi(|\boldsymbol{e}(t)\boldsymbol{h}|, N, T) F_0(\boldsymbol{h}, N) \times \exp\left[-\int_0^t \beta(\boldsymbol{e}(t')\boldsymbol{h}, N)dt'\right] d\boldsymbol{h} \ , \tag{22 a}$$

$$\Psi(t, t') = \Sigma_N \iiint \phi(|\boldsymbol{e}(t)\boldsymbol{e}^{-1}(t')\boldsymbol{h}|, N, T) G(\boldsymbol{h}, N, t') \times \exp\left[-\int_{t'}^t \beta(\boldsymbol{e}(t'')\boldsymbol{e}^{-1}(t')\boldsymbol{h}, N)dt''\right] d\boldsymbol{h} \ . \tag{22 b}$$

Green-Tobolsky called $\Phi_n$ the "strain free energy". Differentiating this with respect to $t$, we obtain the rate of change of the strain free energy

$$\frac{d\Phi_n}{dt} = \frac{1}{2}\mathrm{Sp}\left[\frac{d\boldsymbol{e}(t)}{dt}\boldsymbol{S}(t)\boldsymbol{e}^+(t)\right] + \frac{1}{2}\mathrm{Sp}\left[\boldsymbol{e}(t)\boldsymbol{S}(t)\frac{d\boldsymbol{e}^+(t)}{dt}\right] - \frac{\delta W}{dt} \tag{23}$$

where

$$\frac{\delta W}{dt} = \Sigma_N \iiint \phi(|\boldsymbol{h}|, N, T) \times [\beta(\boldsymbol{h}, N)F(\boldsymbol{h}, N, t) - G(\boldsymbol{h}, N, t)]d\boldsymbol{h} \ , \tag{24}$$

Now, we may consider the physical meaning of the right-hand side of Eq. (23).

The work done by the external force is given essentially by the product of the three factors: The first is the stress $\boldsymbol{s}_n$, the next is the area $\boldsymbol{e}^{-1}$, and the last is the deformation-length $d\boldsymbol{e}/dt$. Thus, remembering Eq. (17), the first two terms on the right-hand side are the work done by the external force. As is well known, the change of the free energy in the isothermal processes is the sum of the work done by the external forces and the negative of the heat generated within the system through the dissipative mechanisms. The third term on the right-hand side of Eq. (22) is, therefore, considered to give the energy of dissipation.

Actually, Eq. (24) shows that the dissipation arises from the chain-breakage-reformation processes. This result is consistent with our basic assumption (v). The viscosity coefficient can be calculated from this energy of dissipation, as will be shown in the next paper.

## § 7. Small Deformation

As was mentioned in § 2, the deformation of our system is in general large and the procedure of the symmetrization of the deformation tensor cannot be taken into the theory. These circumstance have made the results rather complicated. However, if the deformation is sufficiently small, these difficulties will no longer occur, as will be shown in this section, and the (differential) stress-deformation-time relation is expressed in a simpler form. Furthermore, this relation is essentially equivalent to that of the phenomenological generalized Maxwell model and the chain-breakage coefficient corresponds to the reciprocal of the relaxation time of this model.

In the case of the small deformation, we can introduce "prime" quantities as follows:

$$\boldsymbol{e}(t) = \boldsymbol{1} + \varepsilon\boldsymbol{e}'(t) \ , \tag{25}$$

$$\boldsymbol{s}_n(t) = \boldsymbol{s}_{n,0} + \varepsilon\boldsymbol{s}'_n(t) = -P_0\boldsymbol{1} + \varepsilon(\boldsymbol{s}'(t) - P'(t)\boldsymbol{1}) \ , \tag{26}$$

$$G(\boldsymbol{h}, N, t) = G_0(\boldsymbol{h}, N) + \varepsilon G'(\boldsymbol{h}, N, t) \ , \tag{27}$$

$$F(\boldsymbol{h}, N, t) = F_0(\boldsymbol{h}, N) + \varepsilon F'(\boldsymbol{h}, N, t) \ , \tag{28}$$

where $\varepsilon$ is the parameter characterizing the order of magnitude of the deformation. In these expressions, the zeroth order quantities are those of the natural state, in which $\boldsymbol{e}(t) = \boldsymbol{1}$, $\boldsymbol{s} = \boldsymbol{0}$. After substituting these expressions into Eq. (13), we can equate the coefficients of equal powers of $\varepsilon$ on both sides:

$$G_0(\boldsymbol{h}, N) = \beta(\boldsymbol{h}, N)F_0(\boldsymbol{h}, N) \ , \tag{29}$$

$$\frac{\partial F'(\boldsymbol{h}, N, t)}{\partial t} + \beta(\boldsymbol{h}, N)F'(\boldsymbol{h}, N, t) = -\nabla F_0(\boldsymbol{h}, N)\frac{d\boldsymbol{e}'}{dt}\boldsymbol{h} - F_0(\boldsymbol{h}, N)\frac{d(\mathrm{Sp}\,\boldsymbol{e}')}{dt} + G'(\boldsymbol{h}, N, t) \ . \tag{30}$$

Eq. (29) is the relation between the chain-distribution function and the chain-reformation function in the natural state, as expected. Eq. (30) gives the correction of the chain-distribution function due to the small deformation $\boldsymbol{e}'(t)$, when $F_0(\boldsymbol{h}, N)$ and $G'(\boldsymbol{h}, N)$ are known. Hereafter, we assume that $G_0(\boldsymbol{h}, N)$, $\beta(\boldsymbol{h}, N)$ and then also $F_0(\boldsymbol{h}, N)$ are spherically symmetric. Because of the fact that in the natural state the system is isotropic, this assumption is quite reasonable. Substituting Eqs. (29) and (30) into Eq. (3) and carrying out the elementary calculations, we have

$$\frac{d\boldsymbol{s}'_n}{dt}=\kappa\frac{d}{dt}\left(\boldsymbol{e}'_s(t)+\frac{1}{2}v'(t)\mathbf{1}\right)+P_0\frac{dv'(t)}{dt}\mathbf{1}+\left(\frac{d\boldsymbol{s}'_n}{dt}\right)^{b,r}, \quad (31)$$

$$\left(\frac{d\boldsymbol{s}'_n}{dt}\right)^{b,r}=\Sigma_N\iiint(\boldsymbol{hh})\left(\frac{1}{r}\frac{d\phi}{dr}\right)_{r=|\boldsymbol{h}|}\times[G'(\boldsymbol{h}, N, t)-\beta(\boldsymbol{h}, N)F'(\boldsymbol{h}, N, t)]d\boldsymbol{h}\,. \quad (32)$$

$$\kappa=-\frac{8\pi}{15}\Sigma_n\int r^5\left(\frac{1}{r}\frac{d\phi}{dr}\right)\frac{dF_0(r, N)}{dr}dr\,, \quad (33)$$

$$P_0=-\frac{4}{3}\pi\Sigma_n\int r^4\left(\frac{1}{r}\frac{d\phi}{dr}\right)F_0(r, N)dr\,, \quad (34)$$

where $\boldsymbol{e}'_s(t)\equiv\frac{1}{2}(\boldsymbol{e}'(t)+\boldsymbol{e}'^{+}(t))$ is the symmetrized deformation tensor and

$$1+\varepsilon v'(t)\equiv1+\varepsilon\,\mathrm{Sp}\,\boldsymbol{e}'(t)=|\boldsymbol{e}(t)|\equiv v(t) \quad (35)$$

is the volume of the volume element which was the unit volume at $t=0$. Owing to the fact that the quantities having the subscript 0 in Eq. (29) are independent of time, the primes in Eqs. (31) and (32) can be removed. The first two terms on the right-hand side of Eq. (31) give the change in the stress due to the deformation of the network. $\frac{1}{2}\kappa(dv/dt)\mathbf{1}$ is the effect of the volume-change through the deformation of the network, and $\kappa$ has the meaning of the elastic modulus. The third term shows the effect of the volume-change in the sense of hydrodynamics and $P_0$ corresponds to the hydrostatic pressure. The last is the term due to the irreversible processes.

In order to simplify further the stress-deformation-time relation, we consider the re-construction of the network. Let us pick up from the network all the chains which constitute the network at time $t$ with a common value of $\beta(\boldsymbol{h}, N)$. (They may have various values of $N$ and $\boldsymbol{h}$.) Using these chains we re-construct a new network which extends over the same volume and shape as those of the original network. This "subnetwork" is characterized by the magnitude of $\beta$. We shall call it $\beta$-subnetwork. In a $\beta$-subnetwork, by definition, the chain-breakage coefficient $\beta$ is constant and their deformation tensor is just the same as that of the original one i.e. $\boldsymbol{e}(t)$. Although these subnetworks may not always be "networks" in the true sense of the word, it will make no difference in the following discussions. In the mathematical speaking, the chain-distribution function of the $\beta$-subnetwork is

$$\left(\frac{\delta(\beta(r, N)-\beta)}{\mathrm{grad}\,\beta(r, N)}\right)_{r=|\boldsymbol{h}|}F(\boldsymbol{h}, N, t)\,, \quad (36)$$

where $F(\boldsymbol{h}, N, t)$ is the distribution function of the original network.

If we characterize by the parameter $\beta$ the contributions from the $\beta$-subnetwork, we have the following equations instead of Eqs. (31)~(34):

$$\boldsymbol{s}_n=\int\boldsymbol{s}_n(\beta)d\beta\,, \quad (37)$$

$$\frac{d\boldsymbol{s}_n(\beta)}{dt}=\kappa(\beta)\left(\frac{d\boldsymbol{e}_s}{dt}+\frac{1}{2}\frac{dv}{dt}\mathbf{1}\right)+P_0(\beta)\frac{dv}{dt}\mathbf{1}+\frac{d\boldsymbol{s}_n^*(\beta)}{dt}-\beta\boldsymbol{s}_n(\beta)\,, \quad (38)$$

where

$$\kappa(\beta)=-\frac{8\pi}{15}\Sigma_N\int r^5\left(\frac{1}{r}\frac{d\phi}{dr}\right)\frac{dF_0}{dr}\times\frac{\delta(\beta(r, N)-\beta)}{\mathrm{grad}\,\beta(r, N)}dr\,, \quad (39)$$

$$P_0(\beta)=-\frac{4}{3}\pi\,\Sigma_N\int r^4\left(\frac{1}{r}\frac{d\phi}{dr}\right)\times F_0(r, N)\frac{\delta(\beta(r, N)-\beta)}{\mathrm{grad}\,\beta(r, N)}dr\,, \quad (40)$$

$$\frac{d\boldsymbol{s}_n^*(\beta)}{dt}=\Sigma_N\iiint(\boldsymbol{hh})\left[\frac{1}{r}\frac{d\phi}{dr}G(r, N, t)\times\frac{\delta(\beta(r, N)-\beta)}{\mathrm{grad}\,\beta(r, N)}\right]_{r=|\boldsymbol{h}|}d\boldsymbol{h}\,. \quad (41)$$

The last equation gives the change of the stress caused by the chain-reformation.

If the chain-reformation function $G(\boldsymbol{h}, N, t)$ is independent of $\boldsymbol{e}$ and $t$, Eq. (38) becomes*:

$$\frac{d\boldsymbol{e}_s}{dt}+\mu(\beta)\frac{dv}{dt}\mathbf{1}=\frac{1}{\kappa(\beta)}\frac{d\boldsymbol{s}_n(\beta)}{dt}-\frac{1}{\eta(\beta)}\boldsymbol{s}_n(\beta)\,, \quad (42)$$

where

---

*) Since $ds^*_n(\beta)/dt$ becomes a constant scalar, it can be put into the hydrostatic pressure in Eq. (5).

$$\mu(\beta)=(\kappa(\beta)+2P_0(\beta))/2\kappa(\beta)\ , \tag{43}$$

$$\eta(\beta)=\kappa(\beta)/\beta\ , \tag{44}$$

From these expression we can see that $\kappa(\beta)$, $\eta(\beta)$ and $\mu(\beta)$ have the meaning of elastic modulus, viscosity coefficient and compressibility, respectively. If there is no volume-change, i.e. $dv/dt=0$, Eq. (42) is equivalent to the equation of the so-called Maxwell model of visco-elasticity. We can conclude, therefore, that a single $\beta$-subnetwork just corresponds to the above model and that the whole network is equivalent to the "generalized" Maxwell model.

Here a remark may be added on the general and rather large deformations. As was mentioned previously, on the right-hand side of Eq. (13), $\boldsymbol{e}^{-1}\boldsymbol{s}_n$ has the meaning of modulus and the third term expresses the deviation from the linearity between the stress and the deformation by the irreversible processes. We assume as before that $G(\boldsymbol{h}, N, t)$ is spherically symmetric and separate the last term into two. The one is due to $G(\boldsymbol{h}, N, t)$ in Eq. (14) and this can be included into the $P\mathbf{1}$ term of Eq. (5). The other part is due to the chain-breakage and, if we consider a single $\beta$-subnetwork, this term becomes $-\beta\boldsymbol{s}_n(\beta)$. Now we define the "mean chain-breakage coefficient" $\boldsymbol{B}$ and the "mean elastic modulus" $\boldsymbol{K}$: $[\boldsymbol{K}\cdot(d\boldsymbol{e}/dt)]=$(the first three terms on the right-hand side of Eq. (13)), $\boldsymbol{B}\boldsymbol{s}_n=\int\beta\boldsymbol{s}_n(\beta)d\beta$. They are in general non-scalar but tensor quantities. Then Eq. (13) may be written as

$$\frac{d\boldsymbol{s}}{dt}=\left[\boldsymbol{K}\cdot\frac{d\boldsymbol{e}}{dt}\right]-\boldsymbol{B}\cdot\boldsymbol{S}_n\ , \tag{45}$$

This equation has the same form as the Maxwell model. But, $\boldsymbol{K}$ and $\boldsymbol{B}$ are non-scalar quantities and are the functions of $t$ and $\boldsymbol{e}(t)$.

## § 8. Comparison with Green-Tobolsky's Theory

Green-Tobolsky's formulae can be derived from our results subject to the following restrictions:

a) The chains are the Gaussian ones.

b) The number of the chains involved in the network is a constant:

$$\Sigma_N\iiint F(\boldsymbol{h}, N, t)d\boldsymbol{h}=M=\text{const}\ . \tag{46}$$

c) The probability of the chain-breakage is independent of the state of the chain:

$$\beta(\boldsymbol{h}, N)=\beta=\text{const}. \tag{47}$$

d) The chain-reformation function is independent of the deformation:

$$G(\boldsymbol{h}, N, t)=\beta F_0(\boldsymbol{h}, N)\ . \tag{48}$$

where $F_0(\boldsymbol{h}, N)$ is the chain-distribution function in the natural state.

For example, let us consider the differential stress-deformation-time relation. Define the scalar quantity $Q$:

$$\frac{3kT}{a^2}\Sigma_N\frac{1}{N}\iiint(\boldsymbol{h}\boldsymbol{h})F_0(\boldsymbol{h}, N)d\boldsymbol{h}=Q\mathbf{1}\ . \tag{49}$$

and Eq. (15) becomes

$$\begin{aligned}\frac{d\boldsymbol{s}}{dt}+\beta\boldsymbol{s}=&\frac{d\boldsymbol{e}}{dt}\boldsymbol{e}^{-1}\boldsymbol{s}+\boldsymbol{s}\boldsymbol{e}^{+-1}\frac{d\boldsymbol{e}^+}{dt}\\&-P\left[\frac{d\boldsymbol{e}}{dt}\boldsymbol{e}^{-1}+\boldsymbol{e}^{+-1}\frac{d\boldsymbol{e}^+}{dt}\right]\\&+\left(\frac{dP}{dt}+\beta Q+\beta P\right)\mathbf{1}\ .\end{aligned} \tag{50}$$

This equation may be compared with Green-Tobolsky's equation (B.7), namely:

$$\begin{aligned}\frac{d\boldsymbol{s}}{dt}+\beta\boldsymbol{s}=&\frac{d\boldsymbol{e}}{dt}\boldsymbol{e}^{-1}\boldsymbol{s}+\boldsymbol{s}\boldsymbol{e}^{+-1}\frac{d\boldsymbol{e}}{dt}\\&+\left(\frac{\mathrm{Sp}\,(\boldsymbol{s}^{-1}(d\boldsymbol{s}/dt))}{\mathrm{Sp}\,(\boldsymbol{s}^{-1})}-\frac{3\beta}{\mathrm{Sp}\,(\boldsymbol{s}^{-1})}\right)\mathbf{1}\ .\end{aligned} \tag{51}$$

The quantity in the round bracket of this equation can be obtained by rewriting that of Eq. (50) by means of the boundary conditions. In their Eq. (51), there is no term corresponding to the quantity in the square bracket of Eq. (50). Without this quantity, however, the well-known stress-deformation relation of the rubber-like elasticity can not be derived even if the breakage and reformation of the chains do not occur.

## § 9. Conclusion

For the purpose of the molecular theoretical explanation of the visco-elastic behaviours displayed by the amorphous high-polymeric substances, we have made the statistical-mechanical studies of the modified rubber-like networks. In this paper, the general formalisms have been given to the stress-deformation-time relation and the energy of dissipation.

The main assumptions adopted in our treatment are as follows:

a) The application of the theory of equilibrium rubber-like elasticity to the derivation of the stress in each "instant" in which the measurement is carried out,

b) The application of the requirement of proportionality to the displacements of the junctions.

As was mentioned in § 2, the first one is allowed as the first approximation to the treatment of our irreversible processes, if the rate of the deformation is small. In the case of rapid deformation, it becomes essentially important to consider the irreversible " relaxation phenomena " of the micro-Brownian movements of the molecular segments. The molecular theories of this case are statistical-mechanically formulated by Kirkwood, Rouse, and others⁴⁾. The second one may be correct in the case of the rubber-like network in which the Gaussian chains permanently connect with each other. In our case, however, this is nothing but the assumption. Although it will be very difficult, one of the prospective improvement of the theory may be carried out by the removal of this assumption.

It was shown in § 7 that our network model is phenomenologically equivalent to the generalized Maxwell model. As is well known in the phenomenological theory of visco-elasticity, there are two types of the so-called " mechanical " models, i.e. Maxwell type and Voight type. The general excitation-response-theory shows that the models of these two tppes are essentially equivalent. In the view-point of the application, however, there is a difference between these models. The model of the Voigt type is in general convenient to obtain the deformation under the knowledge of the stress. On the other hand, from the given deformation, the stress is calculated in a simple way by the model of Maxwell type. In our study of the network model, we derive the stress tensor assuming that the deformation tensor is given. This analogy seems to be the reason why our network model corresponds not to the generalized Voigt model but to the Maxwell one.

The author wishes to express his thanks to Professor T. Yamamoto and Mr. E. Teramoto for their constant instructions and encouragements. He is further obliged to the members of Research Group of High Polymer in Kyoto, especially, Professors H. Inagaki, who suggested this probelm, H. Fujita and M. Kurata for their kind discussions.

# The Quadrupole Moment of $V^{51}$

By Kiyoshi MURAKAWA

*Institute of Science and Technology, Komaba-machi, Meguro-ku, Tokyo*

(Received November 14, 1955)

The hyperfine structure (hfs) of the spectrum of V I was investigated. From the hfs of $\lambda$ 4851 the quadrupole coupling constant of the ground level $3d^34s^2\,{}^4F_{3/2}$ was deduced. Assuming that the screening correction for the $d$-electron of V I is 13, the quadrupole moment of $V^{51}$ was calculated to be $(0.2_8 \pm 0.15)10^{-24}\text{cm}^2$, in which the polarization correction due to Sternheimer is taken into account. The indicated probable error does not include the uncertainty of the screening correction of the $d$-electron. In addition to the hfs of $\lambda$ 4851, the hfs of $\lambda\lambda$ 4881, 4875, 4832, 4594, 4330 were measured, and the interval factors of the quartet levels $3d^34s^2\,{}^4F$ and of $3d^34s4p\,{}^4G_{11/2}$ were obtained.

## § 1. Introduction

The quadrupole moment ($Q$) of $V^{51}$ is worthy of special investigation, because the current shell model of the nucleus predicts negative $Q(V^{51})$, whereas the regularity among the actual $Q$'s of numerous nuclei leaves a slight amount of room for positive $Q(V^{51})$. In view of this interest, Kamei and the author[1] studied some years ago the hyperfine structure (hfs) of the spectrum of VI and deduced $Q(V^{51}) = (0.3 \pm 0.2) \times 10^{-24}\text{cm}^2$. The investigation of the screening correction of the $d$-electron[2] gave the author an opportunity of studying again the hfs of VI; the result of this study will be reported in the present paper.

Kopfermann and Rasmussen[3] had previously studied the hfs of the spectrum of VI, but they detected no deviation from the cosine interval rule in any level of VI. The accuracy of the interval factors given by them is not sufficient enough to allow us to investigate the regularity of the hfs contribution of the $3d$-electron. It is therefore necessary to investigate the hfs of several lines (having $d^3s^2\,{}^4F$ as the final level) in addition to that of $\lambda$4851.

In the present work the hfs was studied by means of a liquid-air cooled hollow cathode discharge tube and a Fabry-Pérot etalon. The classification of the spectrum of VI was taken from the work of Meggers and Russell[4].

## § 2. Hfs of the Spectrum of VI

As shown in the previous work[1], the hfs of $\lambda$4851 is the most suited for deducing $Q(V^{51})$. In the present work this line was again studied, and the result of measurement is given in Fig. 1; this is essentially the same as the previous work[1], with the exception that this time the splitting of the upper level was detected. Fig. 2 is a reproduction of the hfs of $\lambda$4851 taken with a 15 mm etalon. The first row of Fig. 1 shows the result of measurement on patterns in which the components $b$ and $c$ are recognized to be resolved (although not so sufficiently). The position of the component $d$ is difficult to measure and was therefore calculated. The hfs scheme deduced from the resolved structure has, however, only an accuracy sufficient for determinig the interval factor of the levels, but insufficient for determining the quadrupole coupling constant. The second row of Fig. 1 shows the result when the hfs was measured, assuming that the components $b$ and $c$ are not resolved. Denoting the interval factors of the final and the initial levels of $\lambda$4851 by $A$ and $\delta/4$ respectively and the quadrupole coupling constant of the final level by $B$, we get from the second row of Fig. 1:

$$A - \frac{1}{12}\delta = 0.02073\ \text{cm}^{-1},$$

$$B = -0.004_0 \times 10^{-3}\ \text{cm}^{-1}.$$

Since $\delta = -0.014\ \text{cm}^{-1}$, we get

$$A = 0.0195\ \text{cm}^{-1}.$$

The hfs of $\lambda$4330 is shown in Fig. 3. Denoting the interval factors and the quadrupole coupling constants of the final and the initial levels of $\lambda$4330 by $A$, $B$ and $A'$, $B'$ respectively, we get from Fig. 3:

$$A - \frac{11}{15}A' = 0.0180\ \text{cm}^{-1}, \quad A = 0.0195\ \text{cm}^{-1}$$

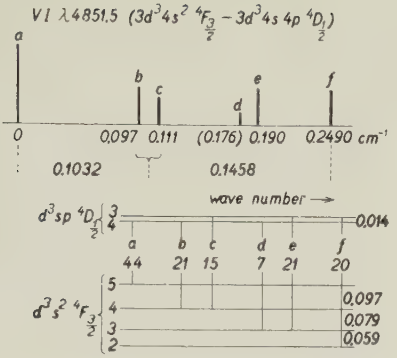

Fig. 1. Hfs of λ 4851.5.

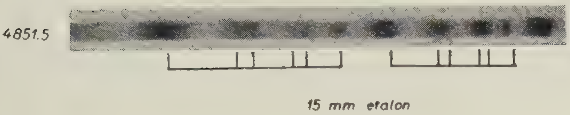

Fig. 2. Interference pattern of λ 4851.5.

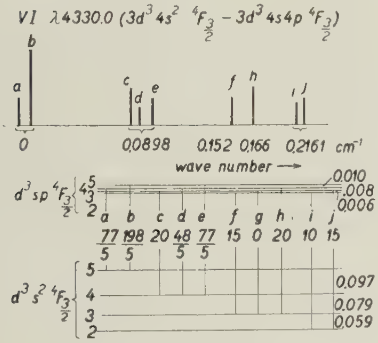

Fig. 3. Hfs of λ 4330.0.

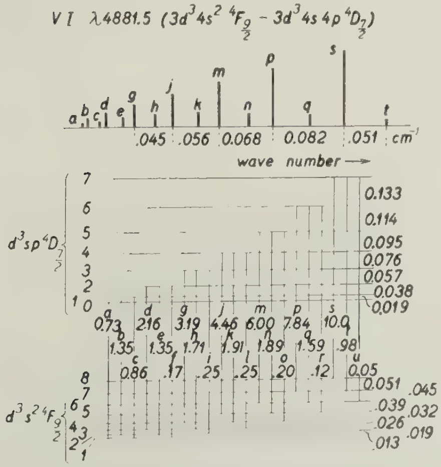

Fig. 4. Hfs of λ 4881.5.

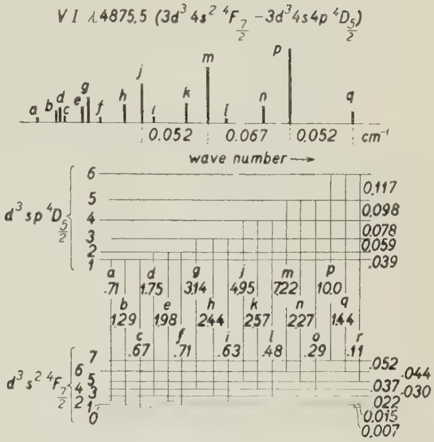

Fig. 5. Hfs of λ 4875.5.

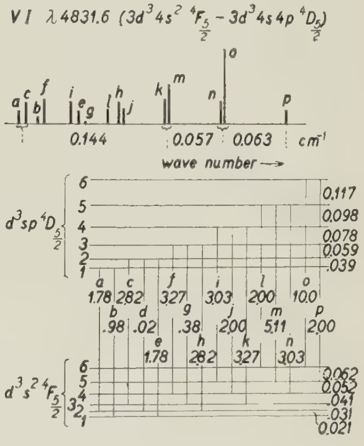

Fig. 6. Hfs of λ 4831.6.

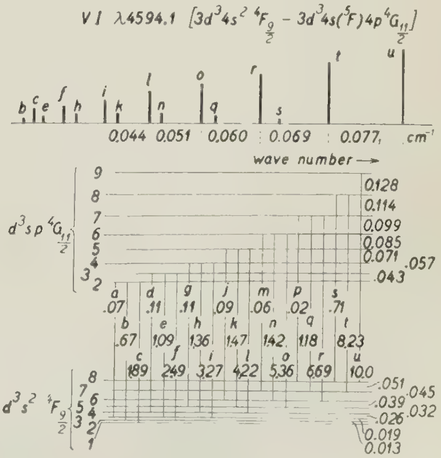

Fig. 7. Hfs of λ 4594.1.

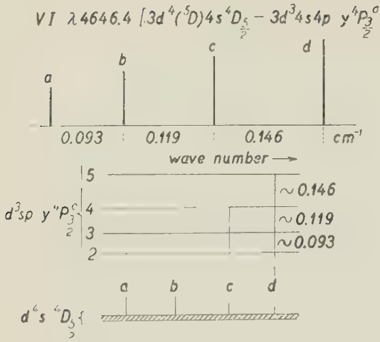

Fig. 8. Hfs of λ4646.4.

$$B-\frac{1}{5}B'=-0.002\times10^{-3}\text{cm}^{-1}\,.$$

In this case the accuracy of measurement is not so good as in the case of λ4851. Moreover the wave function of the upper level $3d^3 4s4p\,{}^4F_{3/2}$ is not pure and therefore difficult to calculate accurately. However it could be probably concluded that the measured hfs of λ4330 does not contradict with the negative value of $B$.

In order to investigate the interval factors of the term $3d^3\,4s^2\,{}^4F$, the hfs of λλ4881, 4875 and 4832 were investigated. The results of measurement are shown in Figs. 4, 5 and 6.

The interval factor of the level $3d^3\,4s\,4p\,{}^4G_{11/2}$ can be deduced from the hfs of λ4594 (Fig. 7). The experimental material for this line is not much different from that of Kopfermann and Rasmussen³⁾, but the hfs splittings of both the initial and the final levels given by them are different from those of the present author.

Finally, the hfs of λ4646 is shown qualitatively in Fig. 8. Since another line lies very close, it was difficult to measure the hfs accurately. In order to isolate λ4646, a large grating (instead of a prism spectrograph) would be needed. The interval factor of the final level must be small, and therefore the hfs of λ4646 could be used as a check for $Q(V^{51})$ if this could be measured accurately.

## § 3. Calculation of $Q(V^{51})$

Before calculating $Q(V^{51})$ from the value of $B(3d^3\,4s^2\,{}^4F_{3/2})$, it is necessary to find the value of the effective charge for the $3d$ electrons of VI. For that purpose the interval factors of the term $3d^3\,4s^2\,{}^4F$ (see Table I) could be used. Since this configuration of VI is of a typical $LS$-coupling, we can use the $LS$-coupling formulas that were derived previously²⁾:

$$A(d^3\,{}^4F_{9/2})=(8a_d'+a_d''+8a_d''')/9,$$
$$A(d^3\,{}^4F_{7/2})=(281a_d'+34a_d''+128a_d''')/315,$$
$$A(d^3\,{}^4F_{5/2})=(712a_d'+163a_d''-424a_d''')/875,$$
$$A(d^3\,{}^4F_{3/2})=(59a_d'+66a_d''-368a_d''')/125,$$
$$a_d'=a(d_{5/2}),\ a_d''=a(d_{3/2}),\ a_d'''=a(d_{5/2},\ d_{3/2}).$$

Putting $a_d'=\dfrac{3}{7}\dfrac{F_2'}{F_2''}a_d''$, $a_d'''=-\dfrac{1}{16}\dfrac{G_2}{F_2''}a_d''$ in each of the above formulas, we can calculate $a_d''$ from the observed value of $A$ of each level. The value of $a(d_{3/2})$ calculated in this way is shown in Table I.

Finally the configuration $3d^3 4s4p$ is also of good $LS$-coupling, so that the level $3d^3 4s({}^5F)\,4p\,{}^4G_{11/2}$ should obey the $LS$-coupling formula:

$$A[d^3s({}^5F)p\,{}^4G_{11/2}]$$
$$=\frac{9}{110}a(s)+\frac{1}{550}(381a_d'+54a_d''+348a_d''')$$
$$+\frac{1}{165}(13a_p'+8a_p''-32a_p''')\,.$$

Putting $F$(relativity correction factor)$=1.07$, $1-\delta$(finite volume correction factor)$=0.994$, $Z=23$, $(dn^*/dn)/n^{*3}_{4s}=0.44$, $\mu/I=1.4709$ in the modified Goudsmit-Fermi-Segre formula, we get $a(4s)=0.091\text{ cm}^{-1}$ for VI. Putting this value in the above formula, we get $a(d_{3/2})=0.015$ cm⁻¹. The actual wave function for $3d^3\,4s({}^5F)4p\,{}^4G_{11/2}'$ would contain a slight amount of $3d^3\,4s({}^3F)\ 4p\,{}^4G_{11/2}$, so the above-mentioned value of $a(d_{3/2})$ would have to be slightly corrected.

Table I. Interval factors of the levels of V I.

| Level | $A$ cm⁻¹ | $a(d_{3/2})$ cm⁻¹ |
|---|---|---|
| $3d^3 4s^2\,{}^4F_{9/2}$ | 0.0064 | 0.015 |
| ${}^4F_{7/2}$ | 0.0074 | 0.016 |
| ${}^4F_{5/2}$ | 0.0103 | 0.018 |
| ${}^4F_{3/2}$ | 0.0195 | 0.021 |
| $3d^3 4s({}^5F)4p\,{}^4G_{11/2}$ | 0.0142 | ≈0.015 |

From Table I it is apparent that the values of $a(d_{3/2})$ calculated in this way are not satisfactorily consistent. A simple calculation shows that the electrostatic interaction with $3d^4\,4s\,{}^4F$ can not be made responsible for this inconsistency. We would therefore leave this question undetermined, and assume that the screening correction for the $d$-electron of VI is 13, a value obtained by extrapolation from heavier elements.

We can now calculate $Q(V^{51})$ from the level $3d^3\,4s^2\,{}^4F_{3/2}$. For this level the following *LS*-coupling formula is valid according to Schmidt[5)] and Kamei[6)].

$$(d^3\,{}^4F_{3/2}{}^{3/2}|3\cos^2\theta-1|d^3\,{}^4F_{3/2}{}^{3/2})=\frac{8}{875}(13\,R_2'+14\,R_2''-12\,S_2).$$

Putting $Z^*_d=23-13=10$, $R_2'\approx S_2=1.00$, $R_2''=1.004$, in the above formula, and putting $\zeta_{3d}=158$, $\Delta$ (polarization correction due to Sternheimer)$=0.23$, $H_2=1.00$, $I=7/2$ and $B=-0.004\times10^{-3}\text{cm}^{-1}$ in the modified Casimir's formula

$$Q=-B\frac{Z^*H_2(1+\Delta)}{\zeta<\sum(3\cos^2\theta-1)>_{\text{Av}}}\times I(2I-1)J(2J-1)1.988,$$

we get finally

$$Q(V^{51})=(0.2_8\pm0.15)10^{-24}\text{cm}^2.$$

The indicated probable error does not include the uncertainty of the screening correction of the *d*-electron, because it is impossible to estimate the maximum error of $Z-Z_d^*$.

$V^{51}$ is the only nucleus whose $Q$ comes out with an opposite sign in the calculation of Horie and Arima[7)]. However, their calculation shows that by assigning a suitable configuration to $V^{51}$ it is possible to obtain a positive $Q$. The theory put forward by Moszkowski and Townes[8)] and Moszkowski[9)] predicts a positive $Q$ for $V^{51}$.

The investigation of the hfs of the spectrum of vanadium will be continued, and it is hoped that a more knowledge will be gained of the effective charge for the *d*-electrons.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 11, No. 4, APRIL, 1956

# Phosphorescence of Sodium- and Potassium-Acetates

By Kikusaburo OSADA

*Faculty of Engineering, Nagoya University*

(Received November 18, 1955)

Sodium- and potassium-acetates emit green light for a few seconds, after excited *in vacuo* with radiation of 254 mμ. Their spectra are composed of green band with a maximum at 530 mμ and blue one at 465 mμ. The phosphorescence is quenched by oxygen adsorbed in molecular state, and the initial intensity is inversely proportional to the pressure of oxygen, but water vapour and hydrogen do not affect at all. The intensity is also changed by the treatment of the crystal. The activation energy calculated from the temperature dependence of the lifetime is 0.034 eV. Their ultraviolet absorption spectra are also measured in aqueous or acetic acid solution to 220 mμ with a quartz spectrophotometer.

From these results, it may be considered that the phosphorescence is due to imperfections of crystal.

## § 1. Introduction

The luminescent phenomena of organic compounds, *e.g.* acetic salts[1)], dyes etc.[2)], have been known by many works, but nothing is known for sodium- and potassium-acetates. However, we could observe green phosphorescence of the latters after excitation of ultraviolet radiation *in vacuo*.

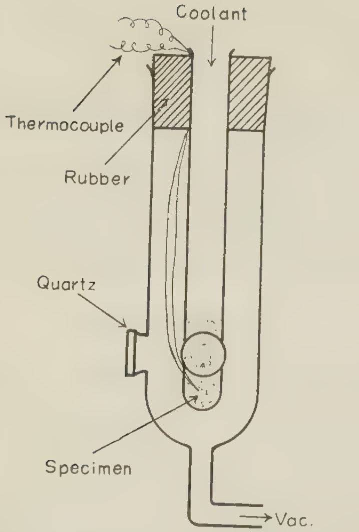

Fig. 1. Apparatus for observation of phosphorescence.

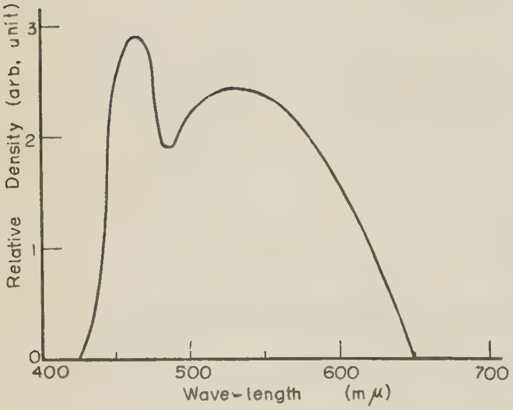

Fig. 2. Phosphorescence spectrum of acetic salt.

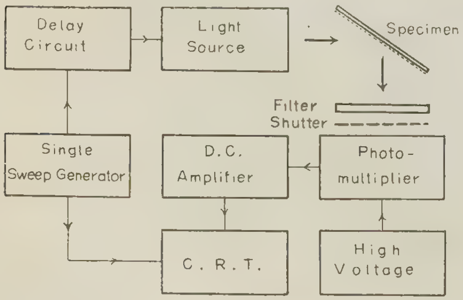

Fig. 3. Block diagram of apparatus for observation of afterglow of phosphorescence.

To investigate the mechanism of this phosphorescence, we observed with an ocilloscope how the intensity and the decay of the afterglow depended on temperature, pressure, and kinds of ambient gas. Further, their ultraviolet absorption spectra were measured to 220 mμ in aqueous or acetic acid solution, as it was difficult to measure the spectra in solid state.

From these results, the mechanism of this phosphorescence is considered.

## § 2. Phosphorescence Spectra

Specimens used were sodium- and potassium-acetates (NaOAc and KOAc), and the former was one of commercial reagents of the special grade and the latter of the first grade. They were powdered and cooled at about −50°C with the mixture of dry ice and amyl acetate in the apparatus shown in Fig. 1. Temperature was measured with a copper-constantan thermocouple inserted in the specimen. They emitted green light for a few seconds after illumination of a germicidal lamp.

The spectra of the afterglow were photographed by using panchromatic photographic film (super-*XX*), and small glass spectrograph whose dispersion is 10 mμ/mm at 400 mμ and 70 mμ/mm at 600 mμ. The density on the film was measured with microphotometer.

The spectrum of every specimen is composed of green band with a maximum at 530 mμ and blue one at 465 mμ. One of the results is shown in Fig. 2.

When they are excited with the light of the lamp passed through a plate of sodium glass, the afterglow can not be observed. So this phosphorescence should appear only by the excitation of radiation of the mercury line at 254 mμ.

## § 3. Afterglow of Phosphorescence

The decay of afterglow of the phosphorescence was measured with an apparatus as shown in Fig. 3. The light of afterglow is sent to a photomultiplier tube (RCA 931 A) supplied a stabilized high voltage[3]. The photo-current is amplified with a d.c. amplifier, and is fed to a cathod-ray tube which is sweeped with a single sweep generator. Trace on the cathod-ray tube is photographed by camera. The instrument is so adjusted as the deflection is proportional to the intensity of light. The germicidal lamp is operated with a constant d. c. voltage. To separate the green band from the blue one, two filters were used; one transmits the light whose wavelength is shorter than 500 m$\mu$ (Matsuda V–C1B), and the other longer than 490 m$\mu$ (Matsuda V–Y1A).

The features of decay of both bands are of exponential type:

$$I=I_0 \exp(-t/\tau)$$

where $\tau$ is lifetime, $I_0$ the initial intensity and $I$ the intensity at time $t$.

We have produced the monochromatic light of 254 m$\mu$ to excite the emission from the specimen by passing the filter[4], but the intensity of monochromatic light was too weak to observe any emission from both specimens. So we could not use the monochromatic light, and it was difficult to measure experimentally the initial intensity. We were able to estimate its value only by the extrapolation of the decay curve.

Effects of temperature, pressure, and kinds of ambient gas on the phosphorescence were measured.

(*a*) *Effect of Temperature*

The lifetime and the initial intensity were measured from room temperature down to about −50°C.

The intensity increases with decreasing temperature. The lifetime of NaOAc is shorter than that of KOAc, and that of the green band is longer than the blue one in both cases. The results obtained are shown in Table I and Fig. 4.

The well-known relation between the lifetime and the activation energy $E$:

$$\tau^{-1}=s \exp(-E/kT)$$

where $s$ is a constant, $T$ absolute temperature, and $k$ Boltzmann's constant, also holds in this case well.

From the slope of the lines in Fig. 4, we obtained $E$ as 0.034 eV in all cases.

Table I. Lifetime of acetic salts.

| Specimen | Temp. | Green Band | Blue Band |
|---|---|---|---|
| $Na(CH_3CO_2)$ | 14.5°C | 1.29 sec. | 1.09 sec. |
| | −38 | 1.75 | 1.46 |
| $K(CH_3CO_2)$ | 10 | 1.11 | 0.99 |
| | −38 | 1.52 | 1.35 |

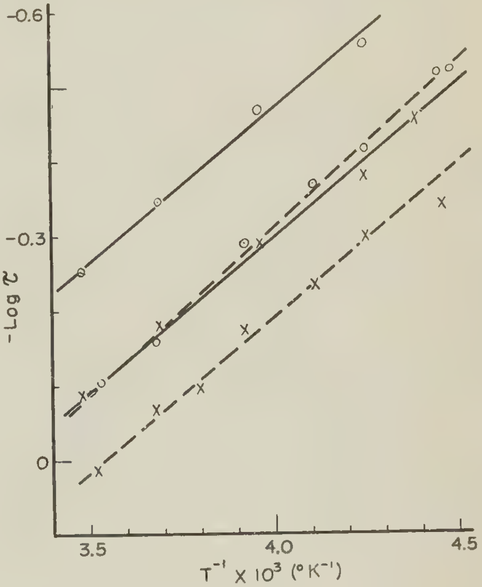

Fig. 4. Temperature dependence of lifetime of NaOAc (——) and KOAc (– – –). (⊙: green band, ×: blue band)

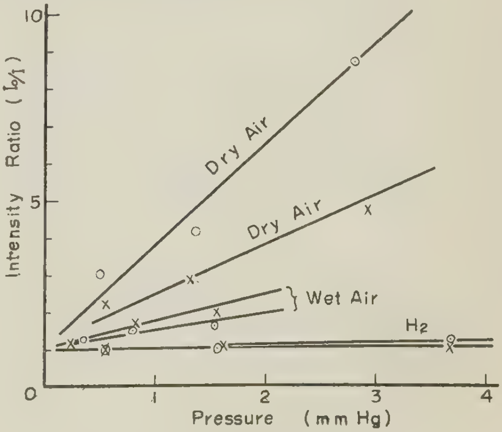

Fig. 5. Quenching by gas of phosphorescence of NaOAc. (⊙: green band, ×: blue band)

(*b*) *Effect of ambient Gas*

To observe how the quenching of phosphorescence depends on pressure and kinds of ambient gas, three kinds of gas were used: hydrogen gotten from Kipp's generator and passed through solution of potassium permanganate and potassium hydorate and traps of calcium chloride, wet air passed through water pool, and dry air passed through calcium chrolide trap. The pressure were changed from $10^{-2}$ to 4 mmHg.

The initial intensity and the lifetime decrease gradually with increasing pressure. Quenching by the dry air is remarkable, and the

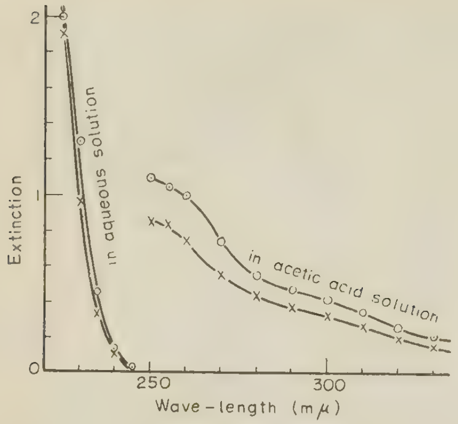

Fig. 6. Absorption spectra of NaOAc (⊙) and KOAc (×) in solution.

green band is more quenched than the blue one. This recovers at once when gas is pumped out. This phenomenon is reversible. The results for NaOAc are shown in Fig. 5, and KOAc behaves in a similar way.

Dry air contains oxygen and nitrogen, but as nitrogen is inactive, the quenching by the dry air must be due to oxygen. Quenching by wet air is smaller than dry air. Although humidity of the wet air was not measured, partial pressure of oxygen in the former is lower than in the latter. So the degree of quenching by water vapour may be very small. Quenching by hydrogen is also very small. This is due to oxygen contained in the residual air.

Here, we shall consider the relation between initial intensity and pressure of oxygen. Assuming that oxygen is adsorbed in molecular state, the following relation is known as Langmuir's isothermal adsorption formula:

$$\theta = \frac{p}{p_0 + p}$$

where $p$ is pressure, $p_0$ a constant, $\theta$ a covering factor. If we assume that the intensity is proportional to $(1-\theta)$, the following equation is derived from the previous one:

$$I = I_0(1-\theta) = I_0\left(\frac{p_0}{p_0+p}\right)$$

and

$$I_0/I = 1 + p/p_0$$

where $I_0$ is the intensity at zero pressure, and $I$ at pressure $p$.

We can see from this equation that $(I_0/I)$ changes linearly with pressure. This relation can be confirmed by the experiments as shown in Fig. 5. This is also similar to the formula for the quenching by oxygen of fluorescence of organic compounds in solution[5].

From these consideration, we can conclude that the phosphorescence is quenched by oxygen adsorbed in molecular state, but water vapour and hydrogen do not affect at all. The initial intensity is inversely proportional to the pressure.

## § 4. Ultraviolet Absorption Spectra

As it was difficult to prepare transparent films of specimens, their characteristic ultraviolet absorption spectra could not be measured in solid state. So we measured their spectra in aqueous or acetic acid solution to 220 mμ with the quartz spectrophotometer of Hitachi Co. Their solutions are contained in a cell of 1cm thickness and their concentration is 0.1 g/cc. The results obtained are shown in Fig. 6.

In the aqueous solution, absorption edge appears at 245 mμ. In the acetic acid solution, edge appears at longer wave-length than 245 mμ and absorption increases gradually as the wave-length becomes shorter. It was difficult to measure the absorption below 250 mμ as the absorption of acetic acid is very large in this region[6].

The reasons for the dependence of the absorption on solvents are as follows. In the aqueous solution the solutes dissociate almost into metallic- and acetic-ions and the interaction between them is small or nearly negligible. But in the acetic acid solution a metallic ion is surrounded with acetic ions, and as there are no other kinds of interaction, they interact mutually very strong. Therefore, in the latter case the absorption near 250 mμ becomes very large.

From these results, their absorption spectra in solid state should also be similar to ones in acetic acid solution.

## § 5. Discussion

Phosphorescence of the acetic salts appears *in vacuo* under the excitation of radiation at 254 mμ and is quenched by oxygen adsorbed in molecular state. From the absorption spectra of solution, the wave-length of this radiation should be in the region of their fundamental absorption spectra. The mechanism of their phosphorescence may be interpreted as follows.

From many results of the phosphorescence of organic compounds, it has been supposed that the emission is due to impurities, triplet state, or imperfections of crystal. The phosphorescence of dyes7) in rigid medium originates from the triplet state. Some organic crystals8), *e.g.* anthracene, naphthalene etc., phosphoresce also for a few minutes. Their emission is not due to the triplet state, but to other causes.

Biacetyl vapour9)10) phosphoresces emitting green and blue band under the excitation of ultraviolet or violet radiation. The lifetime of the green band is longer than the blue. The former band is quenched by oxygen, but the latter is not affected. Aceton vapour11)12) shows also a similar behaviour. It is not yet concluded whether a band is due to the singlet state and the other the triplet one or both are the triplet ones. But these phenomena seem due to the double bond between oxygen and carbon. NaOAc is also found to have the similar bond from its infrared spectrum13).

The following experiments were carried out to determine whether the phosphorescence of the acetic salts originates from impurities or not. In order to purify NaOAc, we make it triply recrystallized and dried hanging over calcium chloride in a desiccator. This specimen emits very weak light. After being left alone in air for some time, it is put instantly *in vacuo*. The intensity of its emission is as strong as the commercial one. On the other hand, when it is dried again in the desiccator before put *in vacuo*, its emission becomes very weak again. On account of deliquescence, the specimen adsorbs water vapour while it is exposed in air, but the water adsorbed may vaporized again when it is put *in vacuo* or desiccator. Speed of vaporization in the former case is faster than in the latter. Owing to the different speed, crystal of specimen in the former case may be more imperfect than in the latter. The commercial one which is dried in the desiccator, also emits weak light.

If the phosphorescence of the acetic salts is due to the triplet state or impurities, the intensity of the emission may not depend on the treatment of the crystal. But this assumption leads to the contradiction to our experiments. Moreover as the activation energy is small, the phosphorescence may be due to imperfections of crystal rather than the other causes.

## § 6. Conclusion

Green phosphorescence of sodium- and potassium-acetates is observed *in vacuo* for a few seconds by excitation of the radiation whose wave-length lies in the region of their fundamental absorption spectra. The emission must be due to imperfections of crystal.

# On the Absorption of Light by Colour-centres in the Region between *F*-band and *M*-band

By Hisao YAGI

*Department of Physics, University of Kyoto*

(Received December 20, 1955)

When the absorption coefficient of *F*-band of coloured alkali-halide crystal is about 2 cm$^{-1}$, six new bands called $R_\alpha$, $R_\beta$, $R_\gamma$, $R_\delta$, $R_\varepsilon$ and $R_\zeta$ respectively are observed in the region between *F*-band and *M*-band. On the other hand, however, Molnar's *R*-bands ($R_1$ and $R_2$) are observed when the absorption coefficient of *F*-band is about 20 cm$^{-1}$. The characteristic properties of our new bands are similar to those of Molnar's *R*-bands.

## §1. Introduction

As is well known, Molnar1) has observed M- and R-bands in coloured alkali-halide crystals in the region of longer wavelength than that of the F-band and has reported that the R-bands ($R_1$ and $R_2$) are very stable and have no photoconductivity. Based upon Molnar's report, Seitz2) has regarded the two R-centres as "$F_2$" and "$F_2{}^+$" respectively. It has been pointed out by Pringsheim3), however, that contrary to Molnar's report, the R-bands are not sufficiently stable. Also, it has been remarked by Oberly and Burstein4) that not only the R-bands but also the M- and N-bands have all photoconductivity. Thus, it may be said that the absorption of light by colour-centres in the region between the F-band and the M-band is not yet well understood.

In our laboratory, six bands called $R_\alpha$, $R_\beta$, $R_\gamma$, $R_\delta$, $R_\varepsilon$ and $R_\zeta$ respectively have been newly observed5) in the said region, and to the precise description of these bands the present paper is mainly directed.

## §2. Formation of R-bands and Measurement of their Absorption

Seitz considered that the R-centres are observed only in crystals coloured by X-rays, but Petroff6) has observed the R-bands, together with F-, M- and N-bands, in additively coloured crystals.

In our experiment, we have coloured alkali-halide crystals by following methods. In order to subject crystals to electrolysis, they were mounted in a furnace in a manner as shown in Fig. 1. (This is called "pointed-electrode method".) A crystal was supported between two iron rods which served as a part of electrical circuit supplying the current for electrolysis. The one rod (A) is pointed sharply at its end and acts as cathode. The other (B) contacts the crystal with the carbon plate covered with platinum foil and acts as anode. All parts except the furnace can be evacuated. Current is supplied by a 450 volts power supply with a 500 KΩ resistor.

After inserting a crystal in the furnace, the temperature of the furnace was first raised up to 450°C–500°C, and the current was supplied, and coloured cloud was made electrolytically in the crystal. (This coloured condition is called "F-coloured".) Then the temperature of the furnace was brought down to 350°–400°C, and the coloured cloud in the crystal was removed by reversing the polarity of the current. (This coloured condition is called "K-coloured".)

For the irradiation with X-rays, a Mazda Sealex tube, operated at a voltage of 30 KV D.C. and a current of 8 mA, was used. During the irradiation the crystal was kept in dark and at room temperature.

NaCl, KCl, KBr and LiF crystals used in our experiment were prepared in our laboratory7) by Kyropoulos's method. The crystals used were always freshly cleaved on all sides at the last possible moment before starting experiment.

The absorption spectra of the crystals were obtained with a large apertured glass-prism spectrophotometer with 1.5 meter focal length objective, and a quartz spectrophotometer of medium size. Monochromatic light from the exit slit was measured photoelectrically by Sb, Rb or Cs photocells and a Dolezaleck quadrant electometer (sensitivity: 1,500 D/V)

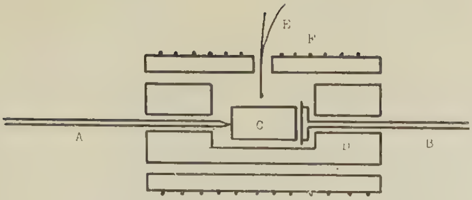

Fig. 1. Arrangement for subjecting crystals to electrolysis.
A: cathode, B: anode, C: crystal, D: holder, E: thermocouple, F: furnace.

connected as shown in Fig. 2.

For light source, a projection lamp (10 volts, 80 watts) was used for visible region, while a hydrogen discharge tube (6,000 volts, 1 Amp.) was used for ultraviolet region. RCA photomultiplier tubes 1P–28 and 1P–22 were also used in place of photocells. A Beckman Quartz Spectrophotometer Model DU was also used.

In our experiment, six bands called $R_\alpha$, $R_\beta$, $R_\gamma$, $R_\delta$, $R_\varepsilon$ and $R_\zeta$ respectively were obtained in every crystal in the region between the F-band and M-band, as shown in Fig. 3. Wavelengths of absorption maxima of these bands are given in Table I, the numerical values having been obtained at room temperature. These R-bands appear conspicuously when a crystal is coloured by X-ray irradiation, but in crystals coloured by electrolysis they are only observed when the crystal is K-coloured.

In the region between the F-band and the M-band, there are Molnar's R-bands ($R_1$ and $R_2$), which were observed in our experiment when the absorption coefficient of F-band was more than 20 cm$^{-1}$ and the temperature of crystals was about −180°C, while our R-bands were remarkable when the absorption coefficient of F-band was about 2 cm$^{-1}$ and enhanced with the increase of F-band. Since the increase of the absorption coefficient of F-band is always accompanied with enhancement of its tail, we cannot discriminate between our R-bands and the tail of F-band as regards these enhancements in the same region. But our R-bands and Molnar's R-bands show similar behaviours as described below, and so we wonder whether these bands can be attributable to the same kind of centres.

## § 3. Characteristic Properties of R-bands

### A. *Classification*

Numerical values of wavelengths of absorption maxima of these bands as shown in Table I are in agreement with those obtained from the empirical formura due to Ivey*. Empirical formulae calculated from the values of absorption bands of NaCl, KCl, KBr and LiF are shown in Table II.

Moreover, among these R-bands, a peculiar wavenumber relationship of the following form holds approximately, namely:

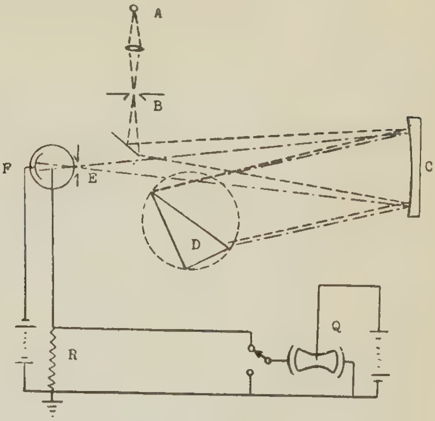

Fig. 2. Arrangement for measuring absorption. A: light source, B: 1st slit, C: collimator mirror, D: prism, E: 2nd slit, F: photocell, R: $10^{10}$ ohms, Q: quadrant electrometer.

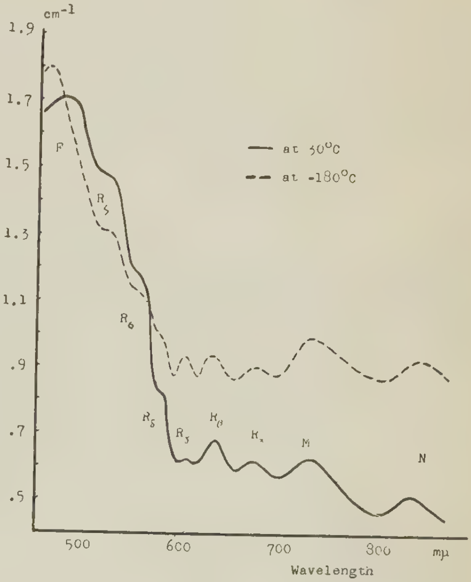

Fig. 3. Absorption of R-bands of X-ray coloured NaCl.

---

* Ivey's empirical formula is given by[8]

$$\lambda_{\max} = cd^x,$$

where $\lambda_{\max}$ is wavelength of absorption maximum of each band, $d$ is the lattice constant of each crystal, $c$ is a certain constant and $x$ is a certain exponent. The latter two vary from band to band.

Table I. *R*-bands of alkali-halide crystals.

| Absorption bands | Crystals | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | NaCl | | KCl | | KBr | | LiF | |
| | mμ | eV | mμ | eV | mμ | eV | mμ | eV |
| $R_\alpha$ | 660 | 1.87 | 782 | 1.56 | 847 | 1.46 | 408 | 3.02 |
| $R_\beta$ | 620 | 1.99 | 738 | 1.67 | 795 | 1.55 | 377 | 3.27 |
| $R_\gamma$ | 596 | 2.07 | 700 | 1.76 | 780 | 1.58 | 355 | 3.47 |
| $R_\delta$ | 572 | 2.16 | 671 | 1.84 | 741 | 1.66 | 338 | 3.65 |
| $R_\varepsilon$ | 552 | 2.23 | 635 | 1.94 | 704 | 1.75 | 315 | 3.91 |
| $R_\zeta$ | 526 | 2.34 | 608 | 2.03 | 669 | 1.84 | 297 | 4.15 |

Table II. Empirical formulae.

$R_\alpha$ : $\lambda_{\max} = 1330 \times d^{1.55}$
$R_\beta$ : $1263 \times d^{1.54}$
$R_\gamma$ : $1227 \times d^{1.53}$
$R_\delta$ : $1165 \times d^{1.54}$
$R_\varepsilon$ : $1124 \times d^{1.54}$
$R_\zeta$ : $1071 \times d^{1.54}$
$F$ : $724 \times d^{1.80}$

$$\frac{\nu_\alpha - \nu_\beta}{\nu_\gamma - \nu_\delta} = \frac{\nu_\beta - \nu_\varepsilon}{\nu_\delta - \nu_\zeta} .$$

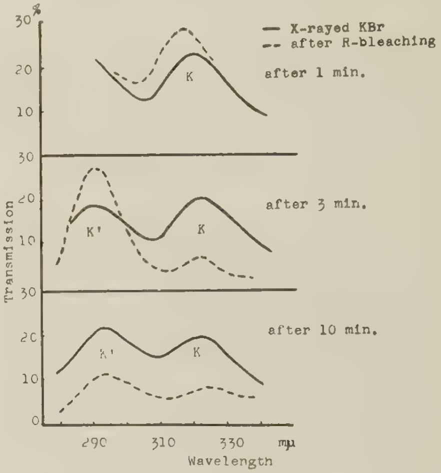

Fig. 4. Changes of K and K′ absorption bands after R-bleaching.

This means that our six bands may be classified into two groups, namely, Group A including $R_\alpha$, $R_\beta$ and $R_\varepsilon$, and Group B including $R_\gamma$, $R_\delta$ and $R_\zeta$. From the results of measurements at different temperatures, it has been found that Group A is enhanced at higher temperatures, while Group B at lower temperatures (see Fig. 3). At lower temperatures, the absorption coefficients of F-, R-, M- and N-bands increase and their wavelength maxima shift to shorter wavelength side.

B. *Phototransformation*

When the coloured crystals are irradiated by the light in any one of our R-bands, all the other R-bands are reduced at the same time with the illuminated R-band, and M-, F-, K- and K′-absorptions are enhanced suddenly for a while and then decrease, approaching final equilibrium values. Therefore, the light lying in any one of R-bands was used to irradiate crystals. Similarly, in order to observe prosperity and decay of R-bands irradiated by the light lying in any one of the

Table III. *F*-bleaching in NaCl.

| Bleaching time in minutes | Centres | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | *F* | $R_\alpha$ | $R_\beta$ | $R_\varepsilon$ | $R_\delta$ | $R_\zeta$ | *M* | *N* |
| 1 | − 1.5 | 0 | 0 | 0 | 0 | 0 | 11 | 9 |
| 3 | − 3.9 | 20 | 15 | 17 | 16 | 14 | 3 | 15 |
| 5 | − 4.8 | − 1.7 | 8 | 8 | 8 | 5.7 | 1 | 15 |
| 10 | − 7.5 | −10 | − 3.5 | 5 | 5.3 | 3.3 | − 2 | 7 |
| 20 | −10.5 | −15 | −13 | 0 | 5 | 2 | − 2.7 | 4 |
| 30 | −12.2 | | −14 | − 1 | 5 | 2 | − 3.5 | 3 |

The values in this table are $[(K-K_0)/K_0] \times 100$, where $K_0$ is initial absorption coefficient and $K$ absorption coefficient after bleaching.

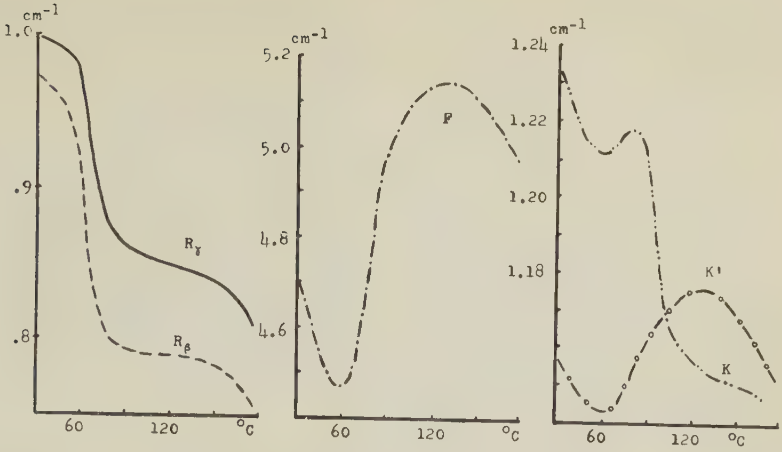

Fig. 5. Thermal transformation of the absorption bands of coloured KBr crystal.

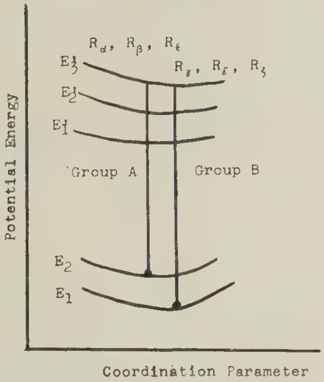

Fig. 6. Electronic levels of R-bands.

other centres, only one of the R-bands was practically measured. This also suggests strongly that all six R-bands are attributable to a single kind of centre.

When a crystal is irradiated by the light lying in the K- and M-bands respectively, the R-absorptions are enhanced. But, when irradiated by the light in the F-band, the M-band is at first enhanced and then reduced, and R-bands are enhanced (see Table III).

Hence, the F→M→R transformation may be a photothermal transformation. This is the case in the R→K→K′ transformation, that is, when a crystal is irradiated by the light lying in the R-bands, the K-absorption is at first enhanced and then the K′-absorption is enhanced after the K-absorption is reduced (see Fig. 4)

When a crystal is irradiated by the light lying in the N- and K′-bands respectively, the R-absorptions are invariable.

### C. *Thermal Transformations*

When coloured crystals are heated at 250°C in the case of NaCl, at 200°C in the case of KCl and at 130°C in the case of KBr respectively, the R-bands are reduced and the F- and K-bands are enhanced remarkably (see Fig. 5).

## § 4. Discussion

According to the experimental results described above, new six R-bands may be attributable to a single kind of centre. It is highly probable that each of the two groups (A and B) is due to the transition between each of the two lower electronic levels and common three higher electronic levels as shown in Fig. 6.

In conclusion, the writer wishes to express his cordial thanks to Professor Yôichi Uchida for his kind advices during the course of this work.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 11, No. 4, APRIL, 1956

# A Divergent Shock Tube for Obtaining Supersonic Flows

By Fumio TAMAKI

*Institute of Industrial Science, University of Tokyo*

(Received November 18, 1955)

A shock tube having a divergent low pressure chamber just downstream of a partition diaphragm is presented as a simple method for obtaining supersonic flows of fairly high Mach numbers. Flow character in the divergent channel is examined both theoretically and experimentally. Interferometric studies of the flow past a double-wedge profile are presented for Mach numbers of 4.0 and 6.0. At $M=6.0$, pressure distribution on the wedge surface deviates considerably from theory due to the thickening of the boundary layers.

## §1. Introduction

A method of generating a hypersonic flow in a shock tube having a diverging section was first presented by Hertzberg¹⁾. In his method, hypersonic flow is obtained by the expansion into the divergent channel of the hot air compressed by the primary shock. The method has the advantage over the conventional blow-down tunnel in that the air-liquefaction after the expansion can be avoided due to the high temperature of the air prior to expansion. However, in order to obtain a steady flow of sufficient duration, a long channel of constant cross-section is necessary between the diaphragm and the divergent channel.

In this paper, a shock tube having a divergent low pressure chamber just downstream of the diaphragm is presented as a simple device for obtaining a flow of Mach number near 5, in which the problem of air-liquefaction is considered not to be serious. In this shock tube, supersonic flow is obtained by the expansion of the cold air, that is, the air which effuses from high pressure chamber after the rupture of the partition diaphragm. Although low air temperature after the expansion is inevitable, the method has some convenience in that the total length of the tube can be made very short and the initial pressure difference between high and low pressure chambers can be made comparatively small.

The use of this type of shock tube may be extended to higher Mach numbers, if the air in the high pressure chamber is heated by some means, say, by a shock wave. A double-diaphragm shock tube, consisting of a high and a medium pressure chamber of equal cross-section and a low pressure chamber with narrow inlet and large area-divergence, seems to be a practical device for such a purpose. Investigation of this type of shock tube is now being carried out as a continuation of the present work.

It should be noted here that the flow of high Mach number can also be realized in the cold air in a conventional shock tube with constant cross-section, provided that sufficiently large pressure difference is applied to the diaphragm. In this case, however, the length of the low pressure chamber must be made long in order to get sufficient duration of the steady flow, and a rather delicate control of the initial pressure ratio is necessary in order to secure reproducibility of the Mach number of the flow.

As the main object of our work was to examine the possibility of the present method for comparatively high Mach numbers, experiments were mainly carried out for the cases of Mach numbers of 4.0 and 6.0. Application of the same shock tube to lower Mach numbers were subsequently made by C. S. Kim⁵⁾.

## §2. Shock Tube and Optical Equipment

After some preliminary experiments, a shock tube shown in Fig. 1 was set up at the Institute of Science and Technology, University of Tokyo. High pressure chamber has a length of about 60 cm and a cross-section of $1\times6\,\mathrm{cm}^2$. Divergent channel in the low pressure chamber are made of wooden walls inserted inside the tube of $14\times6\,\mathrm{cm}^2$ cross-section. Two kinds of straightly diverged channel were used in the experiments.

The first channel has an initial section of $1\times6\,\mathrm{cm}^2$, the same size as the high pressure channel, and a final section, situated 28.2 cm downstream from the initial section, is $11\times6\,\mathrm{cm}^2$. A cellophane diaphragm which separates high and low pressure chamber is situated 5 mm upstream of the initial section.

The second channel has a length of 28.7 cm, with initial and final section of $0.5\times6$ and $14\times6\,\mathrm{cm}^2$, respectively. In this case, there is an area constriction at the inlet of the divergent channel. A short converging duct made of steel is attached to the inlet in order to improve the condition of inflow and to protect wooden walls from the impact of high pressure air.

Compressed air at 4～6 atms. abs. was supplied to the high pressure chamber from a reservoir of $0.7\,\mathrm{m}^3$ volume. Low pressure chamber was evacuated by a 1/4 horse-power rotary pump to the pessure of 5～10 mmHg. A long steel needle with a trigger mechanism fitted to the end of the high pressure chamber was used for breaking the diaphragm.

This shock tube was set vertical in order to facilitate the use of Mach-Zehnder interferometer.

As will be shown later, Mach number of the quasi-steady flow obtained at the end of the divergent channel is related to the ratio of the area of that section to that of the inlet by the usual relation of steady isentropic flow. The first channel has the area-ratio of 11, corresponding to $M=4.03$. The value $M=4.0$ was actually obtained in the experiments. In the second channel, the area-ratio is 28, which corresponds to $M=5.1$. However, much higher Mach number was obtained in the experiments. This seems to be partly due to the viscosity effect which acts to decrease the mass flow at the throat, and partly due to the imperfect removal of the diaphragm, which in this case forms a strip of too small a width to be broken uniformly. From these reasons, Mach number of the flow depended on the initial pressure ratio across the cellophane, and it was necessary to adjust the preesure ratio to a constant value in order to get a constant Mach number. Mach number of 6.0 was obtained when the pressures in high and low pressure chamber were 6 atms. abs. and 5 mmHg, respectively.

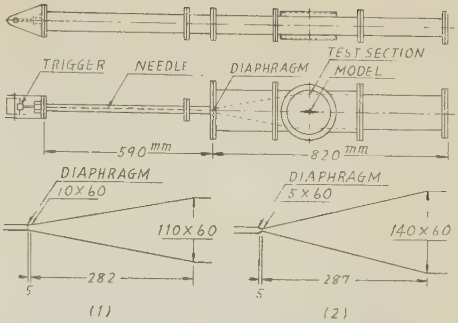

Fig. 1. Shock tube and divergent channels.

For the measurement of density in the flow, a Mach-Zehnder interferometer with glass plates of 21 cm diameters was used. Windows of the test section and the compensater plates were of 16 cm diameters. A spark discharge through magnesium electrodes of a 0.5 $\mu$F paper condenser charged at 6 kV was used as a light source, and monochromatic light of 4481 Å was obtained by using two glass filters.

A pair of spherical concave mirrors, each having 20 cm diameter and 4 m radius of curvature was used for collimating and focusing the light beams.

The same optical system was used for schlieren observations, by wholly cutting off the light rays on the compensater side.

Timing of the spark discharge was effected by the method of Hertzberg and Kantrowitz[2)]. Through a small orifice on the channel wall at the position 5 cm downstream from the inlet of the divergent part, the pressure of the primary shock was conducted into a glass tube having a metallic contact unit at its end. This unit is made of thin aluminum leaf faced with small clearance to the plane brass surface. Contact of the two metallic surfaces due to the pressure wave induces, viâ thyratron and automobile ignition coil, a high voltage pulse in the third electrode placed near the cathode of the spark unit, and initiates the main spark. Glass tubes of various lengths were used for varying the time of spark discharge.

## § 3. Theoretical Considerations

Assuming that the flow in the channel is one-dimensional, the unsteady flow after the rupture of the diaphragm can be calculated by the method of characteristics in the $x$-$t$ plane. Graphical method described by Os-

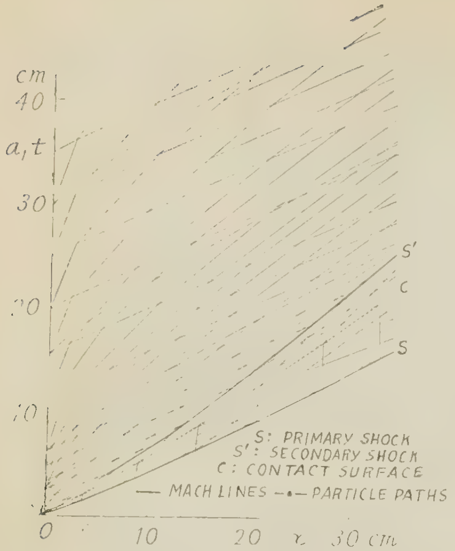

Fig. 2. Wave Diagram for the divergent channel for $M=4.0$ (parallel part at the test section neglected).

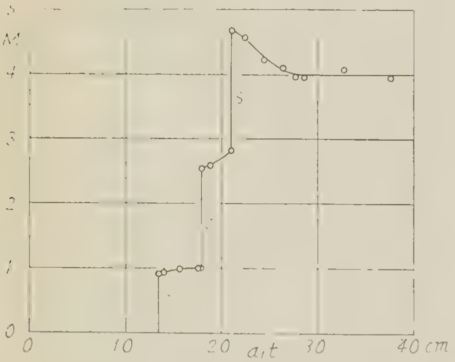

Fig. 3. Mach number at $x=28.2$ cm.

watitsch3) was used in the present calculation.

Fig. 2 shows a typical wave diagram for the divergent channel for $M=4.0$, when the flow behind the primary shock is supersonic at the inlet of the divergent part. Actual channel has a parallel part at the test section, but this was omitted for simplicity and a simpe divergent channell was considered in the calculation. Further, between the diaphragm and the inlet, a parallel part of 5 mm was assumed. Such an entrance region is necessary in theoretical calculation, in order to determine the flow state prior to expansion into the divergent channel. Experimental channel has also such an entrance region, but, owing to the deflection of the cellophane due to pressure, actual length of this region is nearly zero.

In Fig. 2, $x$ is the distance along the channel axis from the initial section, and $t$ the time measured from the instant of removal of the diaphragm. In the diagram, $t$ multiplied by $a_1$ is used, where $a_1$ is the sound velocity corresponding to the initial temperature. Pressure ratio $p_0/p_1$, where $p_0$ and $p_1$ denote the initial pressures in high and low pressure chamber respectively, is assumed to be 304, which corresponds to $p_0=4\times 760$ and $p_1=10$ mmHg. Flow Mach number just behind the shock is 1.29 at the inlet.

The diagram shows that: (1) the primary shock weakens gradually as it advances through the divergent channel, and the flow behind it becomes subsonic at a certain distance from the inlet, and (2) a secondary shock appears behind the contact surface.

In Fig. 3, flow Mach number at $x=28.2$ cm is plotted against $a_1t$. It is shown that nearly steady flow of $M=4.0$ is established for $a_1t$ larger than 25 cm. As the flow at $x=0$ is nearly sonic except for small values of $a_1t$, Mach number of the quasi-steady flow at the test section can be calculated approximately from the ratio of its area to the inlet area, by using the relation of one-dimensional isentropic steady flow and assuming $M=1$ at the inlet. This gives $M=4.03$. Values of $M$ for large $a_1t$ agree with this value within the errors in the graphical solution. In the actual channel, the diaphragm bursts nearly at the inlet, so the assumption that the flow is sonic at the inlet will be a good approximation to the real flow.

As already mentioned, the channel considered in the calculation differs from the experimental channel in that it has no parallel part at the test section. As the flow behind the shock is subsonic near the test section, the existence of this parallel part affects the states upstream and slightly modifies the velocities of contact surface and secondary shock. However, the above simplified calculation seems to be sufficient for roughly estimaing the time necessary for the establishment of the steady flow.

Next, a brief account will be made of the flow temperature in this channel.

Flow states in the high pressure chamber are given by the equation of unsteady isentropic expansion:

$$[2/(\gamma-1)]a+u=[2/(\gamma-1)]a_0\,, \quad \gamma=1.4$$

or $$5+M=5a_0/a \qquad (1)$$
where $a$, $u$ and $M$ are sound velocity, flow velocity and Mach number, $\gamma$ is the specific heat ratio and subscript 0 denotes the state of rest in the high pressure chamber. Assuming that $M=1$ at $x=0$, and using asterisks for the quantities at the sonic condition, we have $a_*/a_0=0.833$. As $a$ is proportional to the square root of absolute temperature $T$, we have $T_*/T_0=0.694$.

Relation between the temperature of the flow at $M=4.0$ and that of the sonic condition is given by the equation of steady isentropic flow:

$$(1/2)u^2+c_pT=const.=(1/2)a_*^2+c_pT_*$$

or $$1+0.2M^2=1.2T_*/T \qquad (2)$$
From this we get $T/T_*=0.286$ for $M=4.0$, whence we have $T/T_0=0.198$. This is lower than the corresponding value in the blow-down tunnel, in which the whole process is considered to follow the equation of steady flow. In this case, we have $T_*/T_0=0.833$, so that $T/T_0=0.238$. At any rate, there is no fear of air-liquefaction yet.

The channel for $M=6.0$ has a throat at the inlet, and the diaphragm is broken nearly at this position. Flow at the throat becomes sonic, provided that the initial pressure ratio is sufficiently large, and the wave diagram downstream of the throat is of the same character as explained above. However, the condition upstream of the throat is somewhat different. Acceleration from rest to sonic condition is considered to occur in two stages: unsteady expansion to a certain Mach number $M'$ and a steady expansion from $M'$ to sonic condition. $M'$ is determined by the ratio of the cross-section of the high pressure chamber to that of the throat. As the effective throat area is estimated to be 1.58 cm², the area-ratio is 6/1.58=3.8, so that $M'=0.15$. Writing $T'$ for the corresponding temperature, we have $T_*/T'=0.837$ from Eq. (2), and $T'/T_0=0.943$ from Eq. (1), so that we have $T_*/T_0=0.789$.

Temperature $T$ ofthe flow at $M=6.0$ is given by Eq. (2) as $T/T_*=0.146$, so we obtain finally $T/T_0=0.115$. This value is slightly lower than the value 0.122 for the case of the blown-down tunnel.

Assuming $T_0=295°\mathrm{K}$, we obtain $T=34°\mathrm{K}$. This is lower than the air-liquefaction temperature, which is estimtated to be nearly 45°K, when $T_0=295°\mathrm{K}$ and $p_0=6$ atms. abs. However, the effect of air-liquefaction may be considered not to be serious in the present experiments, since a ceetain degree of supersaturation may be expected to occur and the expansion of the flow to high Mach number takes place in a very short length in our channel.

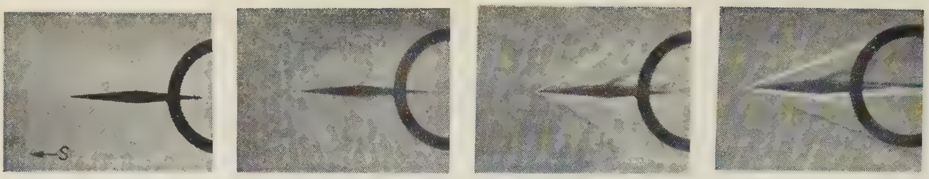
## § 4. Experimental Results and Discussion

Schlieren photographs showing the flow history at the test section of the channel for $M=4.0$ are given in Fig.4. These photographs were obtained under the condition $p_0=5$ atms. abs. and $p_1=10$ mmHg. A double-wedge profile with a wedge-angle of 10° and with 4 cm chord and 6 cm span was placed in the stream. A thin supporting ring was soft-soldered to the mid-span of the airfoil. Photo. (a) shows the primary shock advancing toward the airfoil. Photo. (b) shows flow near the contact surface. Instead of a sharp contact surface, a wide zone appears in which a strong mixing of hot and cold air takes place. Photo. (c) shows the flow near the secondary shock, which too appears as a wide band of compression. This shock is accompanied with the boundary layer separation. After the passage of the secondary shock and the separated region, a quasi-steady flow of $M=4.0$ is established with a time duration of about 1 millisecond.

Similar flow character was observed in the channel for $M=6.0$, though a little higher pressure ratio $p_0/p_1=6\times760/5$ was necessary for establishing the steady flow of this Mach number.

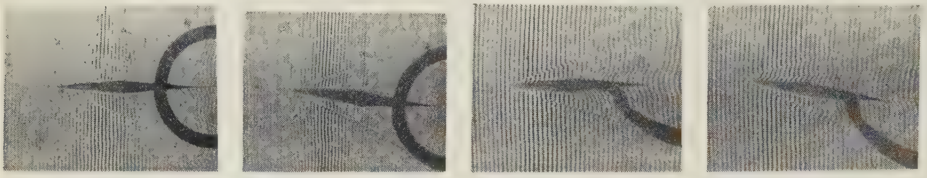
Mach number of the steady flow was determined by two methods, i.e., by the interferogram and by the measurement of Mach angle. For the latter purpose, several strips of thin cellophane tape were sticked to the wall surfaces upstream of the test-section, so as to give weak waves in the flow. These waves can be considered safely as Mach waves, so Mach number is obtained from the measurement of the angle between wave fronts of two families. Both methods agreed in giving the values, $M=4.0$ and 6.0, for the two cases considered in the experiments.

Fig. 5 shows the interferograms of the steady flows past the double-wedge. Pressure distributions on the surface obtained from the fringe shifts from the free stream states are given in Figs. 6 and 7, where $p$ is the pressure



(a) Primary Shock (b) Flow near the contact surface (c) Flow near the secondary shock (d) Quasi-steady flow ($M=4.0$)

Fig. 4. Flow history at the test section.



(a) $M=4.0$, $\alpha=0°$ (b) $M=4.0$, $\alpha=5°$ (c) $M=6.0$, $\alpha=0°$ (d) $M=6.0$, $\alpha=8°20'$

Fig. 5. Steady flow past 10° double-wedge.

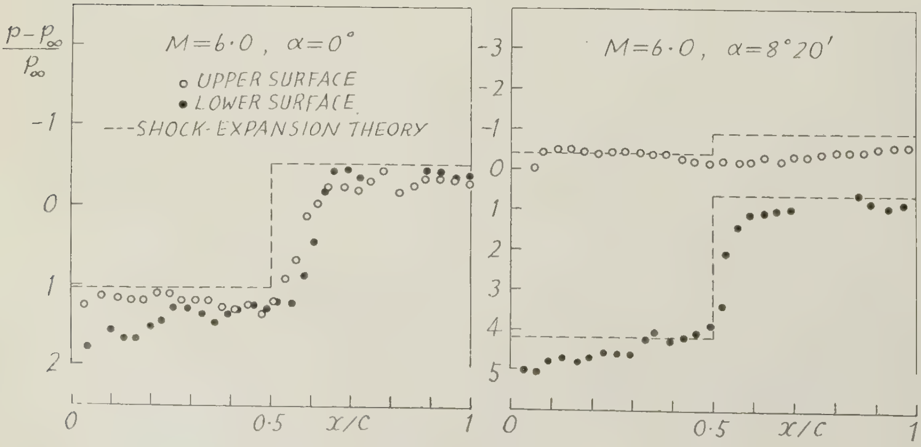
Fig. 6. Pressure distribution on 10° double-wedge ($M=4.0$).



(a) (b)

Fig. 7. Pressure distribution on 10° double-wedge ($M=6.0$).

on the surface, $p_\infty$ the pressure in the free stream, $x$ the distance from the leading edge and $c$ the chord length. Theoretical values based on the shock-expansion theory are given in broken lines. Reynolds numbers based on chord length are $6.6\times10^5$ and $4.7\times10^5$ for $M=4.0$ and 6.0, respectively.

Photographs show that the thickening of the boundary layer becomes considerable at high Mach numbers. Its effect on the pressure distribution along the surface can be clearly seen in Fig. 7; pressure near the leading edge is higher than the theoretical value, and the expansion at the ridge-lines becomes incomplete. These facts agree with the results obtained by McLellan[4] using a hypersonic tunnel of a larger scale.

The author wishes to express his thanks to Mr. S. Fukui for his helpful assistance in carrying out the experiments.

The present work has been partly supported by the fund of the Ministry of Education for scientific researches.

# Experimental Studies of Supersonic Flow past a Circular Cylinder

By Kim, CHUL-SOO

*Department of Physics, Faculty of Science, University of Tokyo*

(Received November 28, 1955)

Experimental studies using shock tubes are presented of the mixed type flow around a circular cylinder placed normal to the general flow of Mach number 1.35, 1.8, 2.7, 3.5, 4.0, and 6.0. With the Mach-Zehnder interferometer and schlieren method the followings were measured: a) shape of detached shock wave, b) distance $d$ of shock wave from the cylinder nose, c) pressure coefficient $C_p$ on the surface of the cylinder, d) density distribution behind the detached shock, e) streamlines in subsonic region.

## § 1. Introduction

The flow field of velocity greater than that of sound, in which a circular cylinder is mounted, is very much complicated, because a detached shock wave is originated ahead of the cylinder and behind it a rotational flow field of mixed type, that is, containing super- and subsonic regions, appears. Theoretical approach of the problem is very difficult because the governing equation of the flow field is of a mixed type and the boundary between sub- and supersonic regions is not given a priori. So all the existing calculations except Uchida's graphical solution [1] are based on the assumption of a certain shape of the detached shock. Further, in most of the earlier works [2] the flow behind the detached shock is assumed to be irrotational and incompressible. Recently more laborious calculations have been reported by Lin and Rubinov [3], Kawamura [4] and Hida [5] taking into account the vorticity behind the shock wave.

Experimentally, the distance between the detached shock and the cylinder nose has been measured by Alperin [6] in the range of Mach number 1.3 to 2.0. As to this distance, some discrepancies are found between theories

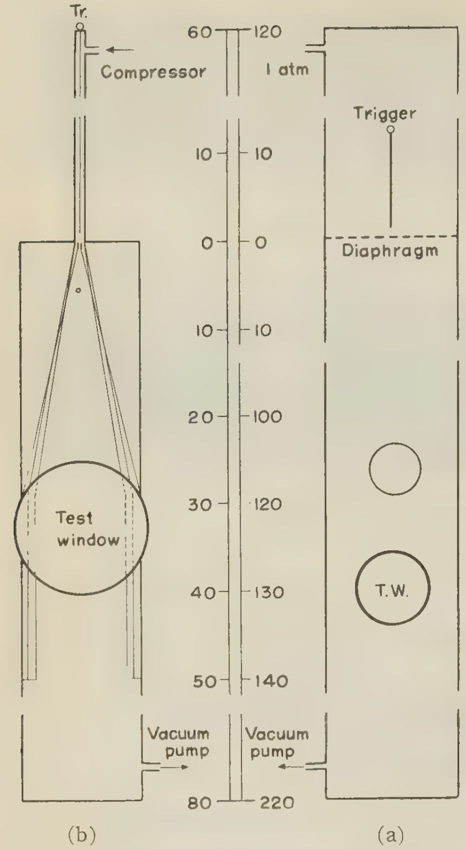

Fig. 1. a) Straight shock tube.
b) Divergent shock tube.

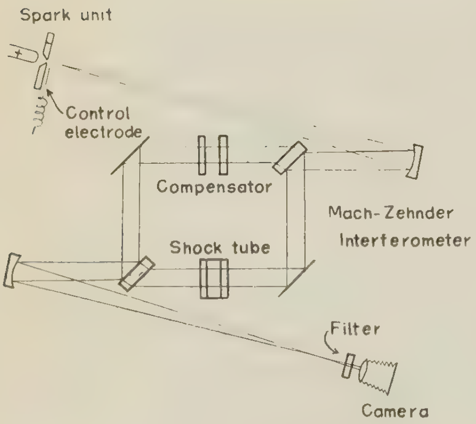

Fig. 2. Optical equipments.

and experiments; the cause for these discrepancies is as yet not clarified. Therefore it seems to the author that the detailed measurements of the whole flow field are necessary for the full understanding of the problem. Experiments at higher Mach number range may be also necessary in order to study the effects of compressibility, vorticity and heat conductivity.

In the present paper, the results of experiments are given for the Mach number from 1.35 to 6.0, and the reason for the disagreement of theories and experiments is discussed.

## § 2. Experimental Methods and Equipments

Two types of shock tubes, straight and divergent, were used for the experiments. Experiments at Mach number of 1.35 were carried out with a straight shock tube of the Institute of Industrial Science [7], having a cross-section of $6\times15\,\text{cm}^2$ (Fig. 1, a)). Cold air, that is, the flow behind the contact surface, was used for the experiments. A divergent shock tube designed by Prof. Tamaki [8] and installed in the Institute of Science and Technology was used for the experiments at higher Mach numbers. In this shock tube, a cellophane diaphragm is situated just in front of the divergent part of the channel, and high Mach number flow is obtained by the expansion of the cold air in the divergent part (Fig. 1, b)). High pressure chamber has a section of $1\times6\,\text{cm}^2$, and compressed air at 4～6 atms. abs. is supplied from the compressor. Low pressure chamber has a section of $14\times6\,\text{cm}^2$, and wooden divergent walls corresponding to each Mach number are inserted in it. The pressure in this chamber is lowered by a vacuum pump to 5～10 mm Hg. Flow history after the rupture of the diaphragm was studied in detail by Tamaki [8]. In the test section situated at the end of the diverging walls, a quasi-steady flow whose duration is of the order of 1 millisecond is obtained after the passage of the primary shock, contact surface and the secondary receding shock. Optical equipments used with the divergent shock tube are shown schematically in Fig. 2. Mach-Zehnder interferometer with glass plates of 21 cm diameter was used for the measurement of density field. Magnesium spark was used as a light source, and the timing of the spark discharge was effected by the method of Hertzberg and Kantrowitz [9]. Detailed description of the optical equipments will be omitted here, as it is found in Reference [8].

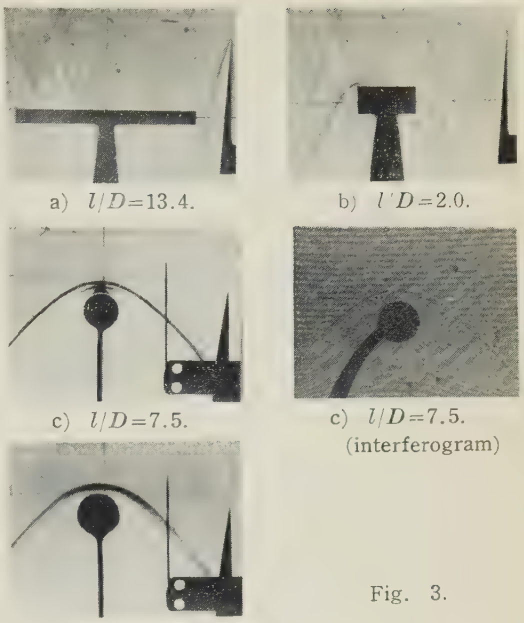
In the experiments reported here, circular cylinders made of brass with diameters of 4, 6, 8, 10 and 12 mm were used. To realize two-dimensional flow, i.e., to avoid the end effects of the cylinder and the interaction between boundary layer and shock wave, the cylinder was mounted in the test section parallel to the light path leaving clearances of 0.4～0.7 mm between both ends of the cylinder and the glass windows. In order to investigate the effects on the flow of the aspect ratio of the cylinder, cylinders of various lengths were also used for schlieren observations. As shown in Section 3, schlieren photographs taken when the axis of the cylinder is set normal to the light beam give good information as to the end effects of the cylinder.

## § 3. Results and Discussions

### *i) Distance between the detached shock and the circular cylinder*

At the first stage of the experiments, the distance $d$ of the shock wave from the cylinder nose was observed for various aspect ratios $l/D$ at constant free stream Mach number $M_1$, where $l$ is the length and $D$ is the diameter of the cylinder.

The distance $d$ was determined from the schlieren photographs taken by setting the cylinder axis perpendicular to both air stream and light path. Such photographs are given in Fig. 3, a) and b). When the aspect ratio is larger than 5.5, there exists a region in which the shock front is straight and parallel to the cylinder. In the case of small aspect ratio, shock front is curved as a whole (Fig. b)), so the shock distance in the central section was adopted for $d$. Fig. 3, c) and d) are the photographs taken by setting the cylinder axis parallel to the light beam. When the aspect ratio is large, detached shock does not appear as a distinct line (Fig. c)). However, when the aspect ratio is small, the shock appears as a sharp line as shown in Fig. d); in this case the shock distance coincides with that of the central section of Fig. b).



a) $l/D=13.4$.
b) $l/D=2.0$.
c) $l/D=7.5$.
c) $l/D=7.5$. (interferogram)
d) $l/D=2.0$.

Fig. 3.

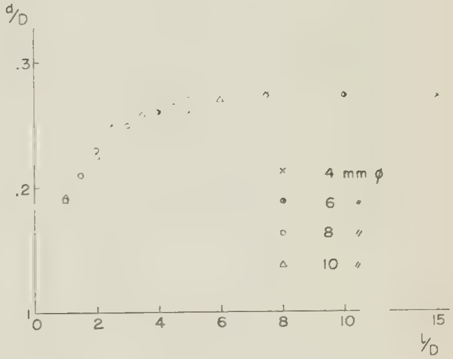


Fig. 4. $d/D$ vs. $l/D$ for $M_1=4.0$.

The relation between $d/D$ and $l/D$ is given in Fig. 4 in the case of $M_1=4.0$. The same character was obtained in the cases of $M_1=2.7$ and 6.0. The results show that two-dimensionality is obtained at the aspect ratio $l/D$ larger that 5.5 in the Mach number range of our experiments $M_1=2.7$～6.0. Sugimoto's [10] experimental data which were obtained in the case of $l/D=1$ agree well with our experiments of the same aspect ratio. But the results obtained in such a low aspect ratio do not satisfy the two-dimensionality as is shown in Fig. 4.

In order to determine the Mach number $M_1$ of the main stream in the divergent shock tube, strips of thin cellophane tape were sticked to several positions on each divergent wall; waves originating from the edges of these tapes are very weak, and its inclination to the main flow can be considered with a good approximation as the Mach angle of the flow. So the Mach number was determined by measuring the angle between the wave fronts originating from the two opposite walls.

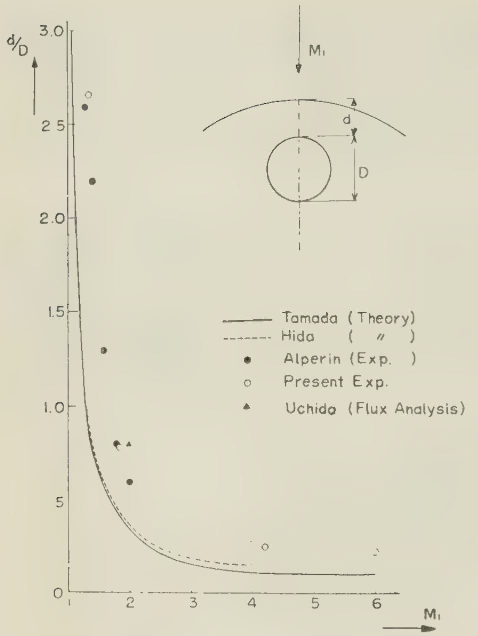

Fig. 5. $d/D$ vs. $M_1$.

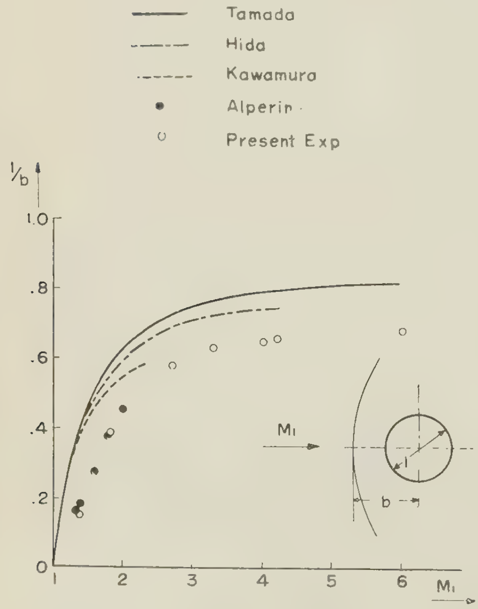

Fig. 6. $1/b$ vs. $M_1$.

Fig. 5 shows the relation between $d/D$ and $M_1$, and Fig. 6 shows the relation between $b=(D+2d)/D$ and $M_1$. In these figures, we have also included Alperin's results obtained for $M_1=1.3\sim2.0$ in a continuous running supersonic wind tunnel. The agreement between our results and Alperin's is very good. These results show some discrepancy to the theoretical values. The author considers that this is due to the facts: a) the shape of the shock wave assumed in the theory is not adequate, b) the effects of compressibility, thermal conductivity and viscosity are neglected in the theoretical analysis. It should be noted here, that Uchida's [1] graphical solution for $M_1=2.0$ by the flux analysis gives a good agreement with our experimental results.

### *ii) Isopycnics and streamlines*

In Fig. 7 the isopycnics (contours of constant density) in the whole flow field for $M_1=4.0$ are given. Streamlines in the subsonic region are also shown in the same figure. As the flow behind the shock is rotational, there is no simple way to calculate the values of pressure, temperature and velocity in this region. However, the values of the density in the whole field can be determined from the interferograms and one is able to calculate the streamlines at each point step by step by using the well-known gasdynamical relations. The simplest way is to use the equation of continuity, $A\rho u=$ const., where $A$ is the area between adjacent streamlines, $\rho$ the density and $u$ the velocity. Of course, the product $A\rho u$ has a fixed value in front of the shock. To draw the streamlines behind the shock, the shock is replaced by several straight tangential segments (in our case it is replaced by five segments between the point $A$ on the $x$-axis to the sonic point $B$ on the shock wave). Then, the entropy change and the stagnation pressure are calculated from the inclination of the segment to the main stream. In this procedure, the following relations are used:

$$\frac{\rho_1}{\rho_2}=\frac{2}{\gamma+1}\left(\frac{1}{M_1^2\cos^2\alpha}+\frac{\gamma-1}{2}\right), \qquad (1)$$

$$u_2=u_1\sin\alpha$$

$$\times\left[\frac{1}{\tan^2\alpha}\left\{\frac{\dfrac{1}{M_1^2\cos^2\alpha}+\dfrac{\gamma-1}{2}}{\frac{1}{2}(\gamma+1)}\right\}^2+1\right]^{1/2}, \qquad (2)$$

$$\beta=\tan^{-1}\left\{\frac{\frac{1}{2}(\gamma+1)\tan\alpha}{\dfrac{1}{M^2\cos^2\alpha}+\dfrac{(\gamma-1)}{2}}\right\}-\alpha, \qquad (3)$$

where suffixes 1, 2 denote the values in front of and immediately behind the shock wave respectively, $\alpha$ is the shock wave angle, and

$\beta$ is the deflection of the stream. Then the velocity at each point behind the shock wave is obtained from the measured $\rho$-values by the use of the adiabatic relation and the gasdynamic equations. Now, the continuity condition for each flow passing through the segment must also be satisfied, and this condition determines the cross sectional area $A$ of stream tubes, the boundaries of which are equivalent to streamlines.

In flows where the deflection of the stream is considerably large, as in our experiment, the approximations involved in this method become rather poor theoretically. Moreover to expect good accuracy for the determination of streamlines a large number of fringe shifts should be read (about 400 points were read by comparator in our experiment). Nevertheless, the followings may be concluded a) Streamlines in the subsonic region behind the shock are nearly straight and parallel to each other except in the vicinity of the cylinder. This suggests that, in subsonic region, the vorticity just behind the shock conserves its intensity along each streamline. b) Sonic line curves inward in the neighbourhood of the shock. It is not clear whether this is the essential feature of the phenomena, or due to the fact that shock wave has some breadth which is caused by the effect of the boundary layers on the test windows.

### *iii*) *Pressure coefficient*

As the flow on the cylinder surface comes from the normal portion of the shock wave ahead of the cylinder, the pressure coefficient $C_p$ can be obtained from the following equation:

$$C_p=\frac{2}{\gamma M_1^2}\left(\frac{p}{p_1}-1\right)=\frac{2}{\gamma M_1^2}\left\{\left(\frac{\rho}{\rho_1}\right)^{\gamma}e^{(\Delta s/c_v)}-1\right\}, \tag{4}$$

where $c_v$ is the specific heat at constant volume, $s$ is the entropy change across the normal shock.

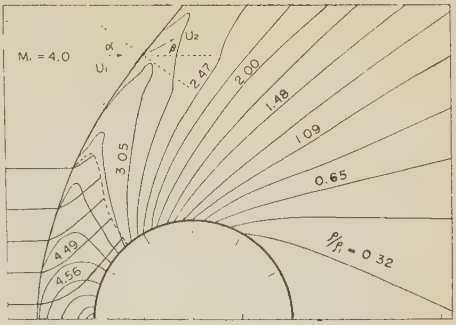

Fig. 7. Isopycnics, streamlines and sonicline for $M_1$=4.0.

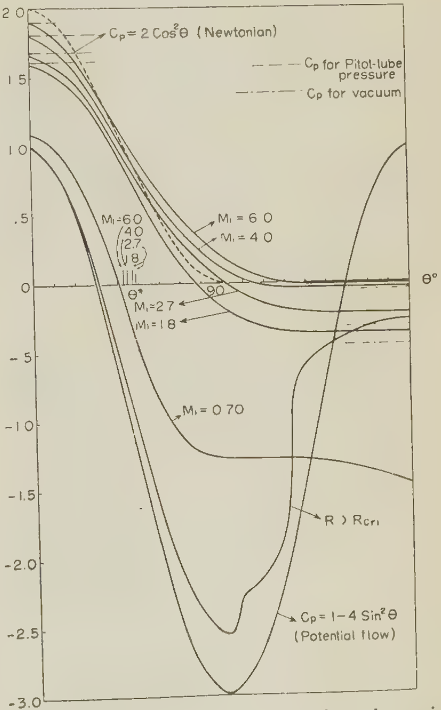

Fig. 8. Pressure coefficient and sonic point.

In Fig. 8 pressure coefficient against $\theta$ are shown in full lines for $M_1$=1.8, 2.7, 4.0, and 6.0. In the same figure the stagnation pressure coefficients calculated from the normal shock relation are given by broken lines at $\theta=0°$. Also in the same figure, the vacuum pressure coefficients, which are calculated from the Eq. (4) by putting $p=0$, are given by chain lines at $\theta=180°$. From this figure, we can see that the pressure at $\theta=0°$ agrees very well with the theoretical stagnation pressure. The pressure coefficient behind the separation point decreases as $M_1$ increases, and at $M_1$=6.0, wide region at the rear of the cylinder is nearly in the state of vacuum. The dotted line in Fig. 8 shows the Newtonian theoretical curve $C_p=2\cos^2\theta$, based on the principle of collisions of fluid elements on a body. Experiments show that in the neighbourhood of the stagnation point, the pressure coefficient approaches the Newtonian theoretical value asymptotically as $M_1$ increases. For comparison, the pressure coefficients of

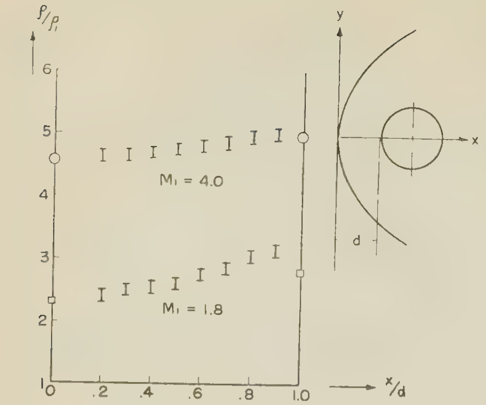

Fig. 9. Density distribution along the $x$-axis.

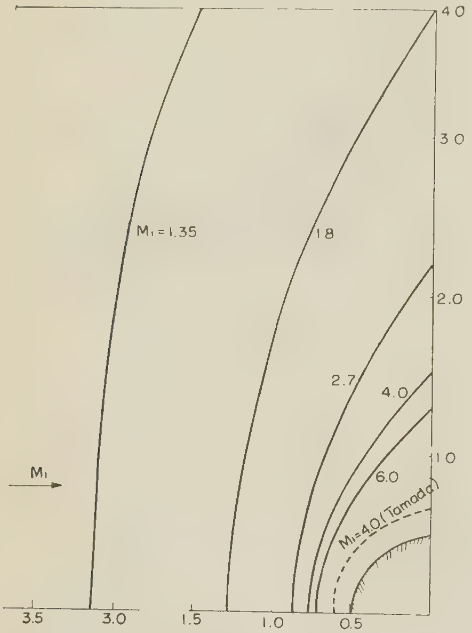

Fig. 10. The shape of the detached shock wave.

subsonic potential flow and of real subsonic flows are also shown in the same figure. In summary, there seems to be no significant change in the pressure distribution on the cylinder, moving with supersonic velocity, from that of high subsonic case.

### *iv) The density distribution along the $x$-axis*

As is pointed out in the previous section, disagreement of the experimental shock distance with the available theories is probably due partly to the fact that the effect of compressibility of the air flow is not accounted in the theory. Density distribution along the $x$-axis seems to be useful for the examination on this effect. Fig. 9 shows such distributions for $M_1=1.8$ and 4.0. In this figure, it is noteworthy that the density distribution for $M_1=1.8$ is more steeper than that for $M_1=4.0$.

### *v) Separation region and sonic point on the surface of circular cylinder*

It is difficult to determine the separation point by optical measurements. This is because of the fact that the observed separation point changes with the sensitivity of schlieren method, and that the separation phenomena themselves are likely somewhat unstable. Nevertheless, a number of data obtained ascertain that: a) the separation point moves downstream as $M_1$ increases, b) the area of separation region decreases as $M_1$ increases, and c) the minimum cross section of the wake also decreases and the location of this minimum cross section approaches the cylinder as Mach number $M_1$ increases.

The sonic point $\theta^*$ on the cylinder, where the flow speed becomes equal to the sound speed, can easily be calculated from the pressure coefficient. The values of $\theta^*$ for various Mach numbers are given in Fig. 8. This shows that $\theta^*$ decreases gradually as $M_1$ increases.

### *vi) The shape of the detached shock wave*

Fig. 10 shows the shapes of the detached shock wave in front of circular cylinder at $M_1=1.35$, 1.8, 2.7, 4.0, and 6.0. For comparison the shape of shock wave assumed by Tamada is given for $M_1=4.0$ in the same figure. Here, Tamada assumed that the most effective element for determining the shock distance is the shape of the shock wave near the $x$-axis. But the author considers that the disagreement of the assumed wave form with the real one, as in Fig. 10, is one of the causes of the discrepancy between the measured and the theoretical values of $d/D$.

### *vii) Supersonic flow around a cut circular cylinder*

Fig. 11 shows the variation of the shock distance when the cylinder is cut at $\theta=\pm\theta_i°$, parallel both to cylinder axis and to wind tunnel axis. If the angle $\theta_i$ is decreased from 90° continuously, we can expect that, the shock wave distance from the cylinder does not change until the value of $\theta_i$ reaches some critical value, say $\theta_{cri}$, and with the value $\theta_i<\theta_{cri}$, the distance will decrease. The value

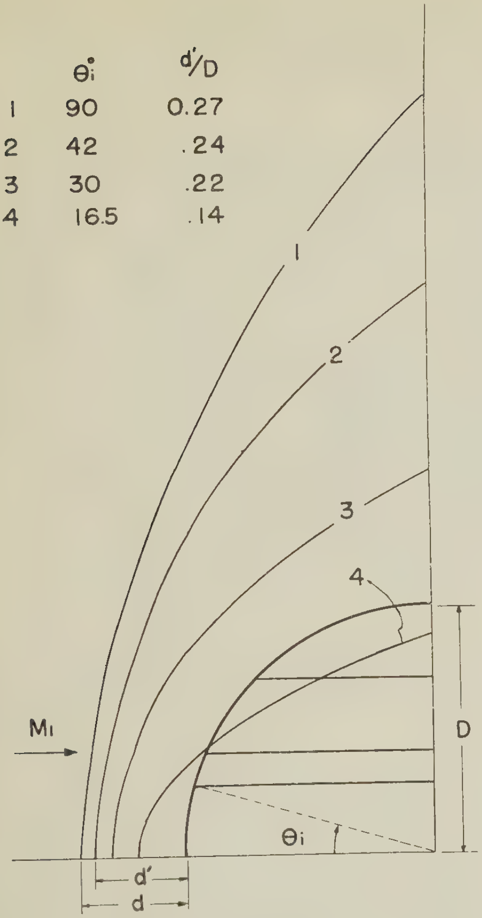

Fig. 11. Variation of detached shock wave for cut circular cylinder ($M_1=4.0$).

of $\theta_{cri}$ must coincide with the foot of the last Mach line. The cases of $\theta_i=42°$, 30°, and 16.5° were experimented for $M_1=4.0$ (the sonic point on the full cylinder is located at $\theta^*=44°$).

In Fig. 12 the relation between $d/D$ to $\theta_i$ is given, where $\theta_{cri}\doteqdot 48°$ is obtained. In this figure the value of $\theta_{cri}$ turned out to be slightly greater than the value of $\theta^*$ determined by means of either pressure coefficient in Fig. 8 or interferogram in § 3. ii), although both giving almost identical value. This fact gives a fairly quantitative justfication to our previous experiments including those of pressure coefficient, isopycnics, sonic point, $M_1$ vs. $d/D$ etc.

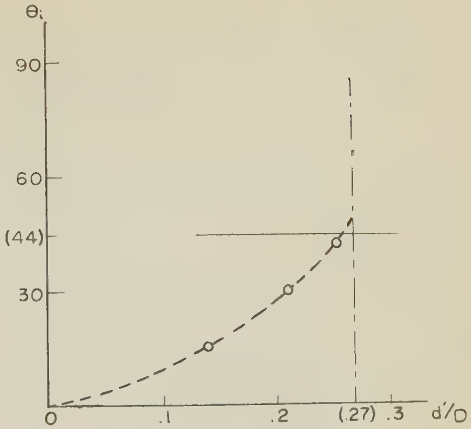

Fig. 12. $d/D$ vs. $\theta_i$ for $M_1=4.0$.

The author would like to express his sincere thanks to Prof. I. Imai for his suggestion of this problem, to Prof. F. Tamaki for his continual guidance and encouragement in the course of the investigation, and to Mr. K. Ôshima and Mr. S. Fukui for their cooperation in conducting the experiments.

# A Study of the Compressible Flow past Tomotika-Tamada's Profiles

By Hideo TAKAMI

*Department of Physics, Faculty of Science, University of Tokyo*

(Received November 29, 1955)

In this paper a number of approximate methods are applied to study the two-dimensional high subsonic flow of the adiabatic gas past a family of profiles given by Tomotika and Tamada.

The velocity distributions over the profiles are calculated by means of Kármán-Tsien's, the WKB, the $M^2$-expansion and Meksyn-Imai's methods, and are compared with Tomotika-Tamada's exact solutions as well as with Naruse's results by the thin-wing-expansion method. The convergency and validity of the above-mentioned methods are discussed.

It is noticed that there exists certain amount of discrepancy between Tomotika-Tamada's results and those of the present calculation, which might be considered as being due to the difference between the characteristic of the hypothetical gas assumed in Tomotika-Tamada's study and that of the adiabatic gas.

## § 1. Introduction

A great many investigations have been made with various approximate methods for the study of the compressible flow past bodies such as circular and elliptic cylinders, Joukowski aerofoils sphere, ellipsoids of revolution, etc.

But, on account of the nonlinearity of the fundamental equations in the physical plane the studies of the flow past a body of prescribed shape have necessarily relied on perturbation methods or on certain approximations in the fundamental equations, so that in spite of the numerous investigations we might say that little is known about the validity of the results and the actual flow patterns near the sonic speed.

On the other hand, it is well known that the difficulty of the nonlinearity in the equations can be removed by means of the hodograph transformation if we give up the study of the flow past a profile of *prescribed* shape; in fact, certain examples of exact solutions of the transonic flow past a cylindrical body have been obtained by the hodograph method [1] [13].

These exact solutions are considered to be of great importance, not only because they have shown the existence of the continuous transonic flow past a body, but also because they may serve as the tests of various approximate methods.

The flow past a profile appearing in one of Cherry's exact solutions has already been studied by the present writer with a number of approximate methods [11]. On account of the existence of the supersonic regions in the flow this example was not quite adequate as the criterion in the above-mentioned sense, but it was found that Cherry's solution might probably correspond to a flow which cannot be obtained by increasing the free stream Mach number continuously from zero.

Also in this paper, a number of approximate methods, such as Kármán-Tsien's, the WKB, the $M^2$-expansion and Meksyn-Imai's methods, are applied to study the compressible flow past a family of profiles for each of which an exact solution of continuous transonic flow has been obtained by Tomotika and Tamada [13].

We shall first calculate the velocity distributions over the surfaces of these profiles by the above-mentioned methods, and compare them with those of Tomotika-Tamada's exact solutions as well as with Naruse's numerical results by the thin-wing-expansion method [10].

Thus we shall see, quantitatively to some extent, how these approximate methods lose their accuracy and applicability when the sonic speed is approached in the flow. Further we shall notice certain amount of discrepancy between the values of the velocity obtained by the present calculation and those in Tomotika-Tamada's solutions; which might be regarded as being due to the difference between the characteristics of the adiabatic gas and the hypothetical gas used in Tomotika-Tamada's investigation.

## § 2. Tomotika-Tamada's Exact Solutions

By means of the hodograph method Tomotika and Tamada [13] have obtained a family of exact solutions of two-dimensional continuous transonic flow past a cylindrical body for a certain hypothetical gas which approximately satisfies the adiabatic gas relation.

Further, by numerical calculation, they have given three examples of transonic flow past a thin profile. The shape of each profile, only slightly different from those of the other two, is symmetrical with respect to the direction of the oncoming flow, and has a finite angle at the leading edge and a cusp at the trailing edge. The Mach numbers of the undisturbed flow are 0.717, 0.745 and 0.752 respectively. For convenience' sake we shall designate these profiles as $P_1$, $P_2$ and $P_3$ (Figs. 1(a), (b) and (c)).

Of these three, the flow past $P_1$ seems to be most important for the purpose of the present paper, since in this flow the sonic speed appears just at the points of the maximum velocity on the surface, while in the others supersonic regions show themselves adjacent to the profiles so that it is anticipated at the outset that the approximate methods which will be employed here are invalid in these regions.

## § 3. The Mapping Functions for Tomotika-Tamada's Profiles and the Incompressible Velocity Distributions

Let $P$ be a profile in the $z(=x+iy)$-plane, and we can map the region outside $P$ conformally onto the region outside the unit circle $Z=e^{i\theta}$ in the $Z$-plane by an analytic function of the form:

$$z=c_{-1}Z+c_0+\frac{c_1}{Z}+\frac{c_2}{Z^2}+\cdots .$$

In practice the coordinates of the profile $(x_P, y_P)$ are evaluated as functions of $\theta$ conveniently by means of Imai's iterative method [2] [11].

His procedure rests on the following relation between $x_P$ and $y_P$:

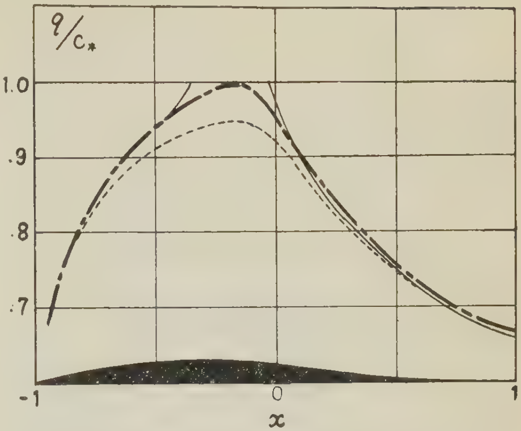

Fig. 1 (a). The profile $P_1$ and the velocity distribution over its surface ($M=0.717$).

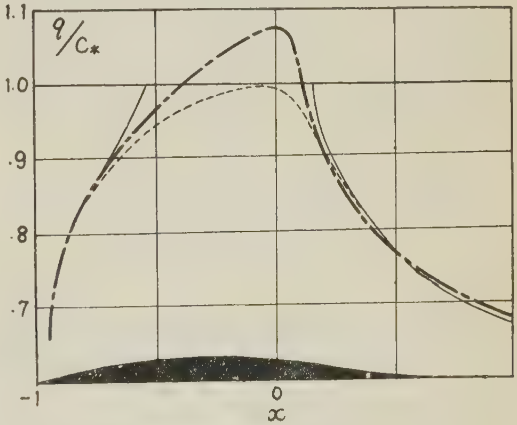

Fig. 1 (b). The profile $P_2$ and the velocity distribution over its surface ($M=0.745$).

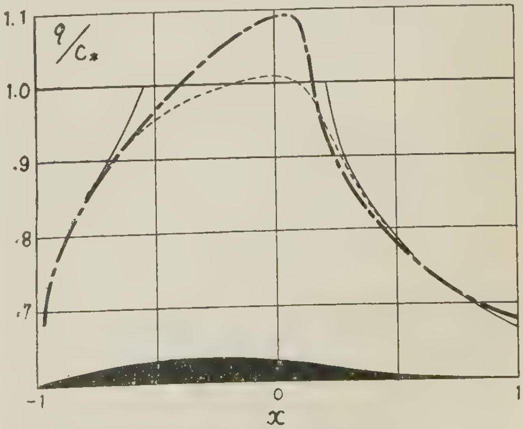

Fig. 1 (c). The profile $P_3$ and the velocity distribution over its surface ($M=0.752$).

—·—·— Tomotika-Tamada's exact solution,

$$x_P(\theta)=\left\{1-\frac{1}{2}y_P{}^*(0)+\frac{1}{2}y_P{}^*(\pi)\right\}\cos\theta+y_P{}^*(\theta)-\frac{1}{2}y_P{}^*(0)-\frac{1}{2}y_P{}^*(\pi)\,, \tag*{(3.1)*}$$

where $y_P{}^*(\theta)$ denotes the conjugate Fourier series associated with $y_P(\theta)$.

In the following we calculate the values of $(x_P, y_P)$ and also the velocities for $\theta=(2\pi/40)k$ ($k=0, 1, 2, \cdots, 39$), which may be sufficient for our purpose.

For $P_1$ the 0th approximation is taken to be $x_{P_1}{}^{(0)}(\theta)=\cos\theta$, and after three steps of iteration the final values of $x_{P_1}(\theta)$ and $y_{P_1}(\theta)$ are obtained. On the other hand, by taking $x_{P_1}(\theta)$ as the 0th approximation, it is found that only one step is sufficient for $P_2$ and $P_3$, which shows how favourably the iteration proceeds if we have already known the values of the mapping functions for approximately the same profile as the original one.

The velocity $q_{\text{inc}}$ on the surface for the incompressible flow is calculated as

$$\frac{q_{\text{inc}}}{U_{\text{inc}}}=\frac{1-\frac{1}{2}y_P{}^*(0)+\frac{1}{2}y_P{}^*(\pi)}{\sqrt{\left(\frac{dx_P}{d\theta}\right)^2+\left(\frac{dy_P}{d\theta}\right)^2}}\sin\theta\,, \tag{3.2}$$

where $U_{\text{inc}}$ is the velocity of the undisturbed flow with its direction parallel to the $x$-axis.

## § 4. The Kármán-Tsien Method

From the incompressible flow velocity we can calculate the velocity $q$ for the compressible flow approximately by means of Kármán-Tsien's formula [14]:

$$\frac{q}{U}=\frac{q_{\text{inc}}}{U_{\text{inc}}}\,\frac{1-\lambda}{1-\lambda\left(\frac{q_{\text{inc}}}{U_{\text{inc}}}\right)^2}\,, \tag{4.1}$$

where $U$ is the velocity of the undisturbed flow with Mach number $M$ and

$$\lambda=\frac{1-\sqrt{1-M^2}}{1+\sqrt{1-M^2}}\,.$$

The velocity distributions for the three profiles are shown in Figs. 1(a), (b) and (c). (In order to show the transonic character of the flow, $q/c_*$ are plotted against the chordwise length $x$, $c_*$ being the critical sound velocity corresponding to the free stream Mach number $M$.)

Strictly speaking, however, the velocity given by the formula (4.1) corresponds to the flow past a different profile from the one in question. But it can be shown that if the thickness of the original profile is small, the deformed profile is almost similar to the original one [5].

In fact, the variations in the thickness ratio are quite small for the present examples. They are shown in Table I together with other examples. In our case only very small corrections will be expected for the velocity distributions even if the effect of the deformation is properly taken into account.

## § 5. The WKB Method

According to Imai's WKB method [6] the problem of the compressible flow is reduced to that of the incompressible flow just as in Kármán-Tsien's method.

The velocity $q$ for the compressible flow is calculated from the related incompressible velocity $Q$ by the following formula:

$$Q=\frac{2}{(1+a)^{1/a}}\,\frac{q}{c_*}\left(1-a^2\frac{q^2}{c_*{}^2}\right)^{(1-a)/2a}\times(1+a\mu)^{1/a}\frac{1}{1+\mu}\,, \tag*{(5.1)**}$$

where

$$\mu=\left(\frac{1-q^2/c_*{}^2}{1-a^2q^2/c_*{}^2}\right)^{1/2},$$

and

$$a^2=\frac{\gamma-1}{\gamma+1}\,.$$

Practically, by using the numerical table [7] for Eq. (5.1) we may proceed as follows:

(i) Calculate $U/c_*$ from the free stream Mach number $M$.

(ii) Calculate $Q_\infty$ from the numerical table.

(iii) From the incompressible velocity $Q/Q_\infty$ ($=q_{\text{inc}}/U_{\text{inc}}$ in § 3) calculate $Q=(Q/Q_\infty)\times Q_\infty$.

(iv) Again by means of the table we obtain $q/c_*$ from $Q$.

The velocity distribution thus obtained does not correspond to the flow past the original profile $P$ as is also the case in Kármán-Tsien's method.

The coordinates $(\xi_{P'}, \eta_{P'})$ of the deformed

profile $P'$ are given by

$$\begin{cases} \xi_{P'} = \displaystyle\int \frac{Q}{(q/c_*)} K^{1/4} dx_P\,, \\ \eta_{P'} = \displaystyle\int \frac{Q}{(q/c_*)} K^{1/4} dy_P\,, \end{cases}$$

where

$$K = \frac{1-\left(\dfrac{q}{c_*}\right)^2}{\left\{1-\dfrac{\gamma-1}{\gamma+1}\left(\dfrac{q}{c_*}\right)^2\right\}^{(\gamma+1)/(\gamma-1)}}\,.$$

The velocity distributions for the three profiles are shown in Figs. 1(a), (b) and (c)*. The velocity in the supersonic region cannot be calculated by this procedure since too large a value of $Q$ does not give a real $q$ as can be seen from Eq. (5.1).

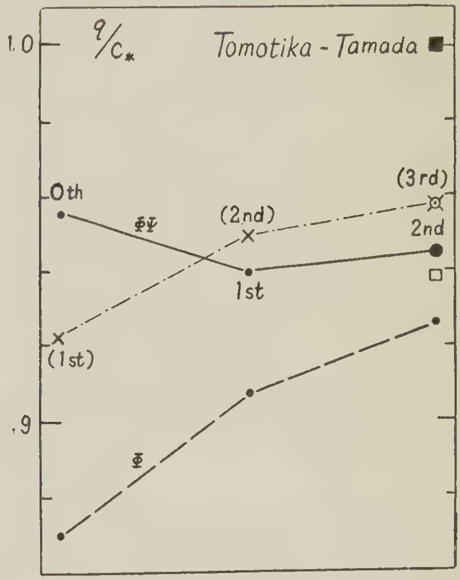

Fig. 3. The maximum velocity on the surface of the profile $P_1$ for $M=0.717$.

Especially for the profile $P_1$, for which no supersonic regions appear in the exact solution, we can calculate the velocity distribution over the whole surface by properly taking account of the deformation of the profile.

The iterative procedure for this purpose is performed in almost the same way as in the Kármán-Tsien method [11], except that this procedure is made somewhat complicated by the occurrence of the seeming supersonic speed in the course of the calculation.

The velocity distribution thus obtained is shown in Fig. 2.

## § 6. The $M^2$-Expansion Method

Now the $M^2$-expansion method is applied to the flow past the profile $P_1$. The velocity distributions are calculated for $M=0.717$ and 0.500 to the order of $M^4$ by means of Imai's $\Phi$-, $\Psi$- and $\Phi\Psi$- procedures [3] [4] [11] (Figs. 2, 3, 4 and 5).

---

* In the following calculations we shall take $\gamma$ as 1.40.

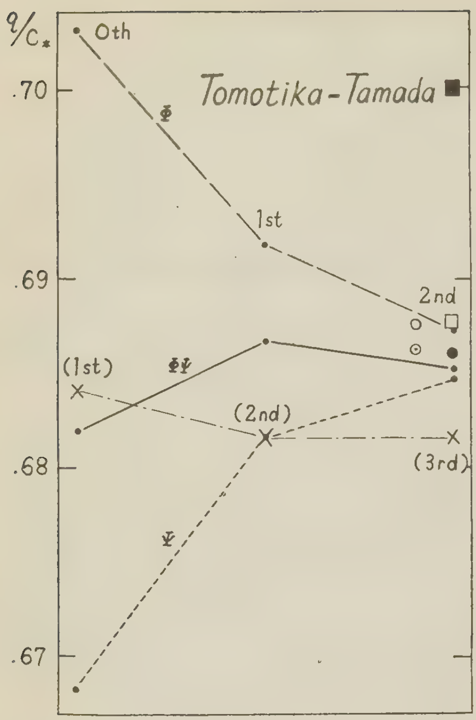

Fig. 4. The velocity at a point on the surface ($x=0.8$) near the trailing edge of the profile $P_1$ for $M=0.717$.

## § 7. The Meksyn-Imai Method

Meksyn-Imai's method [9] [8] [11], as a variant of the usual $M^2$-expansion method, has also been shown to be useful for the study of the high speed flow.

Calculation is made for $P_1$ with $M=0.717$ and 0.500 (Figs. 2, 3, 4 and 5).

The critical Mach number above which the method fails is evaluated to be 0.888.

## § 8. Numerical Results and Discussions

(1) For $P_1$:

(i) M=0.717. As is clearly seen from Figs. 2 and 3, none of the approximate methods gives a satisfactory result in the high speed region.

Numerical results by the $M^2$-expansion method suggest that the iteration will diverge in the neighbourhood of the maximum speed near this Mach number, so that the critical Mach number 0.888 calculated by the Meksyn-Imai method seems to be too large to be regarded as the Mach number below which the $M^2$-expansion method is valid.

Such an over-estimation of the critical Mach number has already been seen in the examples studied by Meksyn [9] and by the present writer [11].

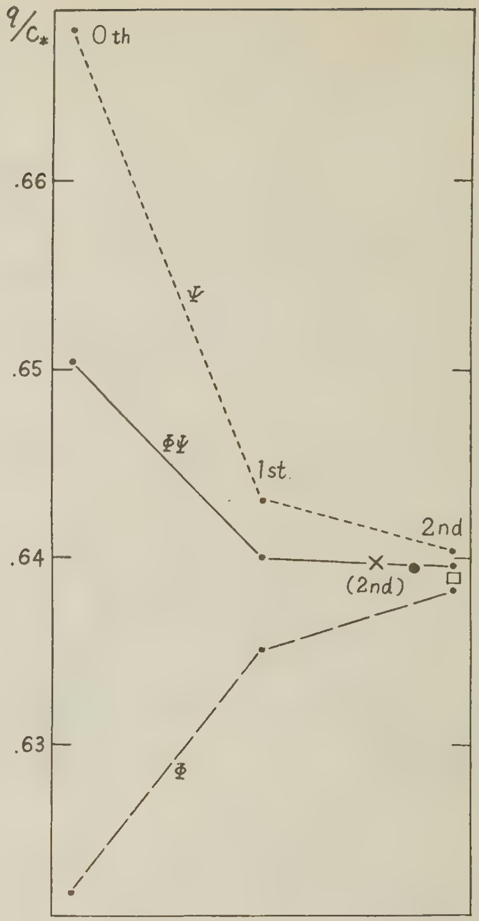

Fig. 5. The maximum velocity on the surface of the profile $P_1$ for $M=0.500$.

| ● | Kármán-Tsien's method (simplified), |
| ○ | the WKB method (simplified), |
| ⊙ | the WKB method, |
| ---×--- | the thin-wing-expansion method (Naruse), |
| — · • —— | the Φ-procedure, |
| • ----- | the Ψ-procedure, |
| —— • —— | the ΦΨ-procedure. |

Considering that the convergency of the iterative method will become poorer and poorer as the critical state is approached, this bad estimation of the critical Mach number is rather a matter of course. Thus the merit of Meksyn's procedure is to be found in its qualitative description of the probable flow pattern at high Mach number.

On the other hand, the results of the approximate methods seem to be reliable in the relatively low speed region (Fig. 4). But it must be noted that there exists some discrepancy between the value of the exact solution and those obtained by the present calculation. Its magnitude, though small, cannot be considered as being within the range of the errors due to the approximate methods; rather we might regard this as a measure of the deviation of the characteristic of the gas assumed in the exact solution from that of the adiabatic gas.

(ii) $M=0.500$. Though the exact solution which may serve as the standard for comparison has not yet been obtained for this case, we may regard Naruse's result of the second approximation by the thin-wing-expansion method [10] as reliable enough in view of the small thickness of the profile and the relatively low values of the free stream Mach number.

The agreement of the present results with that of Naruse is very good; Kármán-Tsien's method and the WKB method are both satisfactory, and the advantage of the $\Phi\Psi$-procedure is clearly seen also in this example [4] [11] (Fig. 5).

(2) For $P_2$ ($M=0.745$) and $P_3$ ($M=0.752$):

The results of Kármán-Tsien's method and the WKB method agree well with each other in the low speed region. There also exist small differences from the values of the exact solutions; we may interpret them just as in the case of the profile $P_1$ (Figs. 1(b) and (c)).

### Acknowledgements

The writer would like to express his hearty thanks to Professor Isao Imai who suggested this problem and has guided and encouraged him throughout this study.

The writer's thanks are also due to Professor Saburô Asaka, Dr Mitutosi Kawaguti and Dr Hidenori Hasimoto for their advice and kind inspection of the manuscript, and also due to Mr Humio Naruse who kindly showed him the numerical data.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 11, No. 4, APRIL, 1956

# Application of Imai's Transonic Approximation Method to the Compressible Flow past a Kaplan Bump

By Yaso'o MATUNOBU

*Department of Physics, Faculty of Science, University of Tokyo*

(Received December 28, 1955)

Imai's transonic thin-wing-expansion method is applied to the compressible flow past a Kaplan bump. Calculation is carried out as far as the fourth approximation. The results are compared with those obtained by means of the usual thin-wing-expansion method which is based on the exact equation of motion, and then with those deduced from von Kármán's similarity hypothesis for the transonic flow, showing that Imai's method is more adequate than von Kármán's; the former presents satisfactory results over a wider range of the free stream Mach number.

## § 1. Introduction and Summary

Recently, as an extension of von Kármán's transonic similarity rule, Imai[1] has suggested an approximate treatment for the two-dimensional compressible flow. His idea is based on the fact that, when the free stream Mach number is considerably large in the subsonic range, the usual thin-wing-expansion method[2] is capable of being subjected to some analytical simplification. In contrast to von Kármán's similarity theory[3] which starts from the two assumptions that the perturbation velocity caused by the presence of an obstacle is sufficiently small and the free stream velocity is close to the sound velocity, Imai's method, here called transonic thin-wing-expansion method, is based only upon the assumption of small disturbance to the main flow, without any restriction about the free stream Mach number. In other words, Imai has succeeded in extending the conception of the similarity law for the transonic flow to the compressible flow at an arbitrary speed, taking exactly the second order perturbations into account.

Here, in connection with a previous paper[4], the author will investigate the transonic flow past a Kaplan bump, using the transonic thin-wing-expansion method. Attempts are made chiefly to calculations of the velocity distribution over the surface and to appreciation of the accuracy of the present method superior to that of the usual similarity theory. Comparison with the results of the usual, or complete, thin-wing-expansion method which have already been obtained exactly up to the third approximation by Kaplan[5] and the present author[4] independently, indicates that our procedure yields satisfactory results over a wider range of free stream Mach number than the ordinary similarity theory does.

Further, based upon our results including the fourth approximation, we point out Kaplan's overestimation for the critical Mach number above which the continuous potential flow ceases to exist. Whereas he guessed this value to be about 0.83 for a Kaplan bump of thickness ratio 0.1, our results show that it may be a little less than 0.8. But it is still open to question whether or not the continuous mixed flow containing both the subsonic and supersonic regions actually takes place.

## § 2. Outline of the Transonic Thin-Wing-Expansion Method

For convenience, a brief account of the transonic approximation method due to Imai will be given here.

The two-dimensional irrotational flow of a compressible fluid is governed by the equations

$$u=\frac{\partial\Phi}{\partial x}=\frac{\rho_\infty}{\rho}\frac{\partial\Psi}{\partial y}\,,\qquad v=\frac{\partial\Phi}{\partial y}=-\frac{\rho_\infty}{\rho}\frac{\partial\Psi}{\partial x}\,, \tag{2.1}$$

$$\frac{\rho}{\rho_\infty}=\left[1-\frac{\gamma-1}{2}M^2\left(\frac{q^2}{U^2}-1\right)\right]^{1/(\gamma-1)}, \tag{2.2}$$

where $(u, v)$ are the component velocities in the $x$- and $y$-directions, $q$ is the magnitude of velocity, $\rho$ the density, $\rho_\infty$ the density of the undisturbed fluid, $\Phi$ the velocity potential, $\Psi$ the stream function, $U$ and $M$ are the magnitude of velocity and the Mach number of the undisturbed flow respectively, and $\gamma$ is the ratio of specific heats. The assumption of small disturbance velocity leads to

$$\Phi = x + \varepsilon\phi\,, \quad \Psi = y + \varepsilon\psi\,, \tag{2.3}$$

where $\varepsilon$ is a certain constant of small quantity, and $U$ has been taken as unity. Further, let us introduce the following quantities:

$$\xi = x,\ \eta = \mu y; \quad \zeta = \xi + i\eta,\ \ \bar{\zeta} = \xi - i\eta, \tag{2.4}$$

$$\chi = \psi/\mu; \qquad G = \phi + i\chi,\ \ \bar{G} = \phi - i\chi, \tag{2.5}$$

where $\mu = \sqrt{1-M^2}$. Then (2.1) and (2.2) can be combined and expressed in terms of the complex variables as

$$\frac{\partial G}{\partial \bar{\zeta}} = -\frac{\varepsilon}{4} M^2 \left(\frac{df}{d\zeta}\right)^2 + \frac{\varepsilon}{4} \nu \left(\frac{\partial \phi}{\partial \xi}\right)^2 + O\left(\frac{\varepsilon^2}{\mu^2}\right), \tag{2.6}$$

which, on integrating, gives

$$G = \frac{\varepsilon}{4} M^2 \left(\frac{df}{d\zeta}\right)^2 (\zeta - \bar{\zeta}) + \frac{\varepsilon}{4} \nu \int \left(\frac{\partial \phi}{\partial \xi}\right)^2 d\bar{\zeta} + O\left(\frac{\varepsilon^2}{\mu^2}\right), \tag{2.7}$$

where $f$ is an arbitrary analytic function of $\zeta$, and

$$\nu = 4M^2 \left(1 + \frac{\gamma+1}{4} \frac{M^2}{1-M^2}\right). \tag{2.8}$$

In most cases we are interested only in the state of affairs on or near the surface of the body, where $\bar{\zeta} - \zeta = -2i\eta = O(\mu t)$, $t$ being the thickness ratio. As for the parameter $\varepsilon$, it is favourable to assume that $\varepsilon = O(t/\mu)$ in view of the similarity hypothesis. This will be clarified later in § **3**. Therefore, neglecting the terms of $O(\varepsilon^2/\mu^2)$ in (2.7), one is led to the basic equation for the present method:

$$\frac{\partial G}{\partial \bar{\zeta}} = \frac{\varepsilon}{4} \nu \left(\frac{\partial \phi}{\partial \xi}\right)^2 = \beta \left(\frac{\partial G}{\partial \zeta} + \frac{\partial G}{\partial \bar{\zeta}} + \frac{\partial \bar{G}}{\partial \zeta} + \frac{\partial \bar{G}}{\partial \bar{\zeta}}\right)^2, \tag{2.9}$$

where

$$\beta = \frac{\varepsilon}{16} \nu\,. \tag{2.10}$$

Noting that the perturbation velocity potential is the real part of $\varepsilon G$ and $G$ is of $O(1)$, we find that the error caused by the adoption of (2.9) in place of (2.1) and (2.2) is of $O(\varepsilon^3/\mu^2) = O(t^3/\mu^5)$.

Since $\beta = O(t)$ for a moderate subsonic flow, $G(\zeta, \bar{\zeta})$ may be expanded as

$$G = G_1 + \beta G_2 + \beta^2 G_3 + \beta^3 G_4 + \cdots. \tag{2.11}$$

Then substituting (2.11) into (2.9) and integrating successively, we obtain*

$$G_1 = f(\zeta)\,, \tag{2.12}$$

$$G_2 = 2f'\bar{f} + \int \bar{f}'^2 d\bar{\zeta} + g_2(\zeta)\,, \tag{2.13}$$

$$\begin{aligned} G_3 = {} & 10f'^2\bar{f} + 2g_2'\bar{f} + 4ff'\bar{f}' + 2f''\bar{f}^2 \\ & + 12f'\int \bar{f}'^2 d\bar{\zeta} + 2f'\bar{g}_2 + 2f\bar{f}'^2 + \frac{10}{3}\int \bar{f}'^3 d\bar{\zeta} \\ & + 2\int \bar{f}'\bar{g}_2' d\bar{\zeta} + g_3(\zeta)\,, \end{aligned} \tag{2.14}$$

$$\begin{aligned} G_4 = {} & \left(\frac{200}{3} f'^3 + 20f'g_2' + 2g_3'\right)\bar{f} + \left\{20ff'^2 + 24f'\int f'^2 d\zeta + 4(fg_2)'\right\}\bar{f}' + 4ff'^2\bar{f}'' \\ & + (40f'f'' + 2g_2'')\bar{f}^2 + 8(ff')'\bar{f}\bar{f}' + (130f'^2 + 12g_2')\int \bar{f}'^2 d\bar{\zeta} + (10f'^2 + 2g_2')\bar{g}_2 \\ & + \left(44ff' + 12\int f'^2 d\zeta + 2g_2\right)\bar{f}'^2 + 4ff'\bar{g}_2' + 4f^2\bar{f}'\bar{f}'' + \frac{4}{3}f'''\bar{f}^3 + 4f''\bar{f}\bar{g}_2 \\ & + 24f''\bar{f}\int \bar{f}'^2 d\bar{\zeta} + 4f'\bar{f}\bar{f}'^2 + \frac{260}{3} f'\int \bar{f}'^3 d\bar{\zeta} + 24f'\int \bar{f}'\bar{g}_2' d\bar{\zeta} + 2f'\bar{g}_3 + 20f\bar{f}'^3 \\ & + 4f\bar{f}'\bar{g}_2' + \frac{47}{3}\int \bar{f}'^4 d\bar{\zeta} + \int \bar{g}_2'^2 d\bar{\zeta} + 10\int \bar{f}'^2\bar{g}_2' d\bar{\zeta} + 2\int \bar{f}'\bar{g}_3' d\bar{\zeta} + g_4(\zeta)\,, \end{aligned} \tag{2.15}$$

where $f$, $g_2$, $g_3$, and $g_4$ are arbitrary analytic functions of $\zeta$ alone which should be determined in compliance with the boundary conditions; and the primes denote differentiation with respect to $\zeta$ or $\bar{\zeta}$ and the bars denote the complex conjugates of the designated variables. It is to be noted that in the above formulae (2.13) to (2.15) the terms multiplied by the factors $(\bar{\zeta} - \zeta)^n$ have been neglected since they become small near the surface of the aerofoil.

---

* These formulae were given in reference (1) in more refined forms. Here we have reproduced them with some modification, correcting an error in the original expression corresponding to (2.15).

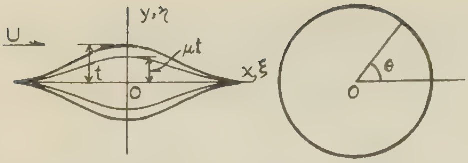

Fig. 1. Profile shapes in the $x$–$y$ and $\xi$–$\eta$ planes (left) and unit circle in the $Z$-plane (right).

## § 3. Boundary Conditions

In calculating $G$, the above-mentioned arbitrary functions $f$ and $g_n$ should be chosen according to the following conditions:

(i) $\partial G/\partial\zeta$ is one-valued and continuous in the field of flow,

(ii) $\partial G/\partial\zeta$ vanishes at infinity,

(iii) $\mathrm{Im}\,(\zeta+\varepsilon\mu^2G)=0$ at the boundary surface.

The last condition corresponds to the fact that the velocity vector at the surface is tangential to the profile contour.

Now consider a Kaplan bump of thickness ratio $t$ at zero incidence (Fig. 1). Then the analytic function which maps the flow region in the $\zeta$-plane onto the region outside the unit circle in the $Z$-plane is given by[4]

$$\zeta(Z)=\frac{1}{2}\left(Z+\frac{1}{Z}\right)+\frac{\mu t}{4}\left(1-\frac{1}{Z^2}\right)^2Z+O(\mu t^2). \tag{3.1}$$

Therefore, by virtue of the relation

$$\mathrm{Im}\,(Z+Z^{-1})=0$$

at the surface, the condition (iii) can be written in the form

$$\mathrm{Im}\left[G+\frac{t}{\varepsilon\mu}\left\{\frac{1}{4}\left(-\frac{3}{Z}+\frac{1}{Z^3}\right)+O(t)\right\}\right]=0\,. \tag{3.2}$$

Hence, if we let

$$f(\zeta)=\frac{k}{4}\left(\frac{3}{Z}-\frac{1}{Z^3}\right), \tag{3.3}$$

with

$$k=t/\varepsilon\mu\,, \tag{3.4}$$

all the conditions (i) to (iii) are satisfied to the first approximation. The foregoing assumption that $\varepsilon=O(t/\mu)$ is then deduced from the requirement that $f(\zeta)$, and hence $k$, be of $O(1)$.

In the present case the mapping function $\zeta(Z)$ can be expressed only in a series expansion; nevertheless, it is favourable to regard as if the condition (iii) would be strictly satisfied by equation (3.3), because we are interested in the results based on the similarity law. Thus, the conditions to be satisfied by the remaining $G_n$ $(n\geq 2)$ are as follows:

(i′) $\partial G_n/\partial\zeta$ is one-valued and continuous in the field of flow,

(ii′) $\partial G_n/\partial\zeta$ vanishes at infinity,

(iii′) $\mathrm{Im}\,G_n=0$ at the surface $(n=2,3,4,\cdots)$.

In other words, the above statement corresponds to applying the prescribed boundary condition to an aerofoil whose thickness is vanishingly small, as is often effectuated in the usual transonic similarity theory.

## § 4. Calculation of the Velocity Potential

If we put

$$\mathrm{Re}\,\zeta(e^{i\theta})=\zeta(\theta),\quad \mathrm{Re}\,G_n[\zeta(e^{i\theta}),\,\bar{\zeta}(e^{-i\theta})]=\phi_n(\theta),$$

then the velocity potential at the surface is expressed in a non-dimensional form

$$\begin{aligned}\Phi(\theta)=\xi(\theta)+\varepsilon\{\phi_1(\theta)+\beta\phi_2(\theta)\\ +\beta^2\phi_3(\theta)+\beta^3\phi_4(\theta)\}\,.\end{aligned} \tag{4.1}$$

Now, from (3.1), there follows

$$\xi(\theta)=\cos\theta \tag{4.2}$$

for a vanishingly thin profile. Further, taking the real part of (3.3), one obtains

$$\phi_1(\theta)=\frac{k}{4}(3\cos\theta-\cos 3\theta)\,. \tag{4.3}$$

As for the higher order terms in (4.1), calculations of $G_n$ are necessary. Thus, substitutions of (3.3) into (2.13) leads to

$$\begin{aligned}G_2=-\frac{3}{4}k^2\frac{1}{Z^2}\left(\frac{3}{\bar{Z}}-\frac{1}{\bar{Z}^3}\right)\\ -\frac{3}{8}k^2\left(\frac{1}{\bar{Z}^3}-\frac{3}{5\bar{Z}^5}\right)+g_2(\zeta)\,,\end{aligned}$$

which, by virtue of the relation $Z\bar{Z}=1$ at the surface, becomes

$$G_2=-\frac{3}{8}k^2\left(\frac{6}{Z}-2Z+Z^3-\frac{3}{5}Z^5\right)+g_2(\zeta)\,.$$

If we assume that

$$g_2(\zeta)=\frac{3}{8}k^2\left(\frac{8}{Z}-\frac{1}{Z^3}+\frac{3}{5Z^5}\right), \tag{4.4}$$

the conditions (i′) to (iii′) for $n=2$ are satisfied. Thus,

$$\phi_2(\theta)=\frac{3}{4}k^2\left(2\cos\theta-\cos 3\theta+\frac{3}{5}\cos 5\theta\right). \tag{4.5}$$

The expressions for $\phi_3(\theta)$ and $\phi_4(\theta)$ can be obtained in a similar manner. The results are as follows:

$$\phi_3(\theta)=k^3\left(12\cos\theta-\frac{36}{5}\cos 3\theta+\frac{18}{5}\cos 5\theta-\frac{18}{7}\cos 7\theta\right), \tag{4.6}$$

$$\phi_4(\theta)=k^4\left(\frac{582}{5}\cos\theta-\frac{388}{5}\cos 3\theta+\frac{1644}{25}\cos 5\theta-27\cos 7\theta+21\cos 9\theta\right). \tag{4.7}$$

(Reference (4) should be referred to concerning practical procedure.)

## § 5. Velocity Distribution

If $ds$ denotes the line element of the profile contour measured in the positive sense, the flow velocity at the upper surface is given by

$$q(\theta)=-\frac{d}{ds}\Phi(\theta)\,. \tag{5.1}$$

Now, provided that the departure of the profile shape from a straight-line segment is negligible, it follows that

$$-ds=dx=d(\cos\theta)\,. \tag{5.2}$$

Hence, from (4.1) together with (4.3), (4.5), (4.6), and (4.7), differentiation of $\Phi(\theta)$ with respect to $\cos\theta$ leads to

$$\begin{aligned}q(\theta)=1+\frac{t}{\mu}\Bigg[&-\frac{3}{2}\cos 2\theta+\frac{3}{32}\frac{\nu t}{\mu}(1+3\cos 4\theta)\\&-\frac{3}{320}\left(\frac{\nu t}{\mu}\right)^2(4+18\cos 2\theta+15\cos 6\theta)\\&+\frac{3}{10240}\left(\frac{\nu t}{\mu}\right)^3(177+160\cos 2\theta\\&+548\cos 4\theta+315\cos 8\theta)\Bigg],\end{aligned} \tag{5.3}$$

or, in terms of $x(=\cos\theta)$,

$$\begin{aligned}q=1+\frac{t}{\mu}\Bigg[&-\frac{3}{2}(2x^2-1)+\frac{3}{8}\frac{\nu t}{\mu}(6x^4-6x^2+1)\\&-\frac{3}{320}\left(\frac{\nu t}{\mu}\right)^2(480x^6-720x^4+306x^2-29)\\&+\frac{3}{640}\left(\frac{\nu t}{\mu}\right)^3(2520x^8-5040x^6+3424x^4\\&-884x^2+55)\Bigg].\end{aligned} \tag{5.4}$$

In deriving (5.3), the dummy parameter $\mathcal{E}$ thus far employed has been automatically eliminated owing to the relations $\mathcal{E}k=t/\mu$ and $\beta k=\nu t/16\mu$.

## § 6. Comparison with the Results of the Complete Thin-Wing-Expansion Method

For simplicity, we write equation (5.3) in the form

$$q=1+t\alpha_1(\theta)+t^2\alpha_2(\theta)+t^3\alpha_3(\theta)+\cdots\,. \tag{6.1}$$

On the other hand, the rigorous result including the terms of $O(t^3)$, obtained by means of the complete thin-wing-expansion method, can be written in a similar form; namely,

$$q=1+tA_1(\vartheta)+t^2A_2(\vartheta)+t^3A_3(\vartheta)\,, \tag{6.2}$$

where $\vartheta$, unlike $\theta$, is exactly equal to $\cos^{-1}x$, and the coefficients $A_n$ are known functions of the free stream Mach number as well as $\vartheta$. Then, comparison of (6.1) and (6.2) shows that $\alpha_1(\vartheta)=A_1(\vartheta)$; but that $\alpha_2(\vartheta)\not\doteq A_2(\vartheta)$, because the loose boundary condition (iii′) for $n=2$ has been applied. Therefore, in order to make a correct estimation of the validity of the transonic thin-wing-expansion method on the basis of equation (2.9), we should prefer

$$\begin{aligned}q=1+tA_1(\vartheta)&+t^2A_2(\vartheta)\\&+t^3\alpha_3(\vartheta)+t^4\alpha_4(\vartheta)+\cdots\end{aligned} \tag{6.3}$$

to (6.1). Thus, if the boundary conditions are strictly fulfilled, the error involved in the basic equation (2.9) is reduced to the difference between $t^3\alpha_3(\vartheta)$ and $t^3A_3(\vartheta)$. In fact, putting $\vartheta=\pi/2$, say, we have

$$\alpha_3(\pi/2)=\frac{87}{320}\frac{\nu^2}{\mu^3}=\frac{87}{20}\left(\frac{M^4}{\mu^3}+2\kappa\frac{M^6}{\mu^5}+\kappa^2\frac{M^8}{\mu^7}\right), \tag{6.4}$$

$$\begin{aligned}A_3(\pi/2)=\frac{15}{16}+\frac{9}{16\mu}+\frac{39}{40}\frac{M^2}{\mu}+\frac{3}{40}(13+62\kappa)\frac{M^4}{\mu^3}\\+\frac{21}{8}\left(\frac{M^2}{\mu^2}+\kappa\frac{M^4}{\mu^4}\right)+\frac{3\kappa}{40}(53+72\kappa)\frac{M^6}{\mu^5}+\frac{87}{20}\kappa^2\frac{M^8}{\mu^7},\end{aligned} \tag{6.5}$$

with $$\kappa=\frac{1}{4}(\gamma+1)\,,$$

whence the difference between $t^3\alpha_3(\pi/2)$ and $t^3A_3(\pi/2)$ is of $O(t^3/\mu^5)$, as was expected in § 2. In general it can be conjectured that both $\alpha_n$ and $A_n$ contain an equal dominant term of $O(1/\mu^{3n-2})$ for $M$ close to unity and their difference is of $O(1/\mu^{3n-4})$ for $n\geqq 2$.

Fig. 2 shows how the curves of $\alpha_3(\pi/2)$ approximate that of $A_3(\pi/2)$ with increasing $M$. In Fig. 3, the maximum velocity $q_{max}=q(\pi/2)$ is plotted against the free stream Mach number for three values of the thickness ratio. These

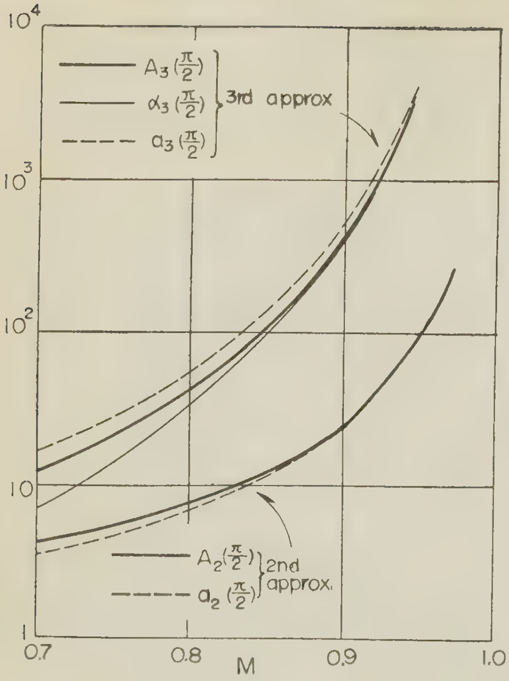

Fig. 2. Comparison of the coefficients of the maximum velocity expanded in $t$ ($\gamma=1.405$).

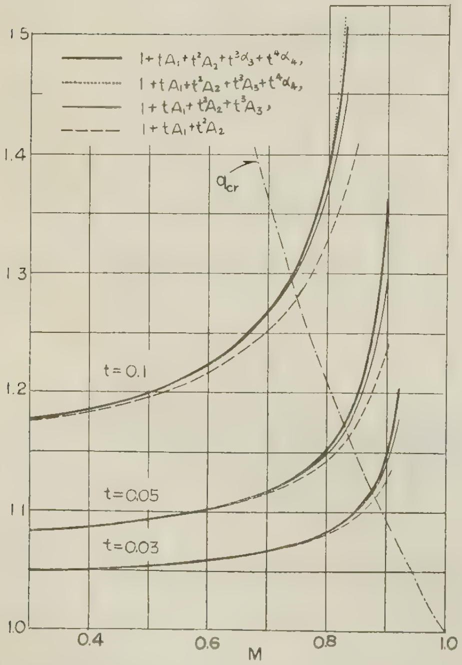

Fig. 3. Maximum velocity distribution vs. free stream Mach number, where $q_{cr}$ denotes the critical speed of sound.

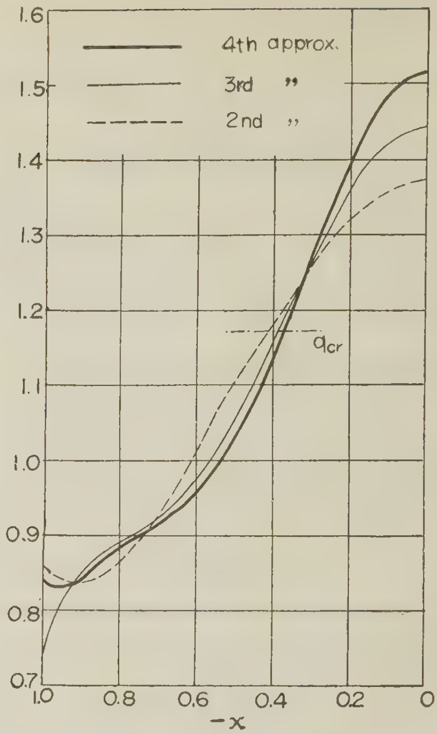

Fig. 4. Chordwise velocity distribution for Kaplan bump of thickness ratio 0.1 at $M=0.83$ ($\gamma=1.405$).

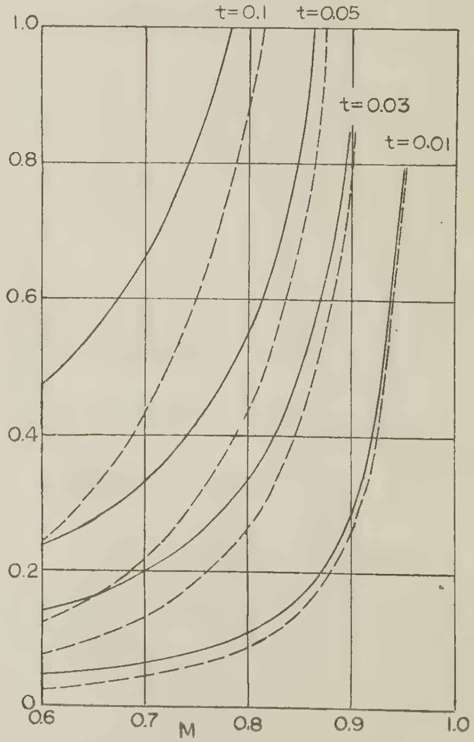

Fig. 5. Two transonic similarity parameters: Imai's (solid lines) and von Kármán's (broken lines), for $\gamma=1.4$.

curves present some information with regard to the critical value of the free stream Mach number. For instance, when $t=0.1$, this value presumably does not exceed 0.8. In this respect the value 0.83 which Kaplan conjectured from the result including $O(t^3)$ due to the complete method, seems too large. In fact, the velocity distribution curves for $M=0.83$ (Fig. 4) do not enable us to expect its convergence, at least, at the mid-chord point.

A recent study of the transonic flow past an infinite sinusoidal wall[6] has presented a plausible inference concerning the critical state of the continuous flow: "Once the local Mach number exceeds unity at the ridge of the wavy wall, the smooth symmetrical potential flow is no longer possible to exist." Our results seem to show, though not affirmatively, that the same statement is also valid with the Kaplan bump, for its shape can be regarded as an isolated single wavy wall without stagnation points.

## § 7. Relation to von Kármán's Transonic Similarity Rule

In the limiting case $M\to 1$ and $t\to 0$, the similarity parameter $\nu t/\mu$ utilized in the foregoing sections is reduced to

$$(\gamma+1)t/(1-M^2)^{3/2}\,. \tag{7.1}$$

This combination composed of free stream Mach number, thickness parameter, and adiabatic index is well known in von Kármán's transonic similarity theory. In Fig. 5 these two parameters are compared for four values of $t$.

From the consideration that the equation on which von Kármán's theory is based can be looked upon as an alternative form of the basic equation (2.9) of the present method (see Ref. 1), the results due to the latter can be converted into those due to the former merely by replacing $\nu t/\mu$ with the parameter (7.1). Thus, the velocity distribution (5.3) is transformed into

$$q=1+ta_1(\theta)+t^2a_2(\theta)+t^3a_3(\theta)+\cdots\,. \tag{7.2}$$

Again, $a_2(\pi/2)$ and $a_3(\pi/2)$ are plotted with broken lines in Fig. 2. Then it will be concluded that the present analysis due to Imai yields more excellent results in comparison with von Kármán's theory, provided that the boundary condition is satisfied correctly up to the second order in thickness ratio.

The author wishes to express his sincere thanks to Professor Isao Imai for his valuable suggestion and continual guidance throughout this work.

# A Direct Reading Counting Rate Ratio Meter

By Hirohide MIWA

*Nucleonics Sec. Kobe Kogyo Corporation, Hyogo, Japan*

(Received June 25, 1955)

A nonlogarithmic direct reading counting rate ratio meter was constructed, which proved to be more stable and precise than the logarithmic one using diode character.

A counting rate $f_1$ of channel 1 was applied to the rate meter which is very similar to the conventional meter only with an alteration in the charging circuit of the pumping condenser, which is made to give the charge modulated by a D.C. voltage proportional to $1/f_2$ ($f_2$ being the counting rate of channel 2). Thus arranged, the out-put of the rate meter became proportional to $f_1/f_2$, namely the rate ratio.

The D.C. voltage propotional to $1/f_2$ was generated by utilizing a low-pass filter and a saw-tooth generator. The height of the saw-tooth voltage was made to be proportional to the pulse interval, $1/f_2$, by controlling the start and stop of the saw-tooth voltage with a pair of adjacent pulse from channel 2.

The statistics of the $1/f_2$ D.C. voltage and the rate ratio was also described.

## § 1. Introduction

The counting rate ratio meter is a direct ratio indicating instrument of two radiation counting rates. Some approximate ratio indicating devices have been reported[1], but theoretically, precise ratio figure and wide ratio range could not be obtained.

Logarithmic indication[2] was also reported, but lability in diode character is inherent. The present ratio meter includes two parts.

(1) The voltage generator, the out put of which is proportional to the inverse of the counting rate. As the inverse of the counting rate is proportional to the mean pulse time interval, the output of a sawtooth voltage generator, whose starting and quenching time of the sawtooth voltage is controlled by the impulse from the counter, led through a low-pass filter indicates a voltage inverse to the counting rate.

(2) The ordinary counting rate meter. Its electric charge associated with each pulse is proportional to the voltage described in (1).

Statistical considerations of the inverse voltage and a practical circuit construction are also given in § 3 and § 4, respectively.

## § 2. Voltage Proportional to the Inverse of the Counting Rate

Each count (Fig. 1–a) is converted into a sharp pulse. This pulse triggers a flip-flop circuit, the out-put of which is a series of rectangular pulses with uniform amplitude and various duration. The moment of rise and fall of the rectangular pulse is determined by the incoming pulse (Fig. 1–b).

The rectangular pulses (b) control the sawtooth voltage generator. The voltage in the low level period of (b) swings the tube $V_{11}$ (Fig. 3) beyond cut-off. This actuates the sawtooth voltage generation, the out put of which is as Fig. 1–c.

A proper low pass filter smooths out the sawtooth voltages and gives a D. C. voltage proportional to the inverse of the counting rate, namely, the pulse interval.

## § 3. Statistic of the "Inverse" Voltage

A series of sawtooth voltage pulses as shown in Fig. 2 (a) is fed to a simple $RC$ integrating net-work as shown in Fig. 2 (b).

The D. C. voltage component is easily found to be

$$E_A = \frac{a t_m}{4} \qquad (1)$$

where $t_m$ is the mean pulse interval and a is a proportional constant between amplitude and pulse interval (Fig. 2). The pulse interval, however, is distributed according to Poisson's law, and consequently, the sawtooth are not uniform. Hence the D. C. voltage component varies with time.

Assumed that only the D. C. component $E_A$ can pass the $RC$ net work, we can determine the out put voltage $E_B$ as follows.

The effect of voltage pulse ($E_A$ in height, $\Delta t$ in duration) at a time $t$ in the past to the present time $t_0$ is (See, Fig. 2(c))

$$\Delta E_B = E_A \cdot \frac{\Delta t}{RC} \exp\left(-\frac{t_0 - t}{RC}\right)$$

$$E_B = \int_{-\infty}^{t_0} \Delta E_B = \int_{-\infty}^{t_0} E_A \frac{\Delta t}{RC} \exp\left(-\frac{t_0 - t}{RC}\right). \quad (2)$$

When $E_A$ is assumed to have a standard deviation $\sigma E_A$ at time $t$, the standard deviation $\sigma E_B$ at present time $t_0$ is obtained in the same manner,

$$\sigma E_B{}^2 = \int_{-\infty}^{t_0} \left\{ \sigma E_A \frac{\Delta t}{RC} \exp\left(-\frac{t_0 - t}{RC}\right) \right\}^2. \quad (3)$$

The observed pulse interval can be determined by observing the elapsed time between $n$ pulses. The probability $W_T{}^n$ with which the $n$th pulse comes between time $T$ and $T + \Delta T$, is

$$W_T{}^n = \frac{T^{n-1}}{(n-1)!\, t_m{}^n} \exp\left(-\frac{T}{t_m}\right) dT.$$

Where $t_m$ is the mean pulse interval. The mean $(\overline{T})$ of time $T$ is

$$\overline{T} = n\, t_m\ .$$

and the standard deviation $(\sigma_T)$ of $T$ is

$$\sigma_T{}^2 = \int_0^\infty T^2\, W\, dT - \overline{T}^2 = (\sqrt{n}\ t_m)^2\,.$$

Thus, the observed pulse interval $(t)$ is

$$t = \frac{\overline{T}}{n} \pm \frac{\sqrt{n}\ t_m}{n} = t_m \pm \frac{t_m}{\sqrt{n}}$$

Hence, the standard deviation of the pulse interval $(\sigma\, t_m)$ observed during $\Delta t$ is

$$\sigma t_m = \frac{t_m}{\sqrt{\dfrac{\Delta T}{t_m}}} \quad (4)$$

From equations (1), (3) and (4), we derive the standard deviation $(\sigma_{EB})$ of the out-put voltage $E_B$

$$\sigma E_B{}^2 = \frac{a^2 t_m{}^2}{32RC/t_m}$$

$$\therefore\ \sigma E_B/E_B = \sqrt{\frac{t_m}{2RC}} \quad (5)$$

Equation (5) gives the fractional standard deviation of a single observation of pulse interval.

The fractional standard deviations of $n$ observations and continuous observation can be obtained similarly and are found to coincide with the case of counting rate meter obtained by R. D. Evans and L. I. Schiff[3].

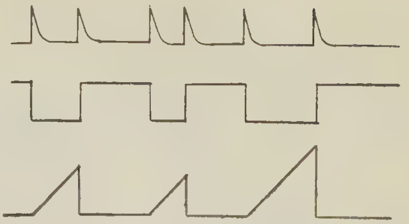

Fig. 1.

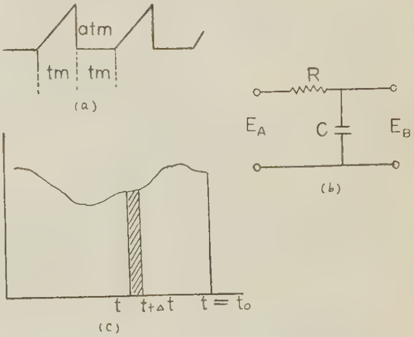

Fig. 2.

## § 4. Practical Construction and Moduration by the "Inverse Voltage"

A practical circuit diagram of the important parts are shown in Fig. 3.

A counting rate ratio $f_1/f_2$ of two channels is considered. Each counting channel of $f_1$ and $f_2$ has a system of a preamplifier and a Schmidt type voltage discriminater. Channel $f_2$ has a scale of two circuit, the out put of which is rectangular in wave form and is applied to a sawtooth generator comprised of $V_{11}$, $V_{12}$, $V_{10}$ through an impedance converter $V_{10'}$. The sawtooth voltage is fed into a low-pass filter, and the "inverse" D. C. Voltage is obtained across the resistor $R_{79}$ (between point (a) and (b)).

The out-put of the discriminater of $f_1$ system triggers a scale of two circuit, the out-put of which is rectangular in shape and is fed to pulse height limiter $V_8$ whereby the lower level of the pulse is fixed at 150 V D. C. (b) and the higher level is also caught at the voltage level of the point (a). $R_{78}$ is to compensate for the D. C. voltage produced by the leaking current through $R_{77}$ while point (c)

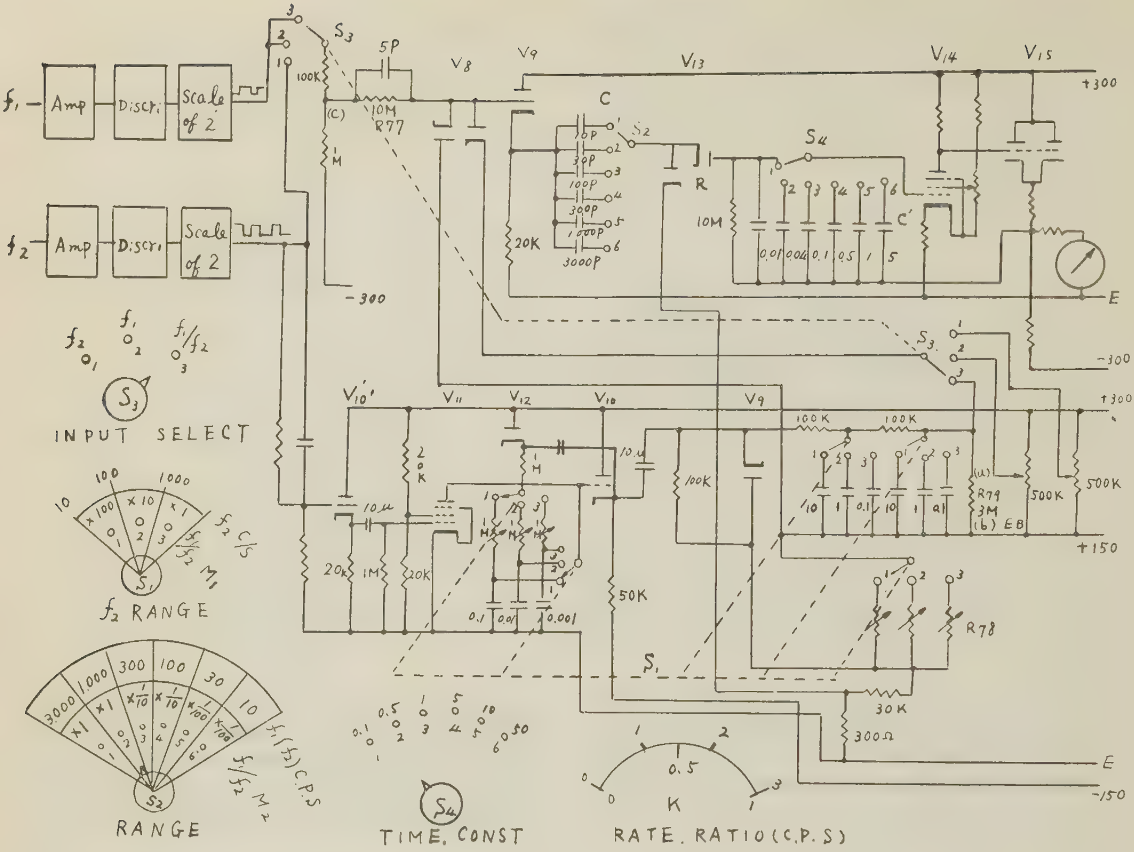

Fig. 3.

lies at a higher voltage than point (a). This effect can be minimized by altering the preceeding scale of two stage to the univibrater circuit, the out put of which being fixed at a lower level than (b) while no triggering occures. The reduction of the internal resistance between (a) and (b) is also effective.

The rectangular pulses synchronized with $f_1$ and modulated in height by the voltage $E(a\sim b)$ which is proportional to $1/f_2$ are fed to ordinary rate meter circuit.

The D. C. out-put appearing across the $RC'$ tank circuit is

$$V=E_B\,CR\cdot\frac{f_1}{2}\quad\text{where } E_B=\alpha\cdot 1/f_2$$

$$=\frac{\alpha}{2}\cdot\frac{f_1}{f_2}\cdot CR=\frac{\alpha CR}{2}\cdot\frac{f_1}{f_2}\qquad(6)$$

This voltage is read by a vacuum tube volt meter $V_{14}$ and $V_{15}$ in ratio figure.

Practically, $f_2$ or $f_1$ can also be measured by selecting the switch position of $s_3$ (See Fig. 3. INPUT SELECT, $S_3$). In this case $S_2$ acts as the range selecter (10 c/s to 3000 c/s, See Fig. 3. RANGE, $S_2$).

$S_1$ should be placed to an apropriate position according to the $f_2$ value and a multiplication facter $M_1$ should be remembered associated with the position (See Fig. 3. $f_2$ RANGE, $S_1$).

When $S_3$ is turned on to the position $f_1/f_2$, $S_2$ acts as a range selector ($M_2=1$ to 1/100). If meter reading gives the value $K$ (See Fig. 3 RATE RATIO), the ratio is obtained by maltiplying $M_1$ and $M_2$ with $K$.

$$\text{Ratio}=K.\cdot M_1\cdot M_2$$

With a proper combination of $M_1$ and $M_2$, it is possible to realize a wide range of 100 to 1/100. $S_4$ functions as a time constant selector (See Fig. 3 TIME CONST.). The time constant ranges from 0.1 to 50 sec.

Experimental data showed an accuracy of ±2%. Some error occured in too high a counting rate for a specified switch positions, because the $1/f_2$ voltage decreases in high $f_2$ value until it conceals itself under the noise level. In too low a counting rate for a specified switch positions, the linear rise of sawtoothwave form cannot hold in such a long pulse interval so that some error were introduced.

These characters were investigated in constant ratio figures of 1.0 and 0.027. In the former, the same signal from an audio frequency oscillator was applied to both channels. In the latter, two thin metal discs, each with different number of slits (the difference being 2.7%) on the periphery, were attached to a common rotating axis. This device, with the aid of light source and a photo-cell, produced an electrical signal of two frequencies that corresponded to the R. P. M. of the axis and number of slits. The beat frequency of the two signals was applied to channel 1. One of the original frequency was applied to channel 2. The R. P. M. of the D. C. motor way controlled by the rheostat. In this way we could vary the frequencies while keeping the ratio constant.

To avoid the nonlinear rise of the sawtooth voltage, proper selection of switch position was necessary, but the accuracy described above was held for specified positions in about 2 decades of frequency range.

## § 5. Statistics of the Rate Ratio

Now we consider two quantities $A$ and $B$, and assume that they have statistical fluctuations. A has the mean value of $\bar{A}$, standard deviation of $\sigma A$ and the probability of $W(A)\cdot\Delta A$ with which $A$ lies between $A$ and $A+\Delta A$. As for $B$, we can define similar expression $\bar{B}$, $\sigma B$, $W'(B)\cdot\Delta B$.

Some relationships as follows are too obvious.

$$\bar{A}=\int A\cdot W_{(A)}\cdot\Delta A.\quad \bar{B}=\int B\cdot W'_{(B)}\cdot\Delta B. \tag{7}$$

$$(\sigma A)^2=\int(A-\bar{A})^2W_{(A)}\cdot\Delta A=\int A^2W_{(A)}\cdot\Delta A-\bar{A}^2.$$

$$(\sigma B)^2=\int(B-\bar{B})^2W'_{(B)}\cdot\Delta B=\int B^2W'_{(B)}\cdot\Delta B-\bar{B}^2. \tag{8}$$

Then we consider the product of two quantities $A$ and $B$. The mean value of $AB$ can be obtained from the next eq. (9).

$$\overline{AB}=\iint ABW_{(A)}\Delta A.\,W'_{(B)}\Delta B\,. \tag{9}$$

As $A$ and $B$ are quite independent of each other, eq, (9) becomes

$$\overline{AB}=\int AW_{(A)}\Delta A.\cdot\int BW'_{(B)}\Delta B=\bar{A}\cdot\bar{B} \tag{9'}$$

Similarly, the standard deviation of $AB$ can be obtained.

$$\begin{aligned}(\sigma AB)^2&=\iint(AB-\overline{AB})^2W_{(A)}\Delta A.\quad W'_{(B)}\Delta B\\&=\iint A^2B^2W_{(A)}\Delta A.\quad W'_{(B)}\Delta B-\overline{AB}^2\\&=\int A^2W_{(A)}\Delta A.\cdot\int B^2W'_{(B)}\Delta B-\bar{A}\cdot\bar{B}^2\end{aligned}$$

From eqs. of (8) and (9′),

$$\begin{aligned}(\sigma AB)^2&=(\sigma A^2+\bar{A}^2)\cdot(\sigma B^2+\bar{B}^2)-\bar{A}^2\cdot\bar{B}^2\\&=\sigma A^2\cdot\bar{B}^2+\sigma B^2\bar{A}^2\,.\end{aligned}$$

Dividing the both side of this eq. with $\overline{AB}^2=\bar{A}^2\cdot\bar{B}^2$,

$$\left(\frac{\sigma AB}{AB}\right)^2=\left(\frac{\sigma A}{A}\right)^2+\left(\frac{\sigma B}{B}\right)^2. \tag{10}$$

Hence, from eqs. (6) and (10), we obtain the fractional standard deviation of the rate ratio output.

$$\left(\frac{\sigma V}{V}\right)^2=\left(\frac{\sigma E_B}{E_B}\right)^2+\left(\frac{\sigma CRf_1/2}{CRf_1/2}\right)^2. \tag{11}$$

As the scale of two of channel 1 cannot change the statistical nature of $f_1$, the statistics of the quantity $CRf_1/2$ of eq. (6) can be obtained from the statistics of the ordinary counting rate meter output $V^1(E_B=\text{const}$, without scale of two).

$$V^1=E_B\cdot C\cdot R\cdot f_1=\beta\frac{f_1CR}{2},\quad(\beta=\text{Const.})$$

$$\frac{\sigma f_1CR/2}{f_1CR/2}=\frac{\sigma V^1}{V^1}=\sqrt{\frac{1}{2\tau_1f_1}}\,, \tag{12}$$

Where $\tau_1$ is the time constant of the tank circuit.

As seen in § 3 eq. (5), the "inverse" voltage of the counting rate $f_2$ has the fractional standard deviation of

$$\frac{\sigma E_B}{E_B}=\sqrt{\frac{1}{2\tau_2f_2}}\,, \tag{13}$$

Where $\tau_2$ is the time constant of the filter circuit of the "inverse" voltage and $f_2=1/t_m$.

From eqs. (11), (12) and (13), we obtain the fractional standard deviation of the counting rate ratio $f_1/f_2$.

$$\frac{\sigma f_1/f_2}{f_1/f_2}=\sqrt{\frac{1}{2\tau_1f_1}+\frac{1}{2\tau_2f_2}} \tag{14}$$

This is an expression for a single observation.

For $n$ observations (at equal time interval $t$) and continuous observation (overall time, $T$), we can derive respective expressions from eq. (10), eqs of the fractional standard deviation corresponding to the ordinary counting rate meter given by R. D. Evans et. al.(3) and the eqs. of the "inverse" voltage described in § 3.

For $n$ observations, whose time interval of observation is uniform and equal to $t$ sec,

$$\frac{\sigma f_1/f_2}{f_1/f_2}=\sqrt{\frac{1+(n-1)(1-e^{-(2t/\tau_1)})}{[1+(n-1)(1-e^{-(t/\tau_1)})]^2 2\tau_1 f_1}+\frac{1+(n-1)(1-e^{-(2t/\tau_2)})}{[1+(n-1)(1-e^{-(t/\tau_2)})]^2 2\tau_2 f_2}} \qquad (15)$$

For continuous observation, whose overall time is $T$,

$$\frac{\sigma f_1/f_2}{f_1/f_2}=\sqrt{\frac{(1+2T/\tau_1)}{(1+T/\tau_1)^2 2\tau_1\cdot f_1}+\frac{(1+2T/\tau_2)}{(1+T/\tau_2)^2 2\tau_2 f_2}} \qquad (16)$$

## § 6. Conclusion

The result was satisfactory and proved to be more stable than the rate meter using logarithmic diode character and a difference amplifier.

Radioactivity measurement, however, needs background correction, and thereby some error might be introduced to the reading if the counting rate of both channels is low. However, the intensity is ordinarily much higher than the background count, so the error will be negligible. If $f_1$ is not high, but $f_2$ high, the correction can be made easily.

Statistical considerations of the rate ratio was made exactly and proved to coincide with the approximate expressions for the ratio of two quantities.

This will be useful in nuclear experiments where the ratio figure is important and the absolute value is not so important, such as in the determination of angular distribution of scattering, or in the $X$ ray analysis using Geiger tubes, which suffers intensity variations from power supply fluctuations; and in the radioisotope tracer experiments of physical and chemical researches, especially when short half life isotopes are their tools.

This rate ratio meter was initially constructed with the financial support of the fund of Aide for Engineering Development of the Ministry of Transportation for the purpose of constructing the radiation defect detector or the radiation thickness gauge of casted irons and welded steel sheets of a ship and her engines. The author wishes to express his gratitude to the persons concerned.

## Specimen Contamination in Electron-microscope

By Y. MIZUSHIMA, S. HIROTA
and H. NOAKE
*Electrical Communication Laboratory,*
*Nippon Telegraph and Telephone*
*Public Corporation, Tokyo, Japan*

(Received January 9, 1956)

In the course of a study of evaporated gold films by an electron-microscope, a curious effect due to electron-bombardment was observed. Pure gold black deposits were evaporated onto a substrate, which was mounted on a mesh, in an inert atmosphere of purified argon. Substrates were evaporated glass films of 100 angstrom thickness, collodion films, or evaporated thin films of germanium. The electron-microscope was evacuated by a diffusion pump using silicone oil. The specimen was subjected to the irradiation of a fine electron probe of relatively low intensity (30 mA/cm$^2$). The temperature rise due to absorbed heat caused by the electron impact at the black particles is estimated as less than 50°C.

During the observation, the specimen changes its shape as shown in series of Photographs 1~4. The contamination of the sample occurs only at the electron-bombarded area within a hole of the mesh. Other area shows no change. Several features observed in this phenomenon are as follows:

1) Contamination spreads roughly proportionally to the bombarding time, independent of the size of the smoke particles.

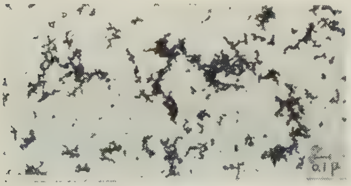

Photo 1. Before irradiation.

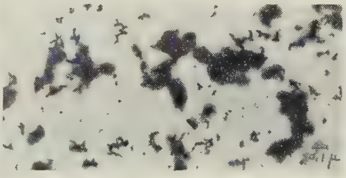

Photo 2. After 20 min. irradiation, 30 mA/cm$^2$.

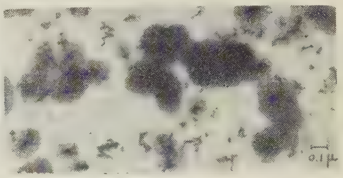

Photo 3. After 40 min. irradiation.

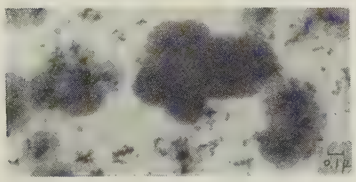

Photo 4. After 60 min. irradiation.

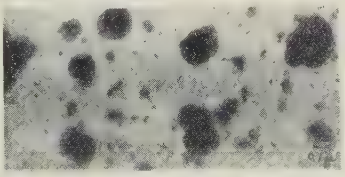

Photo 5. Shadow-cast by germanium.

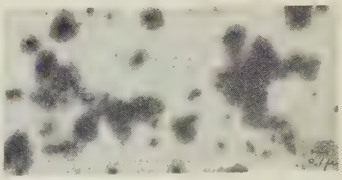

Photo 6. After the 1 hr. heat-treatment at 350°C.

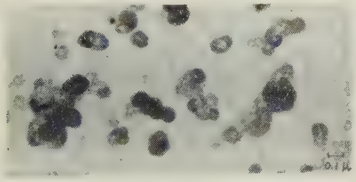

Photo 7. After the treatment with KCN solution.

2) The contamination is independent of the nature or the conductivity of the substrate.

3) Electron-diffraction of the contaminated region shows strengthened background, probably due to the formation of some organic material, while the pattern of gold is weakened as the contamination grows up.

4) The contamination occurs even by the bombardment of low-voltage (1 to 5 kV) electrons in an usual kinetic vacuum chamber of about $10^{-6}$ mmHg.

5) It has been reported that contaminations produced by a discharge method in an organic vapor such as benzene[1)] or di-butyl-phtalate are formed as continuous layers covering all over the substrate. While, shadow-cast micrograph (Photo-5) of the contaminated specimen reveals that the contamination, which is translucent for 50 kV electron, has rather sharply defined edges, and is formed only at the particles.

6) Though it has been confirmed that the black changes its shape remarkably by sintering at above 200°C[2)], the contaminated specimen persists in its original shape even at 350°C. (Photo-6)

7) Heat-treated blacks show the contamination

very little. Also, the vacuum-evaporated films do not suffer any obvious trace of contamination.

8) Electron-impact at the copper part of the mesh has a slight but positive influence on the production of the contamination.

9) When the contaminated specimen is etched in a solution of KCN, gold blacks dissolves away and there remain only shells of the contamination. (Photo-7)

Some considerations have been so far reported on the nature of the contamination[3]. The above evidences seem to indicate that the electron beam in a kinetic vacuum induces unknown interaction with residual organic gas molecules only on metal blacks, probably due to a special activity of a metal black and, or, the sucessively contaminating layer on it.

# On the Elastic Scattering of Electrons observed in Kikuchi Patterns

By Hatsujiro HASHIMOTO

*Kyoto Technical University, Matsugasaki, Sakyoku, Kyoto*

Eiji YODA and Hiroshi MAEDA

*Kyoto University, Kitashirakawa, Sakyoku, Kyoto*

(Received December 30, 1955)

Boersch[1] showed with the use of the electron filter the fact that the Kikuchi lines in electron diffraction are due to the inelastic scattering of electrons, in accordance with the interpretation originally given by Kikuchi[2]. The present authors[3] formerly studied Kikuchi lines from the cleavage surface of zinc-blende by using a net-type electron filter[1,4] inserted between the second specimen holder and the second projector lens in our microscope[5]. By this experiment it was revealed that the Kikuchi lines contain a certain amount of elastically scattered electrons besides the inelastically scattered part. The similar conclusion has been subsequently obtained also for Kikuchi lines in transmission patterns from molybdenite. During the progress of our study, Watanabe[5] reported an energy spectrum of Kikuchi lines which contains clearly the conponent of no energy loss. His result coincides exactly with our observation. In the present paper the results on molybdenite is reported.

We observed the transmission electron diffraction patterns from a thin film of molybdenite containing the Kikuchi pattern and the Kossel-Möllenstedt (K–M) pattern simultaneously. The K–M pattern is useful for the investigation of the elastic and inelastic scatterings, because it has been considered that the K–M pattern consists of elastic scattering of electrons, while the Kikuchi pattern consists of inelastic scattering.

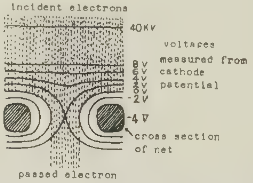

Fig. 1. Potential distribution in electron filter.

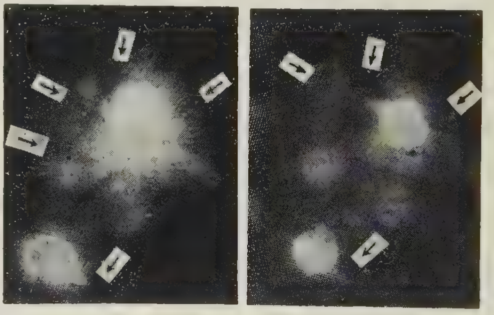

Fig. 2. Kikuchi lines (mark ↾) and K–M patterns which passed through electron filter.
(a) $\Delta v = 180$ volts.
(b) $\Delta v = 2$ volts, Kikuchi lines can be still observed.

The effective potential for filteration is not the same as the potential applied to the net as shown schematically in Fig. 1. Let us denote the voltage difference between the net and the cathode by $\Delta V$, and that between the effective potential for filteration and the cathode by $\Delta v$, then in general $\Delta v > \Delta V$. In our study nets having $50\,\mu$ spacing (with 60% transmission coefficient) and $150\,\mu$ spacing were used. It was confirmed that for these nets $\Delta v = (\Delta V + 8)$ volts and $\Delta v = (\Delta V + 17 \sim 18)$ volts, respectively.

The patterns through the electron filter varied with the variation of the potential of filter as follows:

1) By the change of $\Delta v$ from 200 volts to 20 volts, the intensity of Kikuchi patterns decreased little by little, but they were still observed clearly.

2) At values of $\Delta v$ lower than 20 volts, Kikuchi lines become very weak but were still observed. However, a part of Kikuchi lines far from a spot of K–M pattern faded away.

3) In certain specimens, in spite of Kikuchi lines having been observed for $\Delta v=10$ volts, they disappeared for $\Delta v=8$ volts.

4) In other specimens, Kikuchi lines were still observed even for $\Delta v=2$ volts, as shown in Fig. 2. At the value of $\Delta v=0$, all Kikuchi lines as well as K–M pattern disappeared completely.

From the above observations we can see that in certain specimens Kikuchi lines consist of an inelastic scattering of electrons whose energy loss is more than 20 volts or 8 volts, while in other specimens they contain, besides inelastic part, electrons whose energy loss is less than 2 volts. The existence of electrons of such a small energy loss seems to show that Kikuchi lines are partly due to the thermal scattering or the elastic scattering at imperfections in the crystal. It is probable that the parts of Kikuchi lines far from the spots of K–M pattern are solely due to the inelestic scattering, because it is supposed that when electrons change their directions greatly, they may suffer inelastic scattering at least more than once during the process of multiple scattering.

The authors wish to express their sincere thanks to Prof. K. Tanaka of Kyoto University for his kind guidance. They are also grateful to Prof. R. Uyeda of Nagoya University for his advice to take up this problem.

# Note on the Ferromagnetism of CoTe

By Enji Uchida

*Department of Physics*
*The University of Osaka Prefecture*
*Naniwa University*

(Received January 10, 1956)

In a previous paper[1] on the magnetic measurements of CoTe, the experimental data were so interpreted that CoTe would be a ferrimagnetic substance. At the annual meeting of the Phys. Soc. of Japan, Oct. 12th. 1955, at Tokyo, Professor T. Hirone suggested, however, that $CoTe_x$ $(1.00\leq x\leq 1.20)$ might be an eutectic mixture of metallic cobalt and a nonmagnetic compound $CoTe_{1.20}$ and that the magnetic transition observed at 1003°C could be explained on this basis. The author made

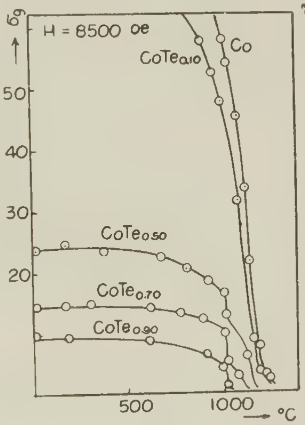

Fig. 1

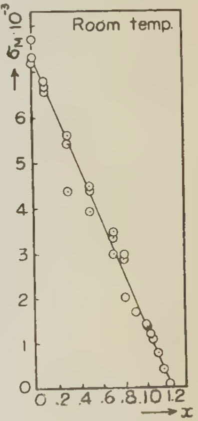

Fig. 2

Fig. 1. Dependence of the magnetization of $CoTe_x$ $(0<x<1.00)$ on temperature.

Fig. 2. The molar magnetization of $CoTe_x$ as a function of molar content of tellurium. Plots in the region $1.00\leq x\leq 1.20$ are reproduced from the data in the previous paper.

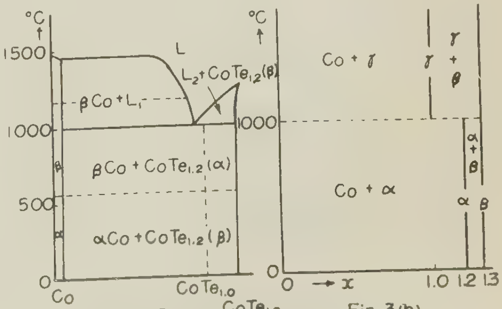

Fig. 3(a) Fig. 3(b)

Fig. 3 (a). Hypothetic phase diagram of $CoTe_x$ $(0<x\leq 1.20)$.

(b). Hypothetic phase diagram of $CoTe_x$, suggested by Dr. Lotgering.

magnetization measurements on samples $CoTe_x$ with $0<x\leq1.00$ and also detailed x-ray investigations on $CoTe_{1.00}$ and $CoTe_{1.20}$, the results of which will settle the question raised above. These results are as follows.

Samples of $CoTe_x$ $(0<x\leq1.00)$ were prepared by the same procedure as mentioned in the previous paper. The temperature of heat treatment in the present case was 1200°C. In the case of $x=0.3\sim0.7$ a precipitation of cobalt was clearly detected in the upper part of the products. In order to give a homogenous composition to the samples, they were ground into powder and were once more subjected to a heat treatment at 900°C for 10 hours in vacuum.

The temperature dependence of the magnetization of these powder samples is shown in Fig. 1. The magnetization curves for $x=0.3\sim0.9$ show a sharp drop at 1003°C and their ferromagnetic Curie point is near that of metallic cobalt. In Fig. 2, the molar saturation magnetization is plotted against $x$, i.e. the molar content of tellurium. Its values distribute along a straight line, which starts approximately from the molar saturation magnetization of Co and ends at $CoTe_{1.20}$. This seems to show the presence of two phases, Co and $CoTe_{1.20}$, in samples of $CoTe_x$ with $0.1\leq x\leq1.20$. That the present observed value of the saturation magnetization for $x=0$ is smaller than that observed by Sucksmith[2] ($\sigma_{\infty 0}=163.9$ gauss/g) would mainly be due to a large demagnetizing effect in powder samples.

Careful x-ray investigations of $CoTe_{1.00}$ and $CoTe_{1.20}$ were performed in cooperation with Prof. Shimomura of our University. The Debye-Scherrer diffraction pattern obtained with $CoTe_{1.20}$ conforms to that of the NiAs-type structure both in arrangement of lines and in intensity distribution, with lattice spacings $a=3.88$ A, and $c=5.37$ A, which are in full accord with those previously reported by Oftendal[3] for $CoTe_{1.00}$. However, the pattern for $CoTe_{1.00}$ showed the presence of three additional lines ($\theta=25.9°$, $45.5°$ and $56.9°$). These three lines were so weak that they could scarcely be detected without taking a special care. It appears that they are coincident in $\theta$ with those of metallic cobalt, the corresponding planes being (0002), $(11\bar{2}0)$ and $(11\bar{2}2)$, respectively. The writer has prepared single crystals of $CoTe_{1.20}$ and $CoTe_{1.50}$ (both about 2 mm × 2mm × 4mm), and a precise x-ray study of them is now being carried out by Prof. Shimomura.

The results obtained in the present experiment support Professor Hirone's suggestion. A hypothetic phase diagram shown in Fig. 3 (a) can interpret all the experimental data, in particular the magnetic transition at 1003°C, a small jump of $\sigma$ at this temperature, and a temperature hysteresis of the transition (Fig. 1 and Fig. 3 of the previous paper).

In the course of preparing this note, I have received a letter from Dr. F. K. Lotgering of the Philips Research Laboratory in Netherlands, who suggested a similar interpretation. He assumed a decomposition of $CoTe_{1.00}$ into metallic cobalt and $CoTe_{1.20}$, with a similar hypothetic phase diagram shown in Fig. 3 (b). He supposes the phases $\alpha$, $\beta$ and $\gamma$ to have NiAs structures, $\alpha$ having the composition $x=1.2$, $\beta$ a composition $x>1.2$ (for example $x=1.3$) and $\gamma$ the composition $x=1.0$ (or $x<1.0$).

The writer is much obliged to Professor T. Hirone for kind suggestions, to Professor T. Nagamiya and Professor Y. Mashiyama for kind discussions, to Professor Y. Shimomura for his cooperation in $x$-ray study and to Messrs. M. Kojima, S. Saito, H. Kondoh and N. Fukuoka for their eager assistance. The writer also wishes to express his thanks to Dr. Lotgering for his kind communication.

## On the Electroluminescence in ZnS phosphor

By Morihiko KIMATA and Tsutomu NOMURA

*Department of Electrical Engineering of Waseda University Tokyo*

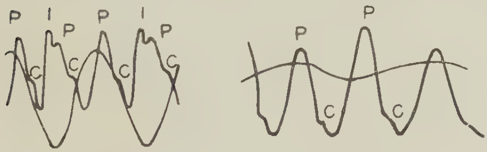
(Received February 10, 1956)

An investigation has been made of the properties of electro-luninescence of ZnS phosphor doped with Pb and Cu[1]. The powder phosphor is imbedded in Lucite, which is sandwiched between a conductive glass and an alminium plate, before Lucite solidifies. Luminous light outputs are received by the photomultiplier, amplified and observed by a two beam oscilloscope.

At low voltage two peaks were observed per half cycle of the external field. One was almost in phase and the other appeared at the maximum of time derivative of the external field. This is the well known experimental result of many authors. But increasing the voltage, a third peak was found at the time of exact maximum of the external field (Fig. 1, a). For the sake of simplicity we named these peaks P, C and I in the order they were referred above. Simultaneous results were obtained with samples using the same phosphor not imbedded in Lucite, but sandwiched between two conductive galses (Fig. 1, b). The reason for this was to eliminate any possible blocking of the electrode caused by the use of Lucite. In this case the I-peak did not show a smooth form on the oscilloscope pattern, but exhibited a rugged form. Considering the shape and the stability of this peak, it is not reasonable to conceive that the peak is caused by discharge light.

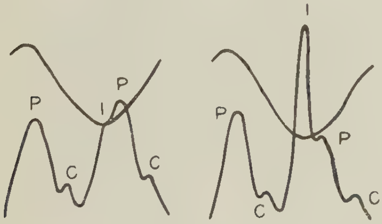
When DC bias is superposed on the AC field, the different characteristics were induced for three peaks. (Fig. 2)

1) I-peak was strengthened at the maximum of the field and weakened at the minimum.



(a) (b)

Fig. 1. (a) Sinusoidal voltage (1800 V/mm) and light output. I, P and C-peaks are seen, but I-peaks do not always appear twice a cycle.
(b) Light output shape is identical with those of the above. The I-peak does not appear in this figure but was observed to have a rugged shape.



(a) (b)

Fig. 2. Bias effects. (a) No bias. (b) Bias. (AC. 1800 V/mm, DC. 400 V/mm)

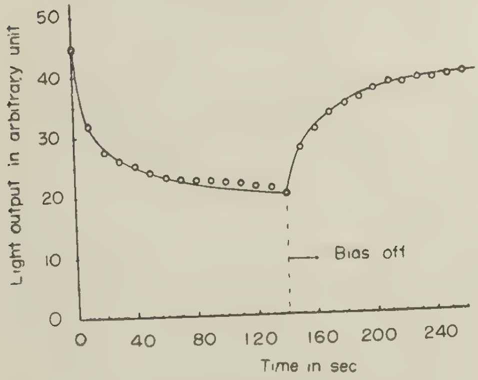


Fig. 3. DC bias was on, at $t=0$ and off at $t=140$ sec. The decreased light gradually recovered after the bias was removed. (AC. 800 V/mm, DC. 1200 V/mm)

2) The behavior of the P-peak was very interesting in contrasts with I-peak. This peak was weakened at the maximum of the field, and slightly strengthened at the minimum field.

3) Change in the C-peak is not distinct because of the effects of the others, but this is not likely to be affected by the DC bias.

From these observations we can conclude that these three peaks were induced by quite different mechanisms.

From the result 1) the I-peak can be explained by the impact model[2]. But from 2) the P-peak cannot be explained by this mechanism, because, if it is so P-peak should have to increase by the increased field. The P-peak may be closely related with the polarization of the phosphor. To explain this effect, a more elaborate experiment must be devised.

From the result 3) in which C-peak is independent of the field intensity but depends only on the field change, the C-peak cannot be explained by the recombination at 0 field[3]. We prefer to explain the C-peak as having arisen from the effect of field changes. Such mechanism may be obtained by the release of the carrier at the trap by abrupt change of the field.

The total light output is lowered by the DC bias and its time dependence is shown in Fig. 3.

The authors wish to thank Prof. H. Tsutsumi for his encouragements and invaluable comments.

# On the Correlation between Screw Dialocations and Twin Structure in $WO_3$ Crystal

By Terutaro NAKAMURA

*Department of Physics, University of Tokyo*

(Received January 25, 1956)

Recently S. Tanisaki[1] observed growth spirals on the tungsten trioxide crystal, indicating that screw dislocations imerge on the surface. This substance was reported to have ferro- or antiferroelectric properties[2] and to posses twin structure[3]. The present note suggests that the screw dislocations parallel to [001] axis may affect the twin structure.

It is well known that the crystal is composed of domains (90° domains), twinned on (110) plane. Furthermore, each domain contains a number of repeated twins (180° domains), twinning plane being (100), as showh in Figs. 1 and 2[3]. Unit cell is monoclinic with lattice constants:[3] $a=7.27$ A, $b=7.50$ A, $c=3.82$ A, $\beta=90°56'$ (Fig. 2).

Some of photographs by Tanisaki indicate the existence of screw dislocation parallel to $c$-axis[1]. These dislocations must cause stress $Z_x$, whereas each (100) type domain has spontaneous strain $z_x$. Therefore, stress $Z_x$ may affect (100) type domain structure.

Suppose a screw dislocation parallel to $c$-axis in a domain characterized by positive $z_x$ strain, then in the vicinity of the dislocation a portion of negative $z_x$ strain must be existing. It is possible that this negatively polarized portion provides a nucleous of new domain which may grow when a mechanical stress is applied.

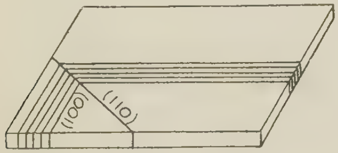

Fig. 1. Twin structure of WO$_3$ according to Ueda and Kobayashi.

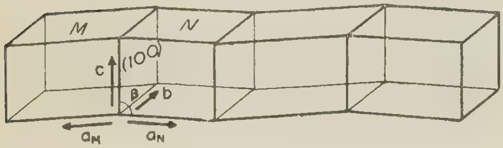

Fig. 2. 180° domain structure according to Ueda and Kobayashi.

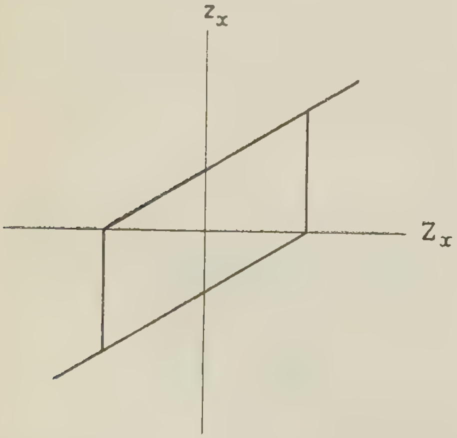

Fig. 3. The $z_x-Z_x$ characteristic curve, assumed.

The information on the size of the nucleous of the domain can be roughly estimated as follows. Strain $z_x$ due to a screw dislocation situated in a positive domain is:

$$z_x=-\frac{b}{2\pi}\frac{y}{x^2+y^2}+z_{xs} \tag{1}$$

provided for brevity that elastic constants are isotropic, and that $z_x-Z_x$ characteristic curve is as shown in Fig. 3; where $z_{xs}$ denotes spontaneous strain $\beta-(\pi/2)=1.6\times10^{-2}$, and $b$ denotes the modulus of Burgers vector. If Burgers vector is equal to the lattice constant in [001] direction, 3.82 A, the nucleous of opposite domain fixed to the dislocation can be roughly estimated from Eq. (1) as a circular cylinder of radious 50 A in the order of magnitude. The nucleous of the domain, therefore, cannot be detected by microscopic study. There is, however, a possibility that stress $Z_x$ applied by a certain treatment may produce observable domains at the screw dislocations parallel to the $c$-axis.

If the $z_x-Z_x$ characteristic shown in Fig. 3, is not the case, (1) is not correct, hence the nucleous of the domain will not be circular cylinder. The estimation of the size, however, will be roughly the case.

# The Effect of Frequency on the Fatigue of Metals

By Alan K. HEAD

*Aeronautical Research Laboratories,*
*Department of Supply*
*Melbourne, Australia*

(Received January 27, 1956)

In the theory of fatigue fracture of Yokobori[1] one of the predictions is that the number of cycles to cause fracture is proportional to the frequency of the applied stress. Recent fatigue tests in these laboratories on 24 S–T aluminium alloy and pure annealed copper have not shown this predicted frequency dependance. Fig. 1 shows the S–N curves for 24 S-T at frequencies from 21 to 12000 cycles per minute obtained by Mann[2] and Table I is a summary of the results obtained by

Mann and Finney for copper.

Some care is necessary in this type of experiment to ensure that the characteristics of the testing machine do not vary with frequency; for instance the reported variations with frequency in X-ray diffraction patterns from copper tested in push-pull fatigue3) have since been shown4) to be mainly due to the characteristics of the fatigue machine used. All the tests in Fig. 1 and Table I (a total of 250 specimens) were run in the same standard A.R.L. 12,000 c.p.m. rotating cantilever fatigue machine5). For the lower frequencies a reduction gear box and pulleys were used between the motor and the machine. Full details of the experimental procedure are given in reference2). The S–N curves in Fig. 1 have been drawn through the logarithmic means of groups of test points since it has been shown6) that the scatter of fatigue tests is approximately log-normal. When the testing frequency is increased from 21 c.p.m. to 12,000 c.p.m. the theory of Yokobori predicts that the fatigue life should be increased by a factor of 571. From Fig. 1 it will be seen that the factor is actually from 1 to 3, depending on the stress level. For the results in Table I the measured factor is from 3 to 4 while the predicted increase is by a factor of 286.

Table I.

| Stress p.s.i. | Fatigue Life at 21 c.p.m. | Fatigue Life at 6000 c.p.m. |
|---|---|---|
| 20,000 | $3.5\times10^4$ | $1.5\times10^5$ |

S-N CURVES AT DIFFERENT TESTING SPEEDS

Fig. 1.

This theoretical prediction that fatigue life should be proportional to frequency is actually composed of two parts. Firstly it is assumed that the initial formation of a crack is a rate process of nucleation and it is then shown that the number of cycles to nucleate a crack is proportional to frequency. It is then assumed that this nucleation takes the major part of the fatigue life and it then follows that the fatigue life will be (approximately) proportional to frequency. As the above experimental results do not show this proportionality the following alternatives exist:—

(i) If the number of cycles to initiate a fatigue crack is the major part of the fatigue life then the formation of the crack cannot be by the mechanism described by Yokobori.

or (ii) If the number of cycles to initiate a crack is only a small part of the fatigue life then Yokobori's mechanism could be correct but it is not then possible to compare the theory directly with experiment as done in reference (1).

Of the three stages of the fatigue process, the first (the initial work hardening) is very short compared with the total fatigue life. It appears7)8)9) that the crack is formed early in the fatigue life and that the growth of the crack takes the major part of the life. Although there have been no experiments on the effect of frequency on the growth of the crack, a theory of the rate of growth of fatigue cracks9)10), which is in reasonable agreement with experiment11), would predict frequency independent growth. Thus it may be permissable to analyse the fatigue life as the sum of a frequency dependent part (the nucleation of the crack) and a frequency independent part (the subsequent growth of the crack). However if this is done for the data of Fig. 1 the dependence on frequency does not appear to be linear.

# The Crystal Structure of Stannous Selenide SnSe

By Atsushi Okazaki

*Department of Physics, Faculty of Science,*
*Kyusyu University, Fukuoka*

and Ikuhiko Ueda

*General Education Department,*
*Kyusyu University, Fukuoka*

(Received January 30, 1956)

In connection with its semi-conducting properties¹⁾, the crystal structure of stannous selenide was determined.

Stannous selenide was prepared by heating a mixture of tin and selenium in stoichiometric proportions. Single crystals were grown from the melt by slow cooling in a crucible being covered with rock salt powder.

X-ray diffraction data were obtained mainly from oscillation photographs taken with nickel-filtered Cu $K$-radiation. The crystal belongs to the orthorhombic system and the dimensions of the unit cell containing four chemical units, SnSe, are

$$a=4.46,\ b=4.19,\ \text{and}\ c=11.57\ \text{Å}\ .$$

The observed reflections conformed to the following rules:

$hkl$ present for all,
$hk0$ present only for $h+k$ even,
$0kl$ present only for $l$ even.

These rules are satisfied only in the two space groups, $D_{2h}^{16}-Pcmn$ and $C_{2v}^{9}-Pc2_1n$. If all the $y$ parameters of the two kinds of atoms in $C_{2v}^{9}-Pc2_1n$ are equall to $\pm 1/4$, these two space groups give the same results. The results obtained by the application of Wilson's method favour $D_{2h}^{16}-Pcmn$, and after determination of $z$ parameters shown below it is found that the intensities of the $0kl$ reflections are in good agreement, within the probable experimental error, with $y=1/4$. Thus the most probable space group is found to be $D_{2h}^{16}-Pcmn$.

The intensities of the $0kl$, $h0l$ and $hk0$ reflections were estimated visually from oscillation photographs which were taken by the multiple film technique. Since the linear absorption coefficient is $1.10\times10^3$ cm$^{-1}$, it was necessary to correct for the absorption effect; the method suggested by Grdenić²⁾ was followed.

The signs of about five-sixths of all $F(h0l)$ were at once determined from the coordinates given by the Patterson peaks. By successive approximations using the two-dimensional Fourier syntheses and structure factor calculations, the following atomic coordinates for the two kinds of atoms were obtained:

| | $x$ | $z$ |
|---|---|---|
| Sn | 0.103 | 0.118 |
| Se | 0.479 | 0.855 |

The reliability index $R=\sum||F_0|-|F_c||/\sum|F_0|$ has the value 0.27 including all the non-observed reflections. If they are excluded $R$ becomes 0.24.

It is found that this structure is of a distorted NaCl type, isomorphous with GeS and SnS³⁾. The Sn–Se distances in SnSe and the Sn–S ones in SnS are as follows:

| | |
|---|---|
| Sn–Se | 2.77(1), 2.82(2), 3.35(2), 3.47(1) |
| Sn–S | 2.62(1), 2.68(2), 3.27(2), 3.39(1). |

Numbers in the brackets show the number of the Sn–Se or Sn–S bonds corresponding to the ones between the nearest neighbours in NaCl. Distances are given in Å.

The full paper will be soon published in the Memoirs of the Faculty of Science, Kyusyu University.

The authors wish to thank Dr. T. Watanabe and Dr. M. L. Huggins for their kind discussions.

# Second Virial Coefficient of Helium from the Square-well Potential*

By Shobu KANEKO and Taro KIHARA

*Department of Physics, Faculty of Science, University of Tokyo*

(Received January 12, 1956)

The second virial coefficient of helium at low temperatures has been investigated by use of the square-well model of the intermolecular potential for a systematic set of potential parameters.

The notion of depth parameter introduced by Blatt and Jackson¹⁾ for nuclear potentials can also be applied to the potential $U(r)$ between helium molecules, $r$ being the intermolecular distance. Let us choose a dimensionless positive number, $s$, in such a way that the reduced potential, $s^{-1}U(r)$, gives a resonance at the zero energy and no discrete energy level. The number $s$ is called the depth parameter. If one or more discrete levels exist in the two-body system, $s$ is greater than unity; if no discrete level exists, $s$ is less than unity.

In the case of the unit depth parameter, the low temperature limit of the second virial coefficient of helium, He$^4$, is independently of the shape of the intermolecular potential,

$$B=-\frac{9}{16}\left(\frac{4\pi\hbar^2}{mkT}\right)^{3/2}, \tag{1}$$

where $\hbar$ is Planck's constant divided by $2\pi$, $m$ is the mass of a helium atom, $k$ is the Boltzmann constant, and $T$ is the temperature. The second virial coefficient at low temperatures does not sensitively depend on the shape of the intermolecular potential so far as the depth parameter is close to unity.

In fact, it has been known that the depth parameter of He$^4$ is very close to unity²⁾³⁾⁴⁾. For He$^4$, therefore, a highly idealized model of the intermolecular potential can be used, especially for the purpose of deciding whether or not the two-body system of helium has a discrete energy level.

The calculation of the second virial coefficient at low temperature is relatively simple for the intermolecular potential

$$U(r)=\begin{cases}\infty & \text{for} \quad r<\sigma \\ -\varepsilon & \text{for} \quad \sigma<r<g\sigma \\ 0 & \text{for} \quad g\sigma<r\,,\end{cases} \tag{2}$$

where $\varepsilon>0$, $\sigma>0$ and $g>1$ are three model constants. The depth parameter for this model is given by

$$s=\left(\frac{2(g-1)}{\pi\hbar}\sigma\right)^2 m\varepsilon\,. \tag{3}$$

The second virial coefficient $B$ of He$^4$, which obeys Bose-Einstein statistics and has zero spin, is expressed in the form⁵⁾

$$B=-\frac{1}{16}\left(\frac{4\pi\hbar^2}{mkT}\right)^{3/2}+2\sum_{\text{even } l}(2l+1)B_l\,, \tag{4}$$

where summation is to be taken over even quantum numbers $l=0, 2, \cdots$ of the angular momentum. The $B_l$ is given by

$$B_l=-\frac{1}{2}\left(\frac{4\pi\hbar^2}{mkT}\right)^{3/2}\left[\sum_{\text{discrete}}\exp\left(-\frac{E_{nl}}{kT}\right)+\frac{1}{\pi}\int_0^\infty \exp\left(-\frac{E}{kT}\right)\frac{d\eta_l}{dE}dE\right], \tag{5}$$

in which $\eta_l$ is the phase shift defined by the asymptotic form

$$R(r)\sim\sin(\kappa r-\tfrac{1}{2}l\pi+\eta_l) \quad \text{for} \quad r\to\infty \tag{6}$$

of the regular solution of

$$\left[\frac{d^2}{dr^2}+\kappa^2-\frac{m}{\hbar^2}U(r)-\frac{l(l+1)}{r^2}\right]R(r)=0\,, \tag{7}$$

where

$$\kappa^2=mE/\hbar^2\,, \tag{8}$$

$E_{0l}, E_{1l}, \cdots$ ($<0$) being discrete energy levels, if any.

For the square-well potential (2) the phase shifts can be expressed analytically by means of the spherical Bessel functions

$$j_l(x)=(\pi/2x)^{1/2}J_{l+1/2}(x)\,.$$

The function $R$ in (7) with the asymptotic (6) is given by

$$R=\kappa r[\cos\eta_l j_l(\kappa r)+(-1)^l\sin\eta_l j_{-l-1}(\kappa r)]$$

for $r>g\sigma$, while the solution which vanishes at $r=\sigma$ may be written as

---

* A part of this article has been published in Revs. Modern Phys. **27** (1955) 412 and, as a short note, in J. Phys. Soc. Japan **10** (1955) 314.

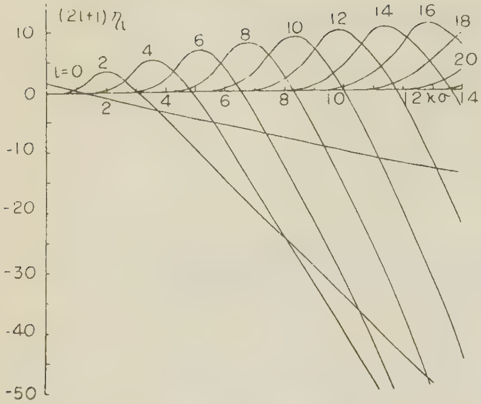

Fig. 1. Phase shift $\eta_l$ for $He^4$–$He^4$ collisions calculated from the square-well potential with $g=3/2$ and $s=1$.

$$R=\text{const}\,\kappa' r[j_{-l-1}(\kappa'\sigma)j_l(\kappa' r)-j_l(\kappa'\sigma)j_{-l-1}(\kappa' r)]$$

for $\sigma<r<g\sigma$, where

$$\kappa'^2=\kappa^2+m\mathcal{E}/\hbar^2$$

or, by use of (3)

$$(\kappa'\sigma)^2=(\kappa\sigma)^2+\pi^2 s/4(g-1)^2\ .$$

The requirement that $R$ and $dR/dr$ be continuous leads to

$$(-1)^l\tan\eta_l=\frac{Aj_{l-1}(g\kappa\sigma)-j_l(g\kappa\sigma)}{Aj_{-l}(g\kappa\sigma)-j_{-l-1}(g\kappa\sigma)}$$

$$A\equiv\frac{\kappa}{\kappa'}\,\frac{j_{-l-1}(\kappa'\sigma)j_l(g\kappa'\sigma)-j_l(\kappa'\sigma)j_{-l-1}(g\kappa'\sigma)}{j_{-l-1}(\kappa'\sigma)j_{l-1}(g\kappa'\sigma)+j_l(\kappa'\sigma)j_{-l}(g\kappa'\sigma)}$$

for $l=0, 1, 2, \cdots$. Here relations

$$\frac{d}{dx}[x^{l+1}j_l(x)]=x^{l+1}j_{l-1}(x)\ ,$$

$$\frac{d}{dx}[x^{l+1}j_{-l-1}(x)]=-x^{l+1}j_{-l}(x)$$

have been used. The phase shifts $\eta_l$ for $s=1$ and $g=3/2$ are shown in Fig. 1 as an example.

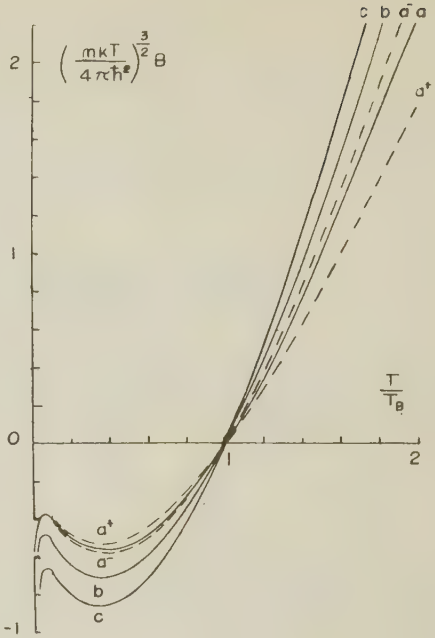

Fig. 2. Reduced second virial coefficient of helium calculated from the square-well potential *vs.* $T/T_B$, $T_B$ being the Boyle temperature. Curve $a$ is for $g=3/2$, $s=1.00$; curve $b$ is for $g=3/2$, $s=1.05$; curve $c$ is for $g=3/2$, $s=1.10$. Broken curve $a^+$ is for $g=2$, $s=1.00$; broken curve $a^-$ is for $g=4/3$, $s=1.00$.

For $s$ slightly greater than unity there exists only one discrete level, $E_{00}$, which is calculated for any $g$ to be

$$E_{00}/\mathcal{E}=-0.00145 \quad \text{for} \quad s=1.05\ ,$$

$$E_{00}/\mathcal{E}=-0.0052 \quad \text{for} \quad s=1.10\ .$$

The expression (4) with (5) for the square-

| $\tau$ | $f(\tau)$ for $g=2$ $s=1.00$ | $f(\tau)$ for $g=3/2$ $s=1.00$ | $f(\tau)$ for $g=4/3$ $s=1.00$ | $f(\tau)$ for $g=3/2$ $s=1.05$ | $f(\tau)$ for $g=3/2$ $s=1.10$ |

| 20 | 3.69 | 2.78 | 2.18 | 2.56 | 2.31 |

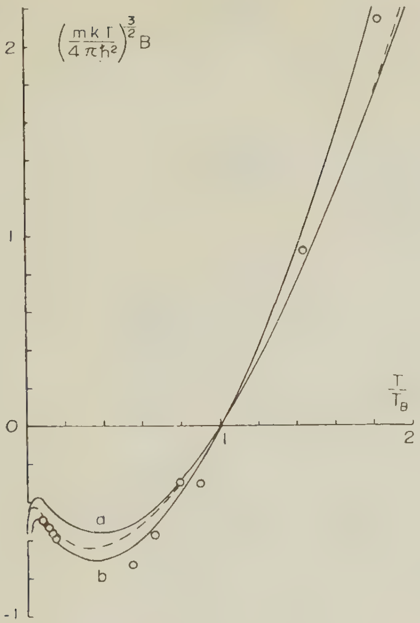

Fig. 3. Reduced second virial coefficient of helium *vs.* $T/T_B$, $T_B$ being the Boyle temperature 26.0° K. Curves *a* and *b* are for the square-well potential with $g=3/2$, $s$ being 1.00 and 1.05 respectively. The broken curve is for Lennard-Jones (61,2) potential with $s=1$. Experimental results are compared with these curves.

well potential then assumes, for each $g$ and $s$,

$$B=\left(\frac{4\pi\hbar^2}{mkT}\right)^{3/2} f(\tau) \quad \text{where} \quad \tau=\frac{\pi^2 skT}{4(g-1)^2\varepsilon}, \quad (9)$$

the function $f$ being given in the table.

Curves of $(mkT/4\pi\hbar^2)^{3/2}$ for ordinary helium, He$^4$, are shown in Fig. 2. The dependence of these curves on the depth parameter $s$ is conspicuous, while that on the "width parameter" $g$ is very slight at low temperatures. For smooth, less idealized models of the intermoleculer potential the calculation of the second virial coefficient at low temperatures is laborious; and at present there is no other result for a systematic set of potential parameters.

In Fig. 3 experimental results[6] for He$^4$ are compared with two curves for the square-well potential with $g=3/2$ and a curve for the Lennard-Jones (6,12)-potential with unit depth parameter. The latter has been drawn taking account of recent calculations by Kilpatric et al[3]. in the case $s=0.99$, slight modification being made by virtue of Fig. 2. From the comparison we know that the depth parameter for the two-body system of He$^4$–He$^4$ is very close to, probably a little greater than, unity.

# Dielectric Breakdown and Pulse Conduction of Silver Halide Crystals

By Tokuo SUITA and Noriaki ITOH

*Department of Electrical Engineering, College of Engineering, Osaka University*

(Received January 9, 1956)

Several experiments on the dielectric breakdown of silver halide crystals were made, concerning about the effect of illumination and temperature. The temperature dependency of the breakdown strength of silver halide crystals seems to be similar to that of alkali halide crystals. The photographic silver specks in the crystals, which were made by illumination and then by being kept in the dark, are found to raise the breakdown strength. The effect of illumination are dependent on the interval between illumination and breakdown and on the repetition rate. These effects seem to be explained by photoelectrons, positive holes, ions and their space charge. Electrical conductivity of pulse electric field was also measured, showing that the ionic current is predominant even in such a short pulse field.

## § 1. Introduction

We have been studying the dielectric breakdown of alkali halide crystals for several years and have found that the actual dielectric breakdown is too complex to be treated by simple theories which mainly concern about ionization by electron collision in the crystal[1)2)]. There seem to be still many other factors, besides this main mechanism, which determine actual breakdown phenomena; for example, space charge of electrons, holes and ions, conditions of the contact surfaces of electrodes, kind of the applied electric field, and mechanical stress or annealing conditions of the specimens.

To clarify some of these second effects we have used silver halide crystals which seem to show some convenient properties for the studies of contact conditions, impurity contents and mechanical stress owing to their photochemical reaction.

On the other hand, in manufacturing photo films there are some damages due to surface electric discharge when the films are rolled. To prevent these phenomena it is necessary to know about dielectric beakdown of silver halide or gelatine itself.

First we tried the dielectric breakdown of AgBr and AgCl crystals under a non-uniform electric field in order to know qualitatively about some photchemical effects on their dielectric breakdown. Next we used a uniform electric field and applied both electrical and optical pulses on the specimens with variation in time interval between the two pulses. Finally the pulse conductivity was measured at various temperatures and then the activation energies were calculated.

## § 2. Experimental Procedures

The specimens were single crystals manufactured by Kyropoulus method such as alkali halides and well annealed. Recrystalization of the parent crystals was necessary to get good specimens. The crystal blocks were cut by a metal wire with emery to roughly proper dimensions. For non-uniform field the specimens were flat plates ($10\times10\times1$ mm$^3$) and for uniform field they were recessed plates ($10\times10\times0.3$ mm$^3$). To prevent mechanical stress in the recessed specimens we used the following process. The flat crystal plates were first coated by paraffin except their center part of radius 1.5 mm on the one side of the crystal, and then dipped in sodium thiosulphate solution for several hours until the desired thickness was obtained. Finally they were washed with distilled water and then well annealed again.

The electrodes used for the non-uniform field were a platinum needle and painted aquaduck plate, and for the uniform field they were evaporated gold and painted aquaduck. All these preparatory works were done in the dark.

Owing to the high ionic conductivity of silver halides, any D. C. dielectric breakdown experiments could not be carried out, and therefore we used (1) non-uniform pulse electric field of normal wave form ($1\times40\,\mu$ sec) and continuous illumination, (2) uniform pulse electric field of rectangular wave form and pulse illumination. The breakdown voltage was measured by sphere gap meter and oscilloscope. Photochemical change of the specimens was produced by a ordinally 100 watt tungsten lamp which was placed 20 cm apart from the specimens. We use insulating oil as an ambient medium to prevent surface discharge of the specimens.

The pulse conductivity was measured by the use of the same rectangular electric field at various temperatures. The voltage across a small series resistance to the specimen was amplified by a transient amplifier[3)] and the conduction current was calculated. The specimen had a guard ring in order to eliminate the effect of leakage current.

## § 3. Experimental Results and Discussions

### (1) *Non-uniform Electric Field*

Some experimental results concerning about AgBr will be shown. In a non-uniform field there are many combinations of the electrode arrangement and the illuminated surface, which we will explain later.

Fig. 1, 2 and 3 show the results of the cases in which the specimens were illuminated for a given time and then kept in the dark for about 12 hours, and at the breakdown the pointed electrode was placed upon the illuminated surface. Even in such a case there are two different relative position, the negative and the positive needle.

Fig. 1 indicates relation between the breakdown voltage and the illuminated period. It is very interesting to see that in the case of the negative needle the effect of the illumination raises the breakdown voltage very rapidly in a first few minutes and then gradually decreases, but in the case of the positive needle the breakdown voltage rather decreases at first and gradually increases with illumination. Therefore the effect of the illumination makes much difference in the both cases.

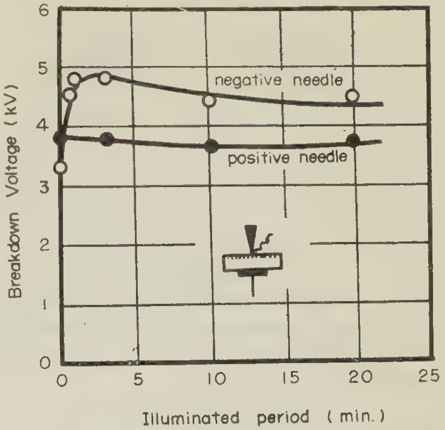

Fig. 1. The curves of the dielectric breakdown voltage of AgBr vs illuminated period at 32°C, the specimens being 1 mm thick and kept in the dark for 12 hours after illumination.

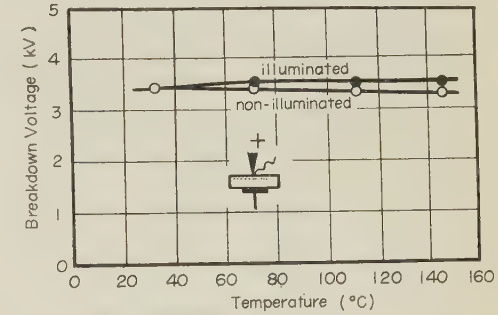

Fig. 2. The temperature dependence of the breakdown voltage of AgBr, positive needle, 1 mm thick, illuminated for 20 min. and kept in the dark for 12 hours.

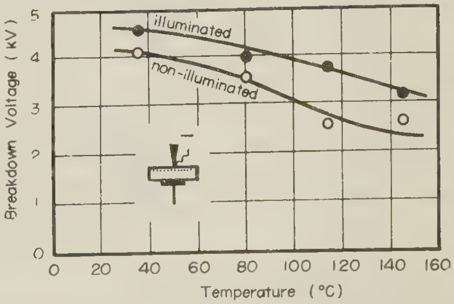

Fig. 3. The temperature dependence of the breakdown voltage of AgBr, negative needle, 1.2 mm thick, 20 min., 12 hours.

We studied the temperature dependence of the breakdown voltage of 20 minutes illuminated specimens under the same conditions. The results are indicated in Fig. 2 and 3.

In the case of the positive needle the breakdown voltages are almost independent of the temperature and the effect of the illumination is also very small, while in the case of the negative needle the breakdown voltages decrease with temperature and the effect of

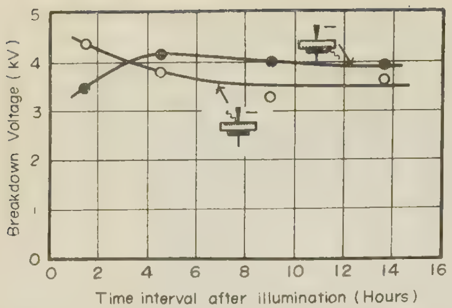

Fig. 4. Time dependence of the breakdown voltage of illuminated AgBr for 20 min., 25°C, 1 mm thick.

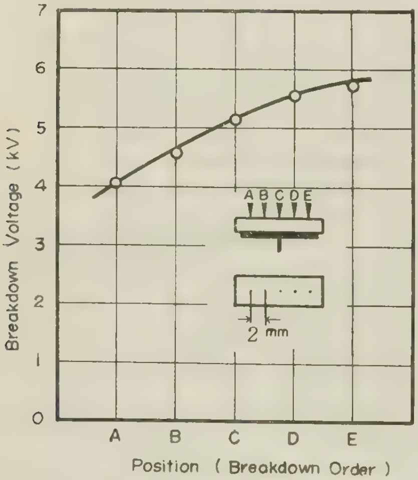

Fig. 5. Partial breakdown effect of AgBr, 32°C, 1.2 mm thick.

Table I. The effect of illumination on the breakdown voltage in non-uniform field. Specimens are illuminated for 20 min. and kept in the dark for 12 hours. Thickness 1 mm. Temperature 25°C.

| Treatment and illuminated side | Non-illuminated | illuminated | |
|---|---|---|---|
| | | Needle side | Plate side |
| Negative needle | 3.2 kV | 4.0 kV | 4.8 kV |
| Positive needle | 3.8 kV | 3.6 kV | 3.6 kV |

illumination is large and nearly constant in the whole temperature range. This dependence of breakdown voltage upon temperature seems to be similar to that of alkali halides above 150°C.

Next we examined the breakdown voltage under various combinations of the electrodes and the illuminated surface at room temperature. The results are shown in Table I. It is very easy to note that in the case of the positive needle the illumination effect is negligible in all positions, but in the case of the negative needle the effect is very large especially in the case where the illuminated surface coincides with the plate electrode, or the illuminated surface is placed under the lower field intensity side. For that reason we are much interested in the case of the negative needle from the standpoint of dielectric breakdown.

Another factor which seems to play an important role upon the breakdown is the period during which the illuminated specimens were kept in the dark, in other words, the time elapsed between the illumination and the breakdown.

The result concerning about this time effect in the case of the negative needle are shown in Fig. 4. The specimens used in this experiment were illuminated for 20 minutes and kept in the dark for different time intervals after light was cut. It is very interesting to note that this time effect is quite different in the both cases, that is, in the case where the negative needle and the illuminated surface are on the same side the breakdown voltage decreases with time, while in the other case it gradually increases and therefore after several hours the order of magnitude is inverted from the beginning. These results show that some internal changes may occur in the illuminated crystal even in the dark and the breakdown voltage depends on the nature of these created impurity centers.

In a non-uniform field something like partial breakdown may easily occur in the crystal. We tried to study the effect of light produced by the breakdown itself upon the following breakdown of the same crystal. The specimen was rectangular as shown in Fig. 5, and the breakdown took place in order of A, B, C, D, and *E* progressively, so that *E* was most influenced by the preceding breakdowns.

The curve taken at the room temperature shows clearly that the preceding breakdowns raise the following breakdown voltages by the effect of the light produced by the breakdowns themselves. From these facts we can conclude that any partial breakdown may influence the following perfect breakdown by the illumination effect of the partial breakdown.

Our results of non-uniform field can be summarized as follows.

1. Light illumination has much effect on

the dielectric breakdown of AgBr crystal.

2. Especially in the case of the negative needle the breakdown voltage increases rapidly with illuminations.

3. The illuminated AgBr crystal changes its electronic properties even in the dark.

4. The breakdown voltage is influenced by its partial breakdown.

### (2) *Uniform Electric Field*

Fig. 6 shows the temperature dependence of the dielectric breakdown strength of AgCl in the dark under rectangular pulse field. The repetition rate was 30 cycles/sec.

It is clearly seen that there exists a critical temperature at which the temperature coefficient of the breakdown strength changes even in such a pulse field. In AgCl the critical temperature was about 50°C. The pulse length has an important role in the temperature dependence of the breakdown strength especially at higher temperatures, which is very similar to that of the breakdown behavior of alkali halide at temperatures higher than about 150°C.

To clarify the effect of photochemical changes of AgCl on the dielectric breakdown we used both optical and electrical pulses with variation of the time relation between the two kinds of the pulses. In addition the breakdown strength with a single optical and a single electric pulse was also tested about the same crystal. Our results under various conditions are given in Table II. Each value corresponds to the average value of about 20 specimens.

Table II. The effect of pulse illumination on the breakdown strength of AgCl in pulse uniform field. Light pulses of 120 $\mu$ sec duration and voltage pulses of 70 $\mu$ sec duration are synchronized and the maximum point of each light pulse coincides to the start point of the corresponding voltage pulse. Temperature 25°C.

| Experimental condition | Non-illuminated | Illuminated |
|---|---|---|
| single pulse | 65 kV/cm | 60 kV/cm |
| repeated pulse, 30 cycles/sec | 90 〃 | 60 〃 |
| repeated pulse, $\frac{1}{2}$ cycles/sec | 90 〃 | 130 〃 |

From these data we can summarise as follows.

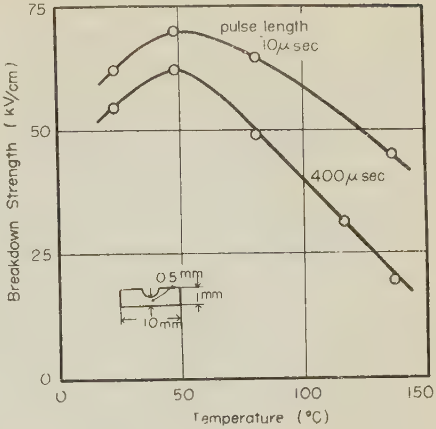

Fig. 6. The temperature dependence of breakdown strength of AgCl by rectangular pulse field repeated 30 cycles/sec.

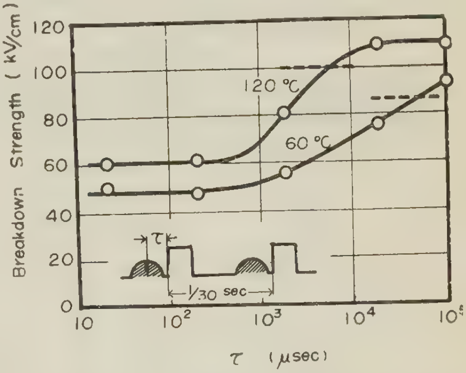

Fig. 7. The curves of the breakdown strength of AgCl vs time interval between illumination and breakdown. The repetition rate of both pulses is 30 cycles/sec except $\tau = 10^5 \mu$ sec where it is 10 cycles/sec. --- denotes the dielectric breakdown strength in the dark.

1. The pulse breakdown strength without illumination become larger when the pulse field is repeated.

2. The breakdown strength is not much affected by illumination when it occurs through a single optical and a single electrical pulse superimposed.

3. The breakdown strength is strongly affected by illumination when the both pulses are repeated.

The time elapsed between the optical pulse and the following electrical pulse seems to be important as in the case of the nonuniform field and the observed results are shown in Fig. 7; the breakdown strength is nearly constant up to the time interval of $10^3 \mu$ sec and then increased with increasing the interval. This time effect also depends on the

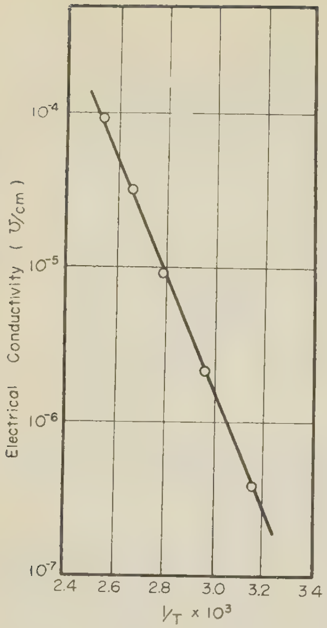

Fig. 8. Temperature dependence of pulse conductivity of AgBr.

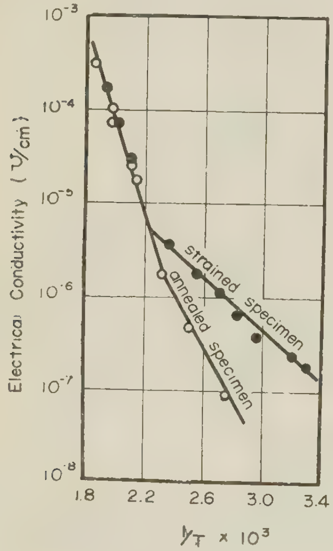

Fig. 9. Temperature dependence of pulse conductivity of AgCl. ○: annealed specimen, ●: strained specimen.

temperature as seen in Fig. 7.

### (3) *Pulse Conduction*

We measured pulse conductivities of AgBr and AgCl, using pulse of length 10 $\mu$ sec at various temperatures.

Our results are shown in Fig. 8 and 9. It is easy to see that logarithm of the conductivity of AgBr linearly increases with decreasing the reciprocal of the absolute temperature, while in AgCl the conductivity has a kink point near $1/T=2.3\times10^{-3}$, and at lower temperatures than this point it is structure sensitive and depends an the anealing process or other second conditions.

The activation energy for AgBr is 0.80ev and for the insensitive point of AgCl it is 0.81 ev. It is of interest to see that these values are almost coincident with D.C. values of Koch and Wagner[4]. Therefore we may conclude that even in such a pulse field $Ag^+$ positive ions would play an important roll in the conductivity as in D. C. field.

It is evident that our present experimental data on the electrical properties of the silver halides is not adequate to provide a complete interpretation of the mechanisms responsible for their intricate behavior.

It seems very likely that electron avalanches play an important role in the dielectric braekdown of silver halides like in that of alkali halides.

In addition, photochemical reaction and dislocation in silver halide seem to be essential factors to determine the breakdown. The illuminated silver halide crystal has many silver specks, or some neutral silver atoms due to the trapping of the photoelectrons by interstitial silver ions near crystal imperfections, on the other hand, the positive holes produced by the light may migrate to the surface by thermal diffusion[5].

Judging from the experimental data on the pulse dielectric breakdown of mixed crystals, any imperfection makes the breakdown strength higher than that of the pure crystals[1]. Moreover in the silver halides, the ionic conductivity is so large even in the pulse field that the breakdown field seems to be much modulated by silver atoms deposited near the cathode which can be seen from the data in Table. II.

From the facts that in the case of single optical pulse or high repetition rate the increase of breakdown strength due to the ionic conduction seems to be cancelled by illumination and shows the minimum value, we can therefore speculate that positive holes produced by illumination migrate toward the cathode and recombine with the neutral silver atoms resulting in the formation of silver ions, or positive holes prevent the silver ions from going toward the cathode to take electron from it by space charge effect of the holes.

It is interesting to note that at the low repetition rate the illumination effect is very large which suggests that some gradually changing factors in the dark come into the breakdown phenomena. This means that, according to the present assumption, about two seconds interval between the optical pulse of one pair and the electrical pulse of the following pair seems to be sufficient to produe neutral silver atoms or their aggregates by recombination of the silver ions and thermally released electrons which had been created by illumination and trapped in imperfections, probably near the surface.

In order to clarify the mechanisms, it would be necessary to carry out further experiments on the existence of space charges of ions, electron and holes at various conditions.

## § 4. Conclusion

Light illumination has much effect on the dielectric breakdown of silver halide crystals owing to their photographic sensitivity.

The dielectric breakdown strength of the illuminated crystals is, in general, larger than that of non-illuminated crystals, and its value depends on relative positions of the illuminated surface and the polarity of electrode, time interval between the illumination and the voltage application, repetition rate of the optical and electrical pulses, and temperature.

We are now trying to investigate the photoelectric conductivity with reference to the dielectric breakdown.

The authors wish to thank to Dr. E. Mizuki and other staffs of Fuji Photo Film Co., Ltd. for supplying silver halide materials and for their valuable discussions.

# On the Coupled Dislocations along a Grain Boundary

By Yasutada UEMURA*

*Matsuda Research Laboratory, Tokyo-Shibaura Electric Co.*
*Kawasaki City, Japan*

(Received January 14, 1956)

By analyzing the interesting patterns of the etch-pits due to the coupled dislocations along a grain boundary in germanium crystals, the direct and quantitative verification of the law of interaction between edge dislocations is obtained.

## § 1. Introduction

In the course of a study of the dislocations in germanium crystals by means of the etching process, J. Okada in this laboratory and J. J. Oberly[1] observed interesting patterns of coupled dislocations along a grain boundary which are shown in Fig. 1 and Fig. 2.

The aims of this paper are to investigate some of the fundamental properties of the observed dislocations and to suggest that the origin of forces which determine the arrangement of these patterns is the simple elastic interaction between coupled dislocations.

## § 2. Qualitative Discussions

The crystals were grown by pulling in the ⟨100⟩ direction, and {100} surfaces perpendicular to the growth direction were etched by C.P.–4 solution. The regular array of etch-pits in Fig. 1 and Fig. 2 corresponds to

the dislocations in the small-angle-of misfit grain boundary. The array runs in the ⟨110⟩ direction and has an interval of 1.7 $\mu$ in Fig. 1 or 4 $\mu$ in Fig. 2.

At first we assume that all dislocations discussed in this paper are the edge type having the same direction of lines as pulling and their Burgers vectors are perpendicular to the surface of the observed grain boundary. This assumption seems to be supported also by the observed characters of these boundaries which were reported by J. Okada[2]. We assume further that the arrangement of etch-pits along a boundary satisfies the condition that the small angle of mis-fit near the coupled dislocations is not so different from that in the regular array. In fact we can find the "vacancies" of etch-pits in the regular array which correspond to the excess pits in the form of coupled dislocations near the "vacancies".

What is the condition that detremine the separation of these coupled dislocations? This is the main problem treated in this paper, and we would like to propose the following interpretation. The condition is the equilibrium of the forces of interaction between dislocations, in the direction perpendicular to the boundary. These patterns may appear in the case in which the temperature is not so high to permit the appreciable climbing of coupled dislocations and they are quenched in their metastable positions near the grain boundary. In fact the doublet of etch-pits shown in Fig. 1 is absorbed into the regular array by heating the crystal for 10 hourse at the temperature about 850°C.

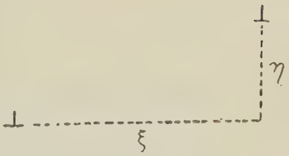

Fig. 3. (A).

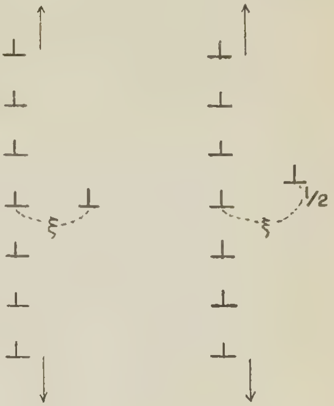

Fig. 3. (B).

## § 3. Simple Models

In order to verify the above interpretation quantitatively, we estimate the separation of coupled dislocations by using the simple models of doublets, triplets and quartets shown in Table I. The equations in Table I represent the condition to balance the forces of interaction between the dislocations along the direction of their Burgers vectors. In these equations, $\xi$ means distance of a dislocation from the boundary measured in the unit of length $w$ which is the regular interval between etch-pits along the array.

If we regard the crystal as an isotropic elastic medium, the functions $R(s)$, $S(\xi)$ and $C(\xi)$ are given by the following expressions[3].

$$R(s)=s^2(s^2-1)(s^2+1)^{-2} \tag{1}$$

$$S(\xi)=\pi^2\xi^2\sinh^{-2}(\pi\xi) \tag{2}$$

$$C(\xi)=\pi^2\xi^2\cosh^{-2}(\pi\xi) \tag{3}$$

The force $F_x$ of interaction between two edge dislocations shown in Fig. 3A is related to $R(s)$ as follows.

$$F_x=F_0\xi^{-1}R(s),\quad s=\xi\eta^{-1},\quad \xi=xw^{-1},\quad \eta=yw^{-1}. \tag{4}$$

The forces $A_x$ and $B_x$ between a dislocation and a regular boundary shown in Fig. 3B are described by the functions $S(\xi)$ and $C(\xi)$ respectively as follows.

$$\begin{aligned} &A_x=F_0\xi^{-1}S(\xi) \\ &\quad S(\xi)=\sum_{n=-\infty}^{+\infty}\xi^2(\xi^2-n^2)(\xi^2+n^2)^{-2}=\pi^2\xi^2\sinh^{-2}(\pi\xi) \end{aligned} \tag{5}$$

$$\begin{aligned} &B_x=-F_0\xi^{-1}C(\xi) \\ &\quad C(\xi)=-\sum_{n=-\infty}^{+\infty}\xi^2\left\{\xi^2-\left(n+\frac{1}{2}\right)^2\right\}\left\{\xi^2+\left(n+\frac{1}{2}\right)^2\right\}^{-2}=\pi^2\xi^2\cosh^{-2}(\pi\xi) \end{aligned} \tag{6}$$

In these expressions, $F_0$ is the unit of force per unit length of a dislocation and is given by

$$F_0=b^2G(2\pi w)^{-1}(1-\nu)^{-1} \tag{7}$$

where $b$ is the length of Burgers vector, $G$ is the rigidity and $\nu$ is the Poisson's ratio.

The total forces appearing in the models of Table I are all described by the combination of $F_x$, $A_x$ and $B_x$. In order to solve the equations in Table I, we employed the graphical method using the calculated curves of $R(s)$, $S(\xi)$ and $C(\xi)$ which are show in Fig. 4 and

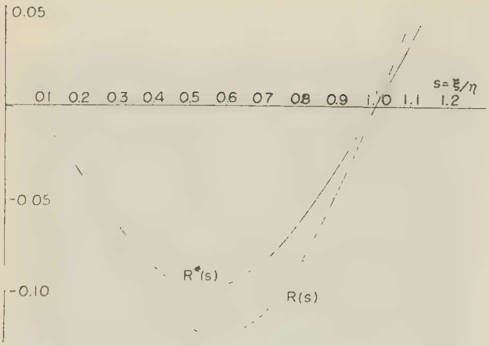

Fig. 4. (A).

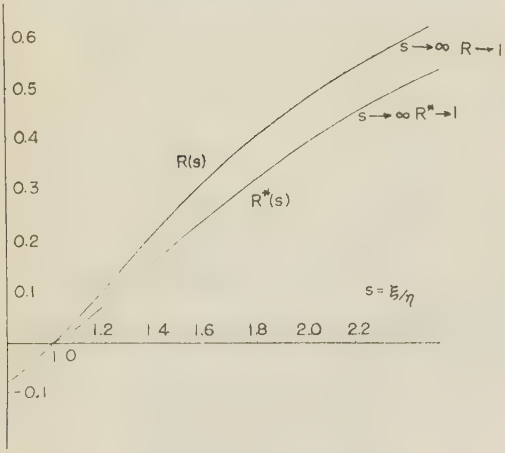

Fig. 4. (B).

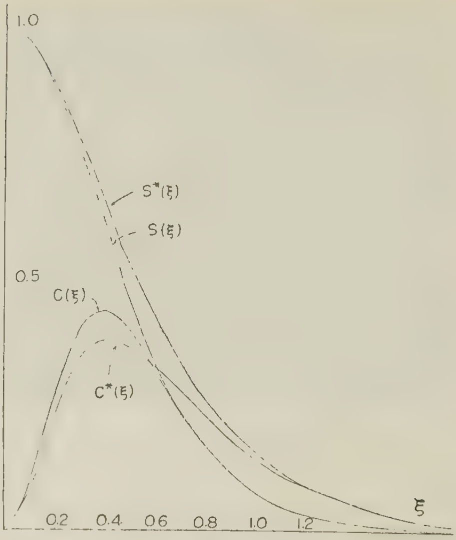

Fig. 5.

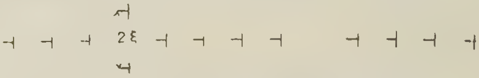

Fig. 6.

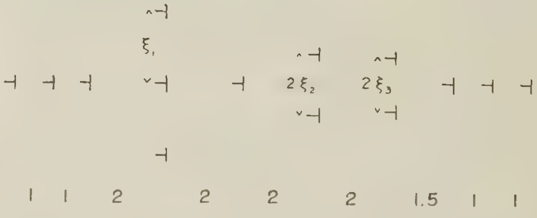

Fig. 7. The numbers indicate the ratio of intervals in the array. Those in parenthesis are the observed values corresponding to Fig. 2.

Fig. 5. In the case of the model Q.B. in Table I, we obtained the coupled equations of two variables $\xi_1$ and $\xi_2$, and solved it by the self-consistent methed.

The calculated separations are also tabulated in Table I, and, roughly speaking, the results suggest that our interpretation may hold quantitatively in the case of more complicated patterns in Fig. 1 and Fig. 2.

## § 4. Analysis of Observed Patterns

To compare the results of calculations with the observed patterns in Fig. 1 and Fig. 2 more quantitatively, we further try to estimate the separations of the models in Fig. 6 and Fig. 7 which have a better fit of arrangement along the boundary than the models in Table I.

The equation for the doublet of Fig. 6 is

$$\xi^{-1}\left[S(\xi)-R\left(\frac{\xi}{5}\right)-\frac{1}{2}\right]=0 \tag{8}$$

and the coupled equations for the coupled dislocations in Fig. 7 are

$$\begin{aligned}&\frac{1}{\xi_1}\left[\frac{1}{2}\{S(\xi_1)-C(\xi_1)\}-\sum_{n=0}^{6}R\left(\frac{2\xi_1}{2n+1}\right)-R(\xi_1)+R\left(\frac{\xi_1}{2}\right)+1\right]+\frac{1}{\xi_1+\xi_2}R\left(\frac{\xi_1+\xi_2}{4}\right)\\&\qquad+\frac{1}{\xi_1-\xi_2}R\left(\frac{\xi_1-\xi_2}{4}\right)+\frac{1}{\xi_1+\xi_3}R\left(\frac{\xi_1+\xi_3}{6}\right)+\frac{1}{\xi_1-\xi_3}R\left(\frac{\xi_1-\xi_3}{6}\right)=0\\&\frac{1}{\xi_2}\left[\frac{1}{2}\{S(\xi_2)-C(\xi_2)\}-\sum_{n=0}^{2}R\left(\frac{2\xi_2}{2n+1}\right)-\sum_{n=0}^{2}R\left(\frac{\xi_2}{2n+1}\right)\right]+\frac{1}{\xi_2+\xi_1}R\left(\frac{\xi_2+\xi_1}{4}\right)\end{aligned} \tag{9}$$

$$+\frac{1}{\xi_2-\xi_1}R\left(\frac{\xi_2-\xi_1}{4}\right)+\frac{1}{\xi_2+\xi_3}R\left(\frac{\xi_2+\xi_2}{2}\right)+\frac{1}{\xi_2-\xi_3}R\left(\frac{\xi_2-\xi_3}{2}\right)=0$$

$$\frac{1}{\xi_3}\left[\frac{1}{2}\{S(\xi_3)-C(\xi_3)\}-R(2\xi_3)-\sum_{n=0}^{2}R\left(\frac{\xi_3}{2n+1}\right)-R\left(\frac{\xi_3}{2}\right)\right]+\frac{1}{\xi_3+\xi_2}R\left(\frac{\xi_3+\xi_2}{2}\right)$$

$$+\frac{1}{\xi_3-\xi_2}R\left(\frac{\xi_3-\xi_2}{2}\right)+\frac{1}{\xi_3+\xi_1}R\left(\frac{\xi_3+\xi_1}{6}\right)+\frac{1}{\xi_3-\xi_1}R\left(\frac{\xi_3-\xi_1}{6}\right)=0$$

If we take the functions (1), (2) and (3) of isotropic case, the calculated separations are obtained as tabulated in Table II, and they are about 10% smaller than the observed separations.

What is the main origin of these discrepancies? Now we would like to show that they are removed by considering the effect of crystal anisotropy.

Table II.

| Models | | Separations | | |
|---|---|---|---|---|
| | | Calc. (iso.) | Calc. (aniso.) | obs. |
| Okada's doublet | $2\xi$ | 0.95 | 1.07 | 1.0~1.1 |
| Oberly's pattern | $\xi_1$ | 1.60 | 1.80 | 1.8~1.9 |
| | $2\xi_2$ | 1.59 | 1.72 | 1.6~1.7 |
| | $2\xi_3$ | 1.38 | 1.54 | 1.5~1.6 |

Table III.

| | |
|---|---|
| $c_{11}'$ | $12.98\times10^{11}$ dyne cm$^{-2}$ |
| $c_{12}'$ | $4.88\times10^{11}$ 〃 |
| $c_{44}'$ | $6.73\times10^{11}$ 〃 |

In the case of the symmetrical boundary in the crystals of cubic system, Eshelby, Read and Shockley[4] deduced the expression of the force $F_x{}^*$ of interaction between two dislocations. Instead of (4) for the isotropic case, it is given as follows:

$$F_x{}^*=F_0{}^*\xi^{-1}R^*(s;\,\beta),\quad R^*(s;\,\beta)=s^2(s^2-1)[(s^2+1)^2+\beta^2s^2]^{-1} \tag{10}$$

By a simple calculation we can also deduce the formula of the force due to the boundary. Corresponding to (5), (6) and (2), (3) of the isotropic case, they are

$$A_x{}^*=F_0{}^*\xi^{-1}S^*(\xi;\,\beta)$$

$$\begin{aligned}S^*(\xi;\,\beta)&=\sum_{n=-\infty}^{+\infty}\xi^2(\xi^2-n^2)[(\xi^2+n^2)^2+\beta^2\xi^2n^2]^{-1}\\&=\pi^2\xi^2\frac{\sinh(\beta\pi\xi)}{\beta\pi\xi}\left[\sinh^2\left(\pi\xi\sqrt{1+\frac{\beta^2}{4}}\right)-\sinh^2\left(\frac{\beta\pi\xi}{2}\right)\right]^{-1}\end{aligned} \tag{11}$$

$$B_x{}^*=-F_0{}^*\xi^{-1}C^*(\xi;\,\beta)$$

$$\begin{aligned}C^*(\xi;\,\beta)&=-\sum_{n=-\infty}^{+\infty}\xi^2\left[\xi^2-\left(n+\frac{1}{2}\right)^2\right]\left[\left\{\xi^2+\left(n+\frac{1}{2}\right)^2\right\}^2+\beta^2\xi^2\left(n+\frac{1}{2}\right)^2\right]^{-1}\\&=\pi^2\xi^2\frac{\sinh(\beta\pi\xi)}{\beta\pi\xi}\left[\cosh^2\left(\pi\xi\sqrt{1+\frac{\beta^2}{4}}\right)+\sinh^2\left(\frac{\beta\pi\xi}{2}\right)\right]^{-1}\end{aligned} \tag{12}$$

In these expressions $F_0{}^*$ is not the same as $F_0$ in (7), but to determine the separations it is not necessary to know the absolute values of $F_0$ and $F_0{}^*$. The effect of anisotropy is taken into account through the single parameter $\beta^2$ which is given as follows:

$$\beta^2=-2\frac{(c_{11}+c_{12})}{c_{11}}\left(1-\frac{c_{44}'}{c_{44}}\right) \tag{13}$$

where $c_{11}$, $c_{12}$, $c_{44}$ and $c_{11}'$, $c_{12}'$, $c_{44}'$ are the elastic constants which are referred to the systems of the caystal axis ⟨100⟩, ⟨011⟩, ⟨0$\bar{1}$1⟩ and ⟨100⟩, ⟨010⟩, ⟨001⟩ respectively, because the Burgers vectors of observed dislocations have ⟨011⟩ directions. Using the known values of $c_{11}'$, $c_{12}'$, $c_{44}'$ tabulated in Table III[5] and the following relations,

$$2c_{44}'=c_{11}-c_{12},\qquad 2c_{11}'=c_{11}+c_{12}+2c_{44},$$
$$c_{11}'+c_{12}'=c_{11}+c_{12} \tag{14}$$

we can estimate $\beta^2=1.506$ in germanium crystals.

The calculated curves of $R^*(s)$, $S^*(\xi)$ and $C^*(\xi)$ are also shown in Fig. 4 and Fig. 5. The separations are calculated by solving the equations (8) and (9) where we replaced $R(s)$, $S(\xi)$ and $C(\xi)$ by $R^*(s)$, $S^*(\xi)$ and $C^*(\xi)$. The results are also tabulated in Table II, and the agreement with observed data is fairly good when we taken into account the effect of crystal anisotropy.

## § 5. Conclusions

Above discussions lead us to the following conclusions.

(A) The observed dislocations have the edge type and their Burgers vectors have ⟨110⟩ directions.

(B) The arrangement of the etch-pits along a boundary satisfies the condition that the small-angle-of misfit near the coupled dislocations is not so different from that in the regular array.

(C) The condition to determine the arrangement of the etch-pits along the direction perpendicular to a boundary, i.e. to determine the separations of the coupled dislocations is the balancing of the forces of interaction between edge dislocations.

Thus we believe that the quantitative analysis of the patterns in Fig. 1 and Fig. 2 is the first attempt to verify the law of interaction between edge dislocations directly.

## § 6. Acknowledgement

The author thanks Drs. H. Inuzuka and H. Miyazawa for their kind encouragement throughout this work. The thanks are also expressed to Messrs. J. Okada, M. Takabayashi, T. Kobayashi and K. Maeda for their valuable information on this problem.

# An Electron Diffraction Study on the Plastic Deformation of Aluminium Single Crystals

By Kazuo KIMOTO

*Physical Institute, Nagoya University, Nagoya, Japan*

(Received February 18, 1956)

Plastic deformation of aluminium single crystals was studied through Kikuchi lines of electron diffraction by the introduction of a new technique: large angle convergent beam method. By this method the irradiated area on the specimen surface can be reduced to 5×20 sq. microns and therefore laminar regions and deformation bands can be studied seperately. For 99.99% aluminium it was found that in laminar regions the distortion is so small that Kikuchi lines are produced even at 10% elongation and that in deformation bands it is large enough to extinguish Kikuchi lines. For 99.55% aluminium, at any place in the crystal the distortion is so large that Kikuchi lines become diffuse at about 3% elongation and are extinguished at about 7% elongation. It was confirmed in all cases that no rotation occurs in the slip plane. The interior of elongated crystals was studied after removal of the surface layer by electro-polishing. Irrespective of the purity of crystals, no recognizable difference was found in the surface layer and in the interior. The order of dislocation density was estimated through Kikuchi line experiment. The results obtained for 99.99% aluminium are $10^6$ lines/sq. cm., $10^7$ lines/sq. cm., and $10^8$ lines/sq. cm. for well annealed crystals, for laminar regions of 10% elongated crystals, and for deformation bands of 10% elongated crystals, respectively.

## § 1. Introduction

Heidenreich and Shockley[1)] first applied the electron diffraction method to the study of slip in aluminium single crystals. According to their results, Kikuchi lines from high purity aluminium single crystals (99.99% French aluminium) disappear when they are elongated more than several percent. However, Heidenreich and Shockley used the ordinary reflection method in which the electron beam falls upon the specimen surface at a grazing incidence. Thus the irradiated area of the specimen is rather large; it was about 0.1×6 sq. mm. in their experiment. The diffraction patterns obtained by them represent the state of crystals in the large irradiated area. Moreover, if the specimen surface is not flat, their diffraction patterns would be influenced by the surface topography.

Recently Fujita, Watanabe, Yamamoto and Ogawa[2)] carried out a similar experiment using the same experimental technique. They studied further the interior of elongated crystals and found that Kikuchi lines which were extinguished by elongation appeared again when the surface layer was removed by electro-polishing.

It is generally accepted that the plastic state of deformed metal single crystals is not homogeneous. Therefore it seems almost certain to the present author that the results of Heidenreich and Shockley, and Fujita et al. are confused because of a large irradiated area. In discussing Kikuchi lines from strained aluminium crystals, careful consideration must be given to the dimension of the irradiated area and to the surface undulation which influences diffraction patterns.

For that reason we performed an experiment similar to that of Heidenreich and Shockley but using the large angle convergent electron beam method by which the irradiated area can be reduced as small as 5×20 sq. microns. Thus laminar regions and deformation bands can be studied seperately. For high purity aluminium (99.99%) we found that laminar regions produce Kikuchi lines even at 10% elongation, and that deformation bands do not produce Kikuchi lines. For low purity aluminium (99.55%), Kikuchi lines are extinguished at about 7% elongation. We also studied the interior of crystals. Contrary to the

result of Fujita et al. we found no recognizable difference between the surface and the interior of elongated specimens. The purpose of the present paper is to describe our experiment and to give an interpretation of the results.

## § 2. Experimental

### (*a*) *Specimen*

In the present experiment two kinds of aluminium materials were used, one of 99.99% and one of 99.55%. Thin plates of these materials 0.5–1.2 mm. thick, 100 mm. long and 5 mm. wide, were converted into single crystals by the strain-annealing method, first introduced by Fujiwara[3]. Orientation of the crystals was determined by transmission Laue photographs. Fig. 1 shows the stereographic projection of the axes of crystals used in this experiment. These single crystals were carefully cut into two parts; the shorter about 4 cm. long and the longer about 6 cm.

Both were polished electrolytically by using Jaquet electrolyte (mixture of perchloric acid 34.5 c.c. and acetate anhydride 63.5 c.c.) at about 5°C until their surfaces became mirror smooth. Immediately after the electro-polishing, the crystals were rinsed in distilled water, then in methanol and finally in acetone-methanol solution. After being dried in the air, they were ready for use. To avoid the surface effects pointed out by Brown and Honeycombe[4], mechanical polishing was not applied to the surface. The shorter pieces were examined to obtain diffraction patterns for non-elongated state. The longer pieces were gripped at one end by a fixed vice and at the other end by a movable vice. By turning a screw on the movable vice manually, the pieces were elongated at room temperature. After elongation, about 15 mm. at both ends of the specimen were carefully cut off with knippers. Then the middle part of the specimen was examined by electron diffraction. The degree of elongation for each specimen is given in Table I. To study the interior of elongated crystals, the specimens were reexamined after removal of their surface layer by electro-polishing. The thickness of the removed layer is given in the last column of Table I.

Specimen No. 0 was furnished through the kindness of Dr. F. E. Fujita of The Research Institute for Iron, Steel and Other Metals, Tōhoku University. It was prepared by Bridgeman's method. The cross section and the length were 3×3 sq. mm. and 100 mm. respectively. Following the procedure indicated by Dr. Fujita, this specimen was mechanically polished with care to remove the coarse surface layer, 0000 and 00000 emery papers being used; then electro-polished to remove the surface layer of more than 100 microns in thickness and finally annealed in vacuum at 630°C for 5 hours. Before the examination the specimen was again electropolished lightly.

(*b*) *Electron diffraction technique*

In the ordinary reflection method, the electron beam is focused on the photographic plate and the electron beam falls upon the specimen surface at a grazing incidence (Fig. 2a). If the specimen surface is undulating[5] the electron beam irradiates only the higher curves of the undulation (Fig. 3). Consequently through diffraction patterns, information is obtained from elevations only and none from lower bends. Even when the specimen surface is perfectly flat, the length of the irradiated area is considerable, usually about 3 mm. in the direction of the incident beam. Since the spacing of deformation bands is usually less than 3 mm, it is impossible to study deformation bands and laminar regions separately.

To reduce the irradiated area, we focused the electron beam on the specimen surface (small angle convergent beam method, Fig. 2b) and the length of the irradiated area was reduced to about 0.7 mm. which is still larger than the spacing of small deformation bands. For further reduction of the irradiated area we deflected the electron beam by a small electric magnet so that the beam falls upon the specimen surface at a large glancing angle (large angle convergent beam method, Fig. 2c). Although larger glancing angles are more suitable for reduction of the irradiated area, Kikuchi lines become weaker as the glancing angle increases, and are finally invisible on the fluorescent screen[6]. Thus in the present experiment we used a glancing angle of 15–20°. The irradiated area under this condition was approximately 5 microns in width and 20 microns in length. It is worth mentioning here that the geometrical arrangement of Kikuchi patterns remains fixed in relation to the crystal, independent of the method of irradiation.

Throughout the experiment, the specimen-to-plate distance was 40 cm. and the accelerating voltage was about 65 kV.

## § 3. Experimental results

(*a*) 99.99% *aluminium*

Unstrained crystals produce good Kikuchi patterns irrespective of the method of irradiation (Photos. 1a, b, c). On the other hand, elongated crystals produce Kikuchi patterns of varying sharpness according to the method of irradiation. When the ordinary reflection method (Fig. 2a) is used, crystals which have been elongated several percent do not produce Kikuchi patterns, as observed by Heidenreich and Shockley. When the small angle convergent beam method is used, elongated crystals produce split Kikuchi lines, running parallel (Photo. 2b).

(a) Ordinary reflection method.
(b) Small angle convergent beam method.
(c) Large angle convergent beam method.

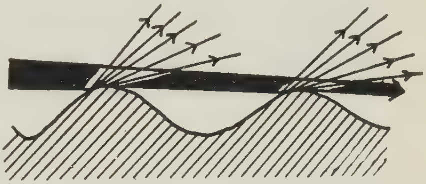

Fig. 3. Schematic illustrations of effective portions of undulated specimen surface when irradiated by the ordinary reflection method.

The split lines can be interpreted as Kikuchi lines produced by crystal blocks having slightly different orientation*. It is certain that slightly disoriented blocks exist in the irradiated area. The angle of disorientation is 20–40′ for neighbouring lines. By the small angle method, it can not be made clear whether split lines are due to crystal blocks connected by boundary walls or to separate blocks (Fig. 3). To eliminate this ambiguity, the large angle convergent beam method was adopted in which it was found that elongated crystals produce good Kikuchi patterns

---

* Heidenreich and Shockley also observed a similar splitting (Fig. 14 of their paper[1]) suggesting that it might be interpreted by using the dynamical theory of diffraction. Uyeda, Fukano and Ichinokawa[7], however, disagreed with Heidenreich and Shockley's interpretation because according to Kainuma[8] no subsidiary maxima are expected in reflection Kikuchi patterns. Uyeda et al. advanced the above interpretation.

(Photos. 2a, 3a) or diffuse Kikuchi bands (Photo. 3b) depending upon the irradiated position. By this we infer that laminar regions produce good Kikuchi patterns and deformation bands produce only diffuse Kikuchi bands.

To prove our inference correct, a specimen which had been elongated about 10% was examined under a light microscope. The surface of the specimen was covered by slip bands spaced 3–5 microns apart and also by fine deformation bands spaced about 300 microns apart. This specimen was set in the diffraction camera so that the electron beam was approximately parallel to the deformation bands. Then it was examined by the large

angle convergent beam method. During the examination, the specimen was moved slowly in the direction normal to the deformation bands, the deformation bands and the laminar regions being alternately irradiated. On the fluorescent screen diffuse Kikuchi bands and good Kikuchi patterns appeared alternately. Displacement of the specimen for the successive appearance of diffuse Kikuchi bands was about 300 microns in agreement with the spacing of deformation bands observed under a microscope. Thus the inference was proved.

Laminar regions produce good Kikuchi patterns even though they are covered by slip bands, independent of the direction of the incident beam as related to the direction of slip bands. The microphotometer curves along the line segments indicated in Photos. 1a and 2a are reproduced in Figs. 5a and 5b. Even when specimens are elongated by 10%, the maximum rate of elongation in this experiment, Kikuchi lines are always produced although the background is somewhat dark. When the electron beam is slightly defocused on the specimen surface, Kikuchi lines are immediately extinguished leaving only diffuse Kikuchi bands, especially when the deformation is large.

When the electron beam irradiates laminar region A (Fig. 4), good Kikuchi lines appear and they do not move on the fluorescent screen even when the irradiated area is moved. When it irradiates B (Fig. 4), which is in the immediate neighbourhood of a deformation band, they fade away leaving only a diffuse Kikuchi band. When the electron beam moves from B to C, the corresponding Kikuchi band jumps to a parallel position and when the electron beam moves from C to D, the Kikuchi band jumps back again to nearly its original position. Sometimes two Kikuchi bands appear indicating that both sides of an extremely fine deformation band are irradiated. From the distance between two bands the bending across a fine deformation band is estimated to be about 1°.

Sometimes, even in laminar regions, Kikuchi lines split in two (Photo. 6). Since this is observed in large angle convergent beam method, this means that both sides of a boundary wall are irradiated. The disorientation across the wall is estimated to be 10–30′. The sharpness of the split lines indicates that neither side is much distorted.

(*b*) 99.55% *aluminium*

Unstrained single crystals of 99.55% aluminium produce as good Kikuchi patterns (Photo. 4a) as 99.99% aluminium. When, however, a crystal is elongated about 3% Kikuchi patterns become diffuse on the entire surface of the crystal (Photo. 4b) even by the large angle convergent beam method. At about 7% elongation no Kikuchi lines are produced and only diffuse Kikuchi bands remain. Under a light microscope no distinct deformation bands are observed. By electron diffraction no alternation of good Kikuchi patterns and diffuse Kikuchi bands are observed. This fact

is essentially different from that observed in 99.99% aluminium.

### (*c*) *Study of the interior of crystals*

When the surface layer is removed by electro-polishing, no definite change was found in diffraction patterns for either 99.99% or 99.55% aluminium* (Photos. 5a, 5b, 5c, and 5d). We could recognize no change in sharpness of Kikuchi lines or in the relative intensity of the background. The microphoto-

---

* For 99.55% aluminium we had one exception in four specimens (No. 8) where no pattern was observed before removal of surface layer, but diffuse Kikuchi patterns were produced after removal. This is probably due to failure in electro-polishing before the first examination.

meter curves along the line segments indicated in Photos. 2a and 5a are reproduced in Fig. 6. No remarkable change is found in the width of Kikuchi lines. For 99.99% aluminium the alternation of sharp Kikuchi lines and diffuse Kikuchi bands was also observed. Strictly speaking, however, we observed slight changes but they did not take definite form; in some cases patterns were improved and in other cases they deteriorated. Such changes are inevitable because the grade of Kikuchi patterns depends not only on the irradiated position but also on the surface topography and the glancing angle. Therefore it is dangerous to draw conclusions by observing slight changes which are generally of trivial importance.

Experimental results may be set forth as:

(1) For high purity crystals, (a) laminar regions produce Kikuchi lines even at 10% elongation, but (b) deformation bands do not produce Kikuchi lines;

(2) For low purity crystals, Kikuchi lines become diffuse at 3% elongation over the whole crystal surface. They are extinguished at about 7% elongation;

(3) Irrespective of the purity of crystals, no recognizable change occurs when a surface layer of about 100 microns is removed.

## § 4. Discussion

### (*a*) *Comparison with the result of Heidenreich and Shockley*

According to Heidenreich and Shockley, when aluminium single crystals are elongated several percent, they have two results: (1) Kikuchi lines are extinguished and (2) Laue spots become multiple. Although their result (1) apparently contradicts our result (1a, § 3c), there is no physical contradiction between them. The apparent contradiction is caused by the difference in the size of the irradiated area. Even in our experiment, Kikuchi lines are extinguished if the irradiated area is increased by defocusing. Heidenreich and Shockley's result (1) is reasonable because the length of the irradiated area was more than 1 mm. Moreover, in their experiment the irradiated area might include deformation bands which extinguish Kikuchi lines.

Based upon their result (2) Heidenreich and Shockley suggested that " the slip band is not a region where only translation has occurred but that rotation about the normal to the slip plane occurs also ". From the splitting of Laue spots in their photographs the angle of rotation is estimated to be the order of $10^{-2}$ radians. Although their suggestion has been cited as an experimental evidence of rotational slip in authoritative literatures[9)10)], our result (1) contradicts their suggestion. In our experiment with large angle convergent beam method, a few slip bands are irradiated simultaneously because the irradiated area is about $5\times20$ sq. microns. Therefore, if there was rotation of the order of $10^{-2}$ radians about the normal to the slip plane, Kikuchi lines would have split into several lines. Since we have never observed such a splitting, we conclude that no such rotation exists. Even if the rotation did exist, it would have to be less than $10^{-3}$ radians which is the resolving power of the present experiment.

It is more likely that the splitting of Laue spots observed by Heidenreich and Shockley is due to deformation bands. The rotation of about $10^{-2}$ radians is the same order of rotation due to deformation bands. The splitting of Laue spots can be caused by random sampling of surface undulations (Fig. 3) although the bending due to deformation band is continuous. Moreover, the splitting is better interpreted by rotation about $[12\bar{1}]$-axis which lies in the active slip plane than by rotation about $[\bar{1}11]$-axis which is normal to the slip plane. This fact will be described in (c).

### (*b*) *Slip in pure and impure crystals*

Blewitt and Koehler,[11)] interpreted result (1) of Heidenreich and Shockley to be that " the material between successive slip bands contains enough internal strain to cause disappearances of Kikuchi lines". We think that their interpretation is not complete because they did not take into account the size of the irradiated area which is most important in the Kikuchi line experiment. Their interpretation may be correct for low purity crystals* because for these crystals the strain is large enough to extinguish Kikuchi lines even in the large angle convergent beam method. For high purity crystals, however, their interpretation can not be accepted because according to our result (1a) laminar regions produce Kikuchi lines in the large angle convergent beam method.

(*c*) *Deformation bands*

It has been made clear that asterism in *X*-ray Laue photographs is due to a large strain of deformation band[12][13][14]. The strain of deformation bands extinguishes Kikuchi lines and a large disorientation across a deformation band causes a jump of Kikuchi band.

We can study the rotation or bending of the crystal produced by deformation bands by the movement of Kikuchi patterns which is described in the next to the last paragraph of § 3a. This is best shown by a photographic plate on which two Kikuchi bands are recorded where under such a condition only the (111)-band appeared and by analysis it was found that the (111)-plane which produced the band is parallel to the active slip plane. From the distance between the two bands, the angle of disorientation is calculated to be the order of $10^{-2}$ radians. The fact that the two bands are separated from each other indicates that the active slip planes are rotated about the axis which lies in the slip plane. If the slip planes are rotated about the normal to themselves, such a separation can not be expected. This is in accordance with the *X*-ray results obtained by Chen and Mathewson[12] and Nishimura and Takamura[14] which indicate that the rotation axis in elongated aluminium single crystals is $[12\bar{1}]$ in the slip plane and is at right angles to the direction of slip, and that this rotation about the $[12\bar{1}]$ is produced by deformation bands. Thus it is most likely that Heidenreich and Shockley's split spots were given by random sampling of surface undulations and that the rotation corresponding to the split spots was caused by deformation bands.

It is noteworthy that we found splitting of Kikuchi lines coming from laminar regions as described in the last paragraph of § 3a. From the sharpness of Kikuchi lines we infer that the two domain which are disoriented to each other about $3\times10^{-3}$ radians are unstrained in the neighbourhood of the boundary. Therefore, the boundary can be considered to be a polygon-wall. Because dislocations are movable in high purity crystals, dislocations on fine slips may arrange themselves in such polygon-walls. This may be the polygonization without climb suggested by Mott[15].

Heidenreich and Shockley reported that Kikuchi lines were extinguished when an aluminium crystal was loaded near its yield point and simultaneously tapped or brought into vibration although no slip bands were visible. Kuhlmann-Wilsdorf, van der Merwe and Wilsdorf[16] explained this phenomenon as fine slips (not observed by Heidenreich and Shockley) extinguishing Kikuchi lines. However, we believe fine slips do not extinguish Kikuchi lines as we describe in the next subsection. The extinguishing cause of Kikuchi lines in Heidenreich and Shockley's experiment may be weak deformation bands. This is supported by observations of Takamura[17] that in aluminium single crystals weak deformation bands appear even for deformation so small that no slip bands are visible under a light microscope.

(*d*) *Interior of crystals*

Heidenreich and Shockley observed that a lightly tapped surface of aluminium crystals after removal of a surface layer of 200–400 microns in thickness again produced Kikuchi lines. Kuhlmann-Wilsdorf at al[16] ascribed this phenomenon to the location of fine slips in the surface layer. Mott[15], in explaining the appearance of fine slips observed by Wilsdorf et al.[18], suggested that fine slips occur in the surface layer approximately 0.1–1.0 mm. thick and below which only coarse slips occur. Suzuki[19] suggested another explanation for this phenomenon.

According to the experiment of Fujita et al.[2] Kikuchi lines were extinguished by several percent elongation and appeared again after the surface layer had been eliminated by electro-polishing. They reported that the re-appearance of Kikuchi lines took place on a rather definite boundary which lies 10–20 microns below the crystal surface. This result contradicts our result (3), and the cause of contradiction is not clear. However, we should be most careful in drawing any conclusion from an experiment of Kikuchi pattern because the quantitative study of Kikuchi patterns is almost impossible, as described in § 3c.

---

* See our result (2).

Fujita et al. suggested that extinguishing is due to fine slips. They considered that the re-appearance of Kikuchi lines is a proof of the fact that fine slips are confined to the surface layer. However, we believe that fine slips do not extinguish Kikuchi lines. If the fine slips extinguish Kikuchi lines, Kikuchi lines would have been extinguished in the initial stage of elongation. We conclude that neither fine slips nor coarse slips extinguish Kikuchi lines so far as they are laminar. Therefore by this experiment it is impossible to test whether or not fine slips are confined to the surface layer.

(*e*) *Estimation of dislocation density*

From our experimental results we can estimate the density of dislocations by the method described by Cottrell²⁰⁾. Let $\Theta$ denote the total angular spread observed in an irradiated area of diameter L. Let 1 be the mean diameter of a block in the crystal and $\theta$ be the mean angle between neighbouring blocks. For simplicity we assume that one dislocation defines one crystal block, then the dislocation density $\rho$ is given by

$$\rho=1/1^2 \tag{1}$$

If we assume that $\theta$ is randomly positive and negative, we have

$$\Theta=\theta(L/1)^{1/2} \tag{2}$$

Eliminating 1 from (1) by the use of (2) and the relation $\theta=b/1$, we obtain

$$\rho=(\Theta/b\times L^{1/2})^{4/3} \tag{3}$$

where $b$ is the Burgers vector. Using (110)-spacing of aluminium for $b$, $b=3\times10^{-8}$ cm. By the equation (3) $\rho$ is estimated if $\Theta$ and $L$ can be measured.

The measurement of $\Theta$ and $L$ in the experiment of Kikuchi lines is not easy. However, it may be adequate to assume that sharp Kikuchi lines disappear when the angular spread $\Theta$ in the irradiated area is about $1\times10^{-3}$ radians. Therefore, if we measure the value of $L_0$, at which sharp Kikuchi lines disappear, dislocation density $\rho$ can be estimated. In our experiment the size of the irradiated area can be easily changed by focusing. Although we did not carry out exact measurements in the present experiment, the order of magnitude of dislocation density was estimated as follows.

*Unstrained crystals of* 99.99% *and* 99.55% *aluminium.* Our specimens of unstrained crystals produce very sharp Kikuchi lines which do not disappear even when the area of irradiation is increased to $L=7\times10^{-2}$cm. Thus we obtain

$$\rho\simeq6\times10^6 \text{ lines/sq. cm.}$$

This result is much smaller than the usually accepted value $10^8$–$10^{10}$ lines/sq. cm. but is in agreement with the more recent value $10^6$ lines/sq. cm. obtained by Noggle and Koehler²¹⁾ for well annealed aluminium single crystals.

*Laminar regions of* 99.99% *aluminium.* In the laminar regions of 10% elongated crystals, Kikuchi lines disappear when the convergent electron beam is slightly defocused. Although the value of $L_0$ was not measured exactly, it was estimated to be the order of 50 microns. Thus we obtain

$$\rho\simeq4\times10^7 \text{ lines/sq. cm.}$$

This indicates that the dislocation density at 10% elongation increases about ten times.

*Deformation band of* 99.99% *aluminium.* In the region indicated by *B*, *C*, and *D* in Fig. 4, only diffuse Kikuchi bands remain even for the irradiated area of 5×20 sq. microns. From the width of Kikuchi band we may assume that $\Theta$ is about $5\times10^{-3}$ radians. Taking $L_0=20$ microns, we obtain

$$\rho\simeq6\times10^8 \text{ lines/sq. cm.}$$

This density is far less than that usually accepted value $10^{12}$ lines/sq. cm. for heavily worked metals even when it is taken into account that deformation is not very heavy in the present experiment. In the above value the dislocations on boundary walls are not considered. If they were estimated and included, the density would be increased.

*Elongated* 99.55% *aluminium.* At 3% elongation, sharp Kikuchi lines disappear for $L_0$ of 20 microns. Thus we obtain

$$\rho\simeq2\times10^8 \text{ lines/sq. cm.}$$

At 7% elongation, only diffuse Kikuchi bands remain as in deformation bands of 99.99% aluminium crystals. Thus the density is increased to

$$\rho \simeq 6\times10^{8}\ \text{lines/sq. cm.}$$

Although the above is a rough estimation of dislocation density, we can recognize the fact that the density in laminar regions of high purity aluminium is very much smaller than that in low purity aluminium. This may be due to the good mobility of dislocations in high purity aluminium.

### Acknowledgement

The author wishes to express his sincere thanks to Prof. Ryozi Uyeda for his kind guidance and encouragement throughout the entire course of this experiment. He also wishes to thank Dr. F. E. Fujita for his stimulating discussions and for his kindness in furnishing an aluminium single crystal. Thanks are also given to Mr. Y. Fukano and Mr. T. Fukatsu for their assistance in the early stage of this experiment.

This study has been supported in part by a Grant in Aid for Scientific Research from the Ministry of Education.

# The Study on Substances having the Ilmenite Structure I. Physical Properties of Synthesized $FeTiO_3$ and $NiTiO_3$ Ceramics

By Yoshikazu ISHIKAWA and Shozo SAWADA

*Institute of Science and Technology, University of Tokyo*

(Received December 2, 1955)

$FeTiO_3$ and $NiTiO_3$ ceramics were synthesized, their thermal, electrical and magnetic properties were investigated and the results obtained were discussed in connection with the crystal structure. Although $NiTiO_3$ is stable up to high temperatures even in air, $FeTiO_3$ is partially oxidized even when it is cooled, being kept in vacuum ($10^{-5}$ mmHg), to room temperature from the maturing temperature (1350°C). Electrical and magnetic properties of annealed $FeTiO_3$, therefore, differ greatly from those of $NiTiO_3$, but properties of quenched $FeTiO_3$, tend to those of $NiTiO_3$. From these facts, it is concluded that the properties of $NiTiO_3$ are characteristics of the ilmenite structure.

In discussion attention was paid especially to the relation between the ilmenite structure and its magnetic properties and to the mechanism of electrical conduction, and it was speculated, from these considerations, what kind of roles $Ti^{4+}$ ions would play in this structure.

## §1. Introduction

Ilmenite ($FeTiO_3$), which is a common constituent of the igneous rocks has recently come to attract special attention of physicists in the field of rock ferromagnetism. Its crystal structure is nearly equal to that of $\alpha$-Hematite1) and natural Ilmenite has weak spontaneous magnetization having the Curie point at about 100°C2), the origin of which is thought to be the same as that of parasitic ferromagnetism in $\alpha$-Hematite. So judging from these results some authors have suggested Ilmenite might be also antiferromagnetic3)4).

On the other hand, $LiTaO_3$ and $LiNbO_3$ which have the ilmenite structure have been reported to be ferroelectric5). It is not easy, however, to imagine that the spontaneous polarization induced by shifting of Ta or Nb ions within distorted oxygen octahedrons follows the reversal of external electric field in such a low symmetrical structure contrary to the perovskite structure which has the higher symmetry. Hence Megaw has proposed an idea that $LiTaO_3$ and $LiNbO_3$ do not belong to the ilmenite structure strictly6). But no detailed investigation of the ferroelectricity of the ilmenite structure has been done until now.

These facts indicate that this structure is interesting from both magnetic and dielectric points of view, and furthermore, considering the fact that this substance contains ferrous ions which have a partially filled $d$-shell, the mechanism of conduction is also thought to be worth investigating.

There have been, however, only a few reports on the measurement of physiclal properties of synthesized Ilmenite. Naylor and Cook, and Shomate measured the heat capacity in a temperature range between 52°K and 1800°K7)8) and Chevallier measured the magnetic susceptibility below room temperature9). The former reported only a marked hump on the heat capacity vs. temperature curve at 52°K which, according to the authors' opinion, is not uncommon in the ferrous ions componds, and the latter reported the paramagnetic property of Ilmenite. In both cases, however, the results obtained were not fully discussed in connection with the crystal structure.

We, then, intended to synthesize Ilmenite as purely as possible, investigate its many physical properties and discuss them in connection with the crystal structure. At the same time, properties of synthesized $NiTiO_3$ which has the same crystal structure as Ilmenite were investigated so that we may clarify the obscurity in Ilmenite which comes from the unstableness of ferrouss ions and may understand the intrinsic character of the ilmenite strucuture.

## § 2. Preparation of Samples

$FeTiO_3$ (sample I) was prepared by stoichiometrically mixing $Fe_2O_3$, $TiO_2$ and Fe powders following the equation

$$Fe_2O_3+3TiO_2+Fe=3FeTiO_3\ ;$$

milling, pressing and sintering the mixture in a vacuum furnace ($10^{-5}$ mmHg) at 1350°C for six hours, then cooling it down to room temperature in an hour in this furnace. Quenched sample of $FeTiO_3$ (sample II) was prepared by sealing sample I into a silica tube in vacuum ($10^{-5}$ mmHg), heating it again up to 1250°C and then quenching it. $NiTiO_3$ was prepared by heating a mixture of NiO and $TiO_2$ powders in stoichiometric proportion at 1350°C in air for three hours.

$Fe_2O_3$, $TiO_2$ and NiO powders used were purified at our laboratory and it was confirmed that they contained no detectable impurities. Fe powder was carbonyl iron (99.99% purity). Chemical analysis for both iron and titanium in $FeTiO_3$ prepared indicated the ratio of iron and titanium was 0.9945:1, where the lack of iron was due to the existence of unreacting $Fe_3O_4$ which was washed out with dil. $HNO_3$ before this analysis. No other impurities were detected.

The crystal structure of these samples was checked by Debye-Sherrer X-ray photographs. The lattice constants obtained are given in Table I.

Table I. Lattice constants of synthesized $FeTiO_3$ and $NiTiO_3$.

| Samples | $a$ (Å) | $\alpha$ |
|---|---|---|
| $FeTiO_3$ (sample I) | 5.55 (5.52) | 54°23′ (54°49′) |
| $NiTiO_3$ | 5.44 (5.45) | 54°49′ (55°08′) |

Values in the brackets are due to Wyckoff.

## § 3. Thermal Expansion

Thermal expansion was measured in air using a simple dilatometer in order to detect any anomalies present in these samples over a range of temperatures between liquid air and 1000°C. No anomalies could be found for $NiTiO_3$, but $FeTiO_3$ (sample I) showed an anomalous expansion from about 420°C ceasing at about 800°C, when heated at the rate of 2°C/sec. (Fig. 1). On cooling, the contraction followed along a broken line illustrated in the figure, which fact indicates this phenomenon is irreversible and seems to be due to the oxidation of the sample.

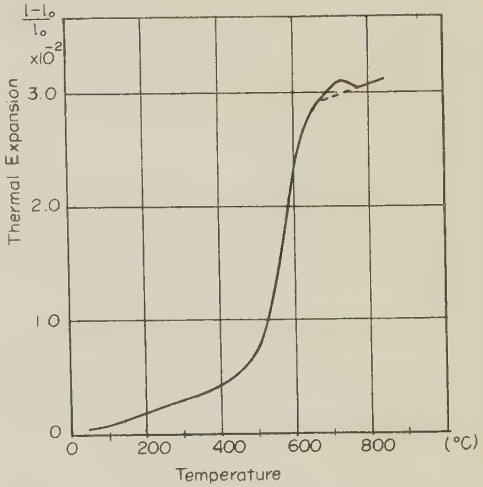

Fig. 1. Thermal expansion of $FeTiO_3$ (sample I) measured in air. The heating rate was 2°C/sec.

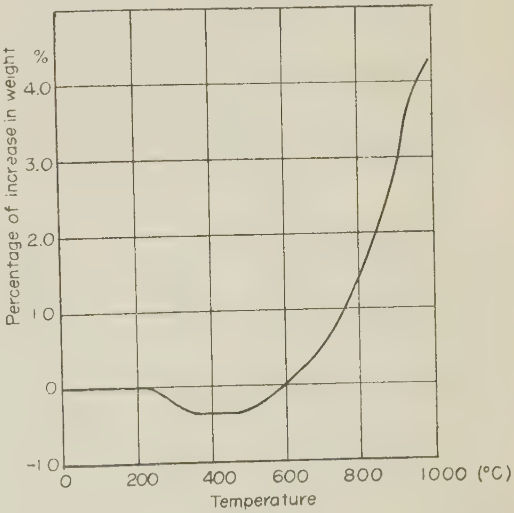

Fig. 2. Percentage of increase in weight of $FeTiO_3$ (sample I) during heaing it at the rate of about 4°C/sec in air.

## § 4. Weighing with a Thermal Balance

In order to confirm the anomaly detected in the above observation to be due to the oxidation, the increase of weight during heating was measured using a thermal balance. The heating rate was about 4°C/sec and a powder sample of 1 g weight was used. The result is shown in Fig. 2, where a decrease of weight from 200°C to 500°C may be an apparent one resulting from ejecting out gases which were

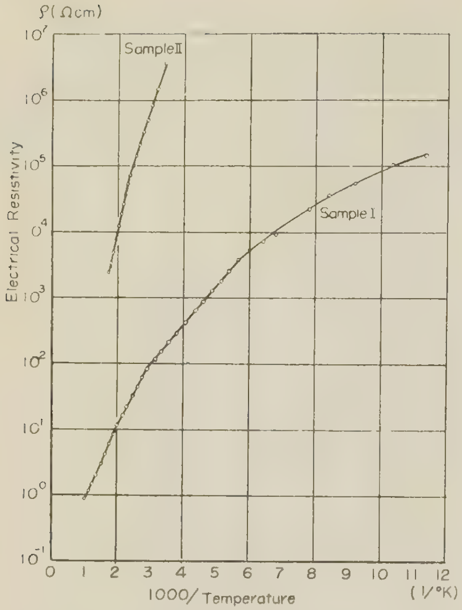

Fig. 3. Direct current resistivity of $FeTiO_3$ measured in vacuum.

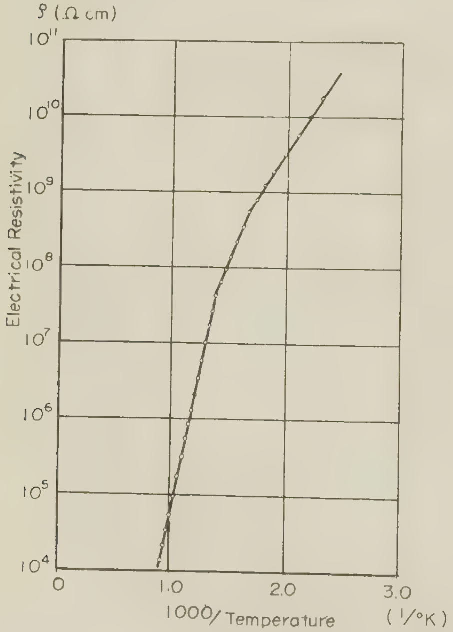

Fig. 4. Direct current resistivity of $NiTiO_3$ measured in air.

present in the powder. The increase of weight at 1000°C was 4.62% and when keeping it at this temperature for a long time it increased up to about 5%, but it is still less than the theoretical value 5.27% calculated assuming all $Fe^{2+}$ in $FeTiO_3$ changed into $Fe^{3+}$.

We find from these results that $FeTiO_3$ is stable even in air up to about 500°C, so measurements can be made in air reproducibly in this temperature region.

Table II. The values of $\rho_0$ and $E$.

| Samples | Temperature ranges | $\rho_0$($\Omega$ cm) | $E$(ev) |
|---|---|---|---|
| $FeTiO_3$ (samples I) | −61.7°C~ 80.3°C | $1.45\times10^{-1}$ | 0.249 |
| | 80.3°C~ 186.0°C | $1.35\times10^{-2}$ | 0.389 |
| | 186.0°C~ 800°C | $8.00\times10^{-3}$ | 0.426 |
| $FeTiO_3$ (sample II) | ~ 180.3°C | 7.00 | 0.662 |
| | 180.3°C~ 300°C | $2.10\times10^{-2}$ | 0.934 |
| $NiTiO_3$ | ~ 310°C | $1.00\times10^{5}$ | 0.901 |
| | 310°C ~ 440°C | $1.60\times10^{2}$ | 1.52 |
| | 440°C ~1000°C | $8.20\times10^{-3}$ | 2.83 |

## § 5. Electrical Conductivity

Direct current resistance was measured by using a potential probe method on low resistance samples, or by reading the current through a sample using a galvanometer on high resistance ones. The dimension of samples used in both cases were approximately 4 mm × 3 mm × 20 mm.

$FeTiO_3$ (sample I) was measured both in vacuum (between liquid air temperature and 800°C) and in air (from 0°C to 400°C), and both results showed no difference. Quenched $FeTiO_3$(sample II) was measured only in vacuum (from 0°C to 300°C) and it was found we could safely repeat the measurement reversibly in this temperature range. These results are given in Fig. 3, which shows the resistivity obeys the formula $\rho=\rho_0 \exp(+E/2kT)$ above room temperature and values of $\rho_0$ and $E$ are given in Table II. Fig. 4 shows the resistivity of $NiTiO_3$ measured in air. The values of $\rho_0$ and $E$ are also given in Table II.

## § 6. Seebeck Effect

Seebeck effect was measured in order to understand the mechanism of conduction. Measurements were made in air by putting Pt–PtRh thermo-junctions on both sides of a sample, and thermo-electric power was measured with respect to a PtRh wire. A temperature gradient was established by putting the sample in an eccentric position of a furnace or heating one side of the sample by an auxiliary heater, and temperature difference between both ends was usually about 5°C at low temperatures and 10°C at high temperatures. The results obtained are shown in Figs.

5 and 6. It was found that the sign of thermoelectric power is positive in both cases.

## § 7. Dielectric Constant and Loss

A sample of 130 mm² area and 1.2 mm thickness with fired-on Ag films on both sides was used in the case of $NiTiO_3$. A resonance method was adopted and the result was shown in Fig. 7. The value of dielectric constant at room temperature is about 13, which is very small for a substance containing $Ti^{4+}$ ions surrounded by oxygen octahedrons and this fact supports the supposition that it would be difficult for $Ti^{4+}$ ions to move following the external electric field in this structure, as expected previously. Increase in permittivity above 200°C is an apparent one which is on account of increase in conductivity. Although we may thus expect this structure has little possibility for ferroelectricity, $D\sim E$ hysteresis loop which is considered to be the most typical characteristic of ferroelectrics can not be observed for such a unipolar substance as this, if existed, unless we use a single crystal, so we can not say any more about ferroelectricity of this crystal structure.

Though dielectric constant of $FeTiO_3$ (sample I) can not be measured with the present method owing to its high conductivity and low permittivity, we may expect the same situation.

Table III. The values of $C$, $\Theta$ and $\mu_{eff}$.

| Samples | $C$/gr | $\Theta$ | $\mu_{eff}$ |
|---|---|---|---|
| $FeTiO_3$ (sample I) | 0.0206 | 65°C | 5.02 |
| $FeTiO_3$ (sample II) quenched from 1250°C | 0.0221 | 30°C | 5.20 |
| $FeTiO_3$ quenched from 1350°C | 0.0260 | 17°C | 5.62 |
| $NiTiO_3$ | 0.0096 | 0°C | 3.47 |

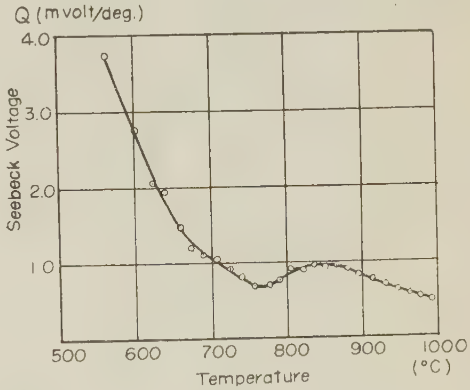

Fig. 6. Seebeck voltage of $NiTiO_3$ measured in air.

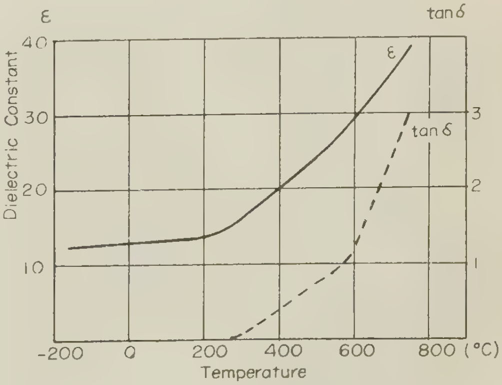

Fig. 7. Dielectric constant and tan $\delta$ of $NiTiO_3$ measured in air.

## § 8. Magnetic Susceptibility

Magnetic susceptibility of these samples above room temperature was measured using a magnetic balance which can detect one percent of a milligram. It was found all samples obey the Curie-Weiss law $\chi=C/T-\Theta$ in this temperature region and the values of $C$, $\Theta$ and the effective Bohr magneton number calculated from the Curie constant are given in Table III. In Table III, we can find the more perfect quenching is the smaller $\Theta$ and the greater $\mu_{eff}$ become, and this can be explained if we consider $FeTiO_3$ may be oxidized even in the vacuum furnace ($10^{-5}$ mmHg) during cooling it, that is, metal vacancies produced by addition of excess oxygens de-

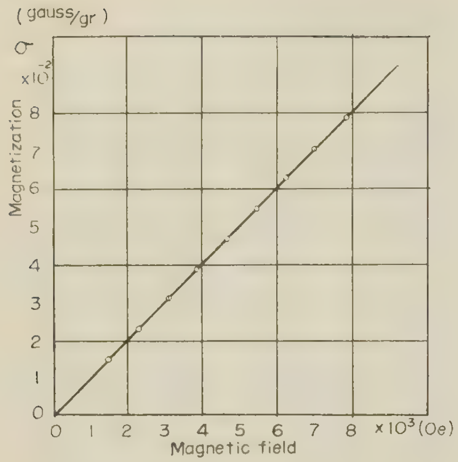

Fig. 8. Field dependence of magnetization of $FeTiO_3$ (sample I) at room temperature.

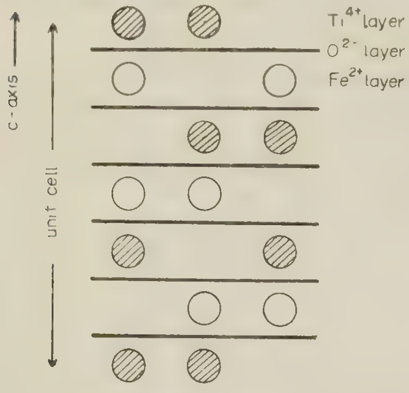

Fig. 9. Schematical representation of the arrangement of ions in Ilmenite.

crease the apparent value of effective Bohr magneton number and some distortion of crystalline field due to the presence of excess oxygens or metal vacancies increases the value of $\Theta$ as was suggested by Van Vleck.[10] This explanation is supported by the fact that quenching and annealing did not affect the behavior of magnetic susceptibility in the case of $NiTiO_3$. The values of the sample quenched from 1350°C agree well with those of Chevallier's sample which was sintered in the hydrogen atmosphere.

Fig. 8 shows the field dependence of magnetization in $FeTiO_3$ (sample I) at room temperature, which indicates clearly there is no spontaneous magnetization in the synthesized Ilmenite, and together with the Chevallier's results and that for $NiTiO_3$, we can conclude spins in the ilmenite structure are left free in the whole temperature region.

## § 9. Discussion

### 1. *Ilmenite structure and its magnetic properties*

According to the X-ray analysis of natural Ilmenite, the arrangement of ions in Ilmenite can be written schematically as shown in Fig. 9. In this configuration, $Fe^{2+}$ ions' and $Ti^{4+}$ ions' layers which are perpendicular to the c-axis are arranged alternately and each is seperated by an oxygen layer. Consequently the superexchange interaction which operates between spins of $Fe^{3+}$ ions through this oxygen layer in $\alpha$-Hematite where $Fe^{2+}$ and $Ti^{4+}$ ions in Ilmenite are all replaced by $Fe^{3+}$ ions can not operate in Ilmenite because of $Ti^{4+}$ ions having zero spin. It is, therefore, rather plausible that spins of $Fe^{2+}$ ions are left free as our experimental results showed and the fact that $NiTiO_3$ and $FeTiO_3$ (unoxidized) have very little $\Theta$ values indicates the dilution of $Ni^{2+}$ and $Fe^{2+}$ ions by $Ti^{4+}$ ions in this structure is nearly perfect.

There are, however, two interesting points relating to this structure. Firstly, if the ordering of $Fe^{2+}$ and $Ti^{4+}$ ions were disturbed, magnetic properties of $FeTiO_3$ would be greatly changed because of the local formation of $Fe^{2+}-O^{2-}-Fe^{2+}$ configuration in it. But the fact that the behavior of magnetic susceptibility of the sample quenched even from above the melting point (1450°C) tends only to be perfect paramagnetic shows, together with the fact that the heat capacity of Ilmenite has no anomaly up to 1800°K in the high temperature region, the disturbance of the order seems not to occur up to this temperature.

Next, when $Ti^{4+}$ ions are partially replaced by other ions having no vanishing spins, it is expected the superexchange which operates between these ions and $Fe^{2+}$ or $Ni^{2+}$ ions through oxygen ions might arrange their spins antiperallel, then an uncompensating component would appear as a spontaneous magnetization and this is realized in the case of solid solutions of $NiTiO_3$ or $FeTiO_3$ and $\alpha-Fe_2O_3$,* details of which will be reported soon.

### 2. *Mechaism of electrical conduction*

The great difference in conductivity between the sample I and sample II of $FeTiO_3$ indicates the conduction in these substances is due to *d*-electrons, that is, as stated in the above paragraph, metal vacancies produced by addition of excecss oxygen contribute to the conduction by changing surrounding $Fe^{2+}$ ions into $Fe^{3+}$ ions and increasing the number of $Fe^{2+}$ ions adjacent to $Fe^{3+}$ ions, which is believed to be the cause of increase of the conductivity of *d*-electrons by many investigators. Carriers in this case are necessarily holes trapped by these metal vacancies.

---

* As to solid solutions of $FeTiO_3-Fe_2O_3$ which were produced naturally, see the reference (2).

Then assuming only holes are carriers, we have the following relations between Seebeck voltage $Q$, concentration of carriers $n_p$ conductivity $\sigma_p$ and mobility $\mu_p$,

$$eQT=E\,, \qquad (1)$$

$$\sigma_p=n_p\mu_p e\,, \qquad (2)$$

$$n_p=N\exp(-E/KT)\,, \qquad (3)$$

where $E$ denotes the Fermi level measured from the filled *d*-electron level and $N$ is $1.89\times10^{22}$ Fe atoms/cm³ in this case, and the kinetic energy term in Seebeck voltage was neglected in the equation (1) following Morin's suggestion¹²⁾.

Hole concentration computed from the value at 20°C given in §§5 and 6, is found to be $1.85\times10^{21}$ atoms/cm³ which is not inconsistent with the increase of weight at high temperatures and observed results of magnetic susceptibility, and mobility calculated using these results is $2{,}14\times15^{-5}$ cm²/volt sec which is very low even comparing with that of carriers in $\alpha$-Hematite having the lowest concentration of carriers. This suggests that $Ti^{4+}$ ions which may not contribute to conduction in this substance prevent *d*-electrons of $Fe^{2+}$ ions from overlapping and reduce their mobilitiy greatly.

On the other hand, in the case of $NiTiO_3$ we can expect both holes and electrons are contributing to conduction as is usually the case with intrinsic semiconductors. Then an analysis is not easy but a rough estimation shows concentration of carriers is very low and mobility is relatively high, so conduction is not expected to be that of *d* levels. We may assume, then, in this case holes which were left in the *sp*. bands of oxygen by jumps of their electrons into unoccupied $Ni^{2+}$ levels (that is, to $Ni^{3+}$ ions) contribute to conduction, which results in high mobility. Though the mechanism seems to be complex because $Ti^{3+}$ ions may contribute to conduction in this case, we may safely say conduction in only *d* levels as in $FeTiO_3$ is hidden because of low concentration of carriers and low mobility.

In conclusion, we should like to say $Ti^{4+}$ ions act always as to dilute the interaction between *d*-electrons of divalent metal ions in the ilmenite structure, so properties $NiTiO_3$ where this dilution seems to be perfect are characteristic of the ilmenite structure and are to be contrasted with those of $\alpha$-Hematite where there is no dilution of this sort.

## Acknowledgement

The authors wish to express their thanks to Prof. A. Minami for the spectroscopical and chemical analysis of $FeTiO_3$ and to Mr. S. Nomura for his various discussions.

# Study of Plastic Deformation in Aluminium Crystals by Electron Diffraction and Electron Microscopy

By F. E. FUJITA, D. WATANABE, M. YAMAMOTO
and S. OGAWA

*The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan*

(Received January 11, 1956)

Single crystals of highly pure aluminium (99.99%) were plastically deformed and examined by means of electron microscopy and electron diffraction. Surfaces of the deformed crystals produce innumerable slip lines of various slip amounts and deformation bands. The latter greatly affect the diffraction pattern; Laue spots are split, Kikuchi lines are extinguished, and a very high background results. So that, the diffraction pattern from the crystal part containing deformation bands becomes obscured after only a few per cent elongation. While, the effect of crystal imperfections associated with slip lines on the electron diffraction patterns appears to be considerably small, Kikuchi patterns being obtained from laminar-slip regions in a crystal even after 20% elongation. The local distortions expected from the diffraction patterns cannot be explained in terms of the rotations about the $[\bar{1}11]$ axis or in the active slip planes, but rather consist with the local bendings about the [211] axis due to deformation bands. Difference between the state of plastic deformation in the vicinity of the surface and that in the interior of the crystal is conjectured from the difference between the corresponding diffraction patterns. Some considerations on this point are also made.

## §1. Introduction

Since the first application of electron microscopy and electron diffraction by Heidenreich and Shockley1) to the study of the slip bands on aluminium crystals, quite many electron microscopical investigations on the surface structures of plastically deformed metal crystals have been carried out, and much information on the nature of the plastic deformation of metal crystals by slip mechanism was provided as shown in the follwing.

1. Heidenreich and Shockley1) have shown that in aluminium crystals the slip band was a laminar region resulting from a stepwise slip process. The thickness of the laminae was about 200 Å and the amount of slip on each step surface was about 2000 Å. From the multiple Laue spots in the electron diffraction pattern they have suggested that a relative rotation of adjacent laminae about an axis normal to the slip plane should occur as well as the simple translation. Kikuchi lines were quite sensitive to the state of plastic deformation in their experiment; at about 5% elongation the lines disappeared leaving only the spots unless the electron beam was parallel to the slip traces. It was also found that even the intermittent stress application by slight tapping or vibrating could extinguish the Kikuchi lines.

2. Recent works by Kimoto *et al.*2) have, however, indicated that when the convergent electron micro-beam was focused on the specimen, laminar slip regions of plastically deformed alminium single crystals produced good Kikuchi lines, while deformation bands produced only diffuse Kikuchi bands. The study was begun in a somewhat different way and is still in progress. We deeply owe our undertaking of the present investigation to their early results.

3. Brown3) has confirmed the regular fine structure of the slip bands revealed by Heidenreich and Shockley, but, soon later, he and Honeycombe4) have pointed out that this kind of slip bands was typical of aluminium crystal with the surfaces subjected to a certain kind of cold-working, and that crystals with the purely electropolished surfaces usualy exhibited the irregular slip

band structures including innumerable fine slips when they were stretched.

4. Wilsdorf and Kuhlmannn-Wilsdorf[5] have reported irregular structures of slip bands on polycrystals of aluminium, copper and silver: The slip distances varied continuously from a few Å to 1200 Å or more but always less than 2000 Å. Especially, a very fine surface structure which they called the elementary structure was found covering the whole surface even at the early stages of deformation.

5. The effect of the surface oxide film on the slip band structure was studied by Takamura[6] and the effect of the surface abrasion together with some other effects by Fujita, Suzuki and Yamamoto[7] for aluminium single crystals.

It may be argued from the above-stated that some essential points are necessary to be further investigated: For instance, it should be noted that the experimental results so far obained do not necessarily lead to the same conclusion for the state of plastic deformation of metal crystals, as the results of electron microscopy and electron diffraction are various and, in some cases, inconsistent with one another. It should be also pointed out that such investigations as mentioned above were confined to the observation of merely the surface structure of deformed crystal, the state of affairs in the interior of the crystal being quite unknown. To examine the interior of the deformed crystal, the electron diffraction method will be very powerful if carefully used.

The first aim of the present study was to elucidate the features of plastic deformation on the surfaces of metal crystals by using ordinary microscopy, electron microscopy and electron diffraction simultaneously. The second aim was to search into the deformation structures in the interior of the crystals by means of electron diffraction and to offer some information to the question, whether or not the deformation texture of the interior of the crystals is appreciably different from that of the surface, for which some theoretical predictions have been made.

## § 2. Preparation of Specimens

The specimens employed were single crystals of high purity (99.99%) aluminium grown from the melt in graphite moulds *in vacuo* by Bridgeman's method. The crystallographic orientations of their rod axes and of the surfaces examined are shown in Fig. 1. The original size of the specimens, about 200 mm in length and 3 mm square in cross-section, was reduced in length to 40 mm. by cutting and in cross-section to about 2.5 mm. × 2mm. by abrasion on a series of emery papers from 0 to 05. The distorted surface layer of about 100 $\mu$ in depth was removed by electropolishing in the Jaquet electrolyte (perchloric acid (S.G = 1.55) 220 cc. and acetic anhydride 780 cc.) or in the De Sy Haemers electrolyte (Perchloric acid 200cc., ethylalchol 790cc. and ether 10cc.). The specimens were then annealed at 630~640°C for about 5 hours *in vacuo*. After annealing they were again electropolished very carefully in the Jaquet electrolyte which contained more than 3 grams of aluminium ions in 1000 cc., quickly washed with distilled water and dried. The surfaces prepared in this manner were sufficiently clean and free from sensible oxide film, so they could be examined by the electron microscope and electron diffraction without any disturbance; for instance, sharp Kikuchi lines and Kikuchi bands were easily obtained from these surfaces even after several hours exposure to the atmospheric air.

## § 3. Experimental

### (a) *Tensile Test and Optical and Electron Microscopy*

Seven specimens with the rod axes of four crystallographic directions illustrated in Fig. 1

Table I.

| Specimen | Elongation (Shear strain) | Surface structure |
|---|---|---|
| 100 B | 1% (2.3%) | Laminar slip lines. |
| 100 A | 5% (11%) | Laminar slip lines. Deformation bands with 0.1∼0.5 mm spacings. |
| 108 A | 7% | Laminar slip lines. Deformation bands. |
| 105 | 10% | Laminar slip lines. Deformation bands with 0.3∼1 mm spacings. |
| 109 | 10% | Slip clusters alternated with very broad non-slipped regions. |
| 108 B | 20% | Laminar slip lines. Many deformation bands. |
| 108 C | 55% | Numerous single slip lines. Quite many random deformation bands. |

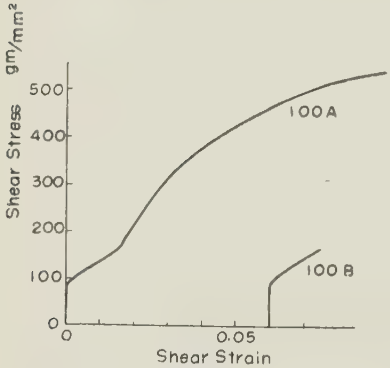

Fig. 2. Stress-strain curves of the specimens 100 A and 100 B.

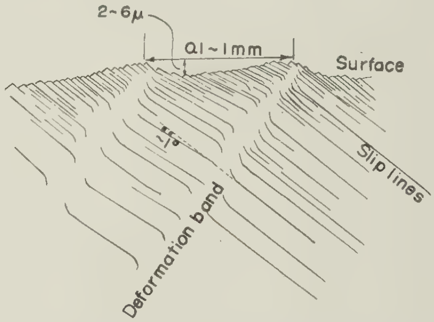

Fig. 5. Schematic representation of vertical section of a plastically deformed crystal.

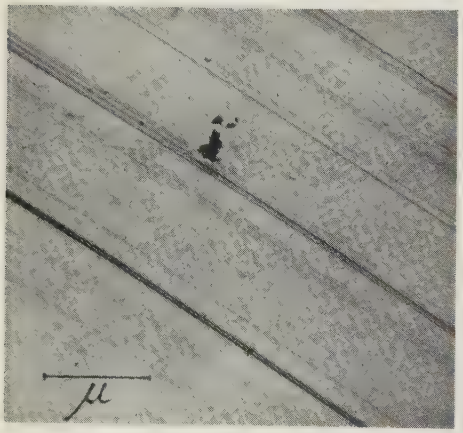

Fig. 3. Electron micrograph of the surface structure of the specimen 108 A after 7% elongation.

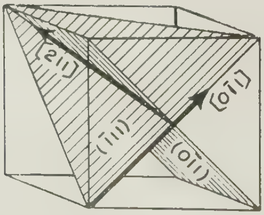

Fig. 4. Relation between some special directions and planes.

were subjected to the tensile test followed by examinations through the ordinary and interferometer microscopes, then electron diffraction photographs were taken immediately after. Some specimens were also examined by means of the electron microscope, collodion one-step chromium-shadowed replica being used. Various amounts of the ultimate tensile deformation cited in Table I were achieved in order to realize the effect of the amount of plastic deformation on the diffraction pattern. A typical stress-strain curve is presented in the left of Fig. 2, which is taken from the specimen 100 A; the critical shear stress is about 90 gms/mm², and the yielding is followed by the linear hardening range or "easy glide" which extends to a few per cent in shear strain, then the range of parabolic hardening.

All specimens except 109 produced laminar slip lines, slip amounts of which varied in a fairly wide range as can be seen in Fig 3. Well-known locally distorted regions, called the deformation bands, were also clearly observed. In general, they form a kind of walls about 0.1 mm. in breadth and nearly in the $(0\bar{1}1)$ plane that is perpendicular to the slip direction $[0\bar{1}1]$, where most of slips are arrested and the crystal is highly distorted and especially bent to an angle of the order of 10° about the [211] axis which is perpendicular to the slip direction [01̄1] and lies in both the slip plane (1̄11) and the deformation band plane (01̄1). The relation between these orientations is illustrated in Fig. 4. Consequently, the original flat surfaces of the specimens had a deformed structure in two topological seneses, after stretched, as shown in Fig. 5, i.e. first the stepwise structure due to the slip lines, in which step heights varied from less than 30 Å to about 1000 Å and their separation distances were a few hundred Å, and secondly the wavy surface unevenness in a larger scale due to the deformation bands, the wave-length of which were from about 0.3 mm. to about 1 mm. and the wave-heights were found by the interferometer-microscope to be several microns. The numbers of slip lines and deformation bands and the local distortion associated with the latter increased with the increasing deformation.

The specimen 100 B, which produced laminar slip lines, exhibited no appreciable deformation bands because of a small amount of tensile deformation, i.e. about 1% elongation, which was in the linear hardening region as illustrated in the right of Fig. 2. The orientation of the specimen 109 was not suitable for single slip, so its stress-strain curve was very steep and parabolic from the beginning. The surface produced neither the regular slip lines nor the deformation bands, but instead another kind of deformation structure, " slip clusters ", in which the main slip lines are clustered into large groups forming broad bands roughly parallel to the active slip plane and they are alternated with bands of similar width in which slip is almost suppressed. These two specimens, 100 B and 109, actually presented behaviours remarkably different from those of the others in producing the electron diffraction patterns.

The mechanical properties and the surface topological structures of the present single crystals subjected to the tensile test were in good agreement with those of previous experiments carried out by other investigators. As will be mentioned below, these made an important rôle in the interpretation of electron diffraction patterns affected by cold-working.

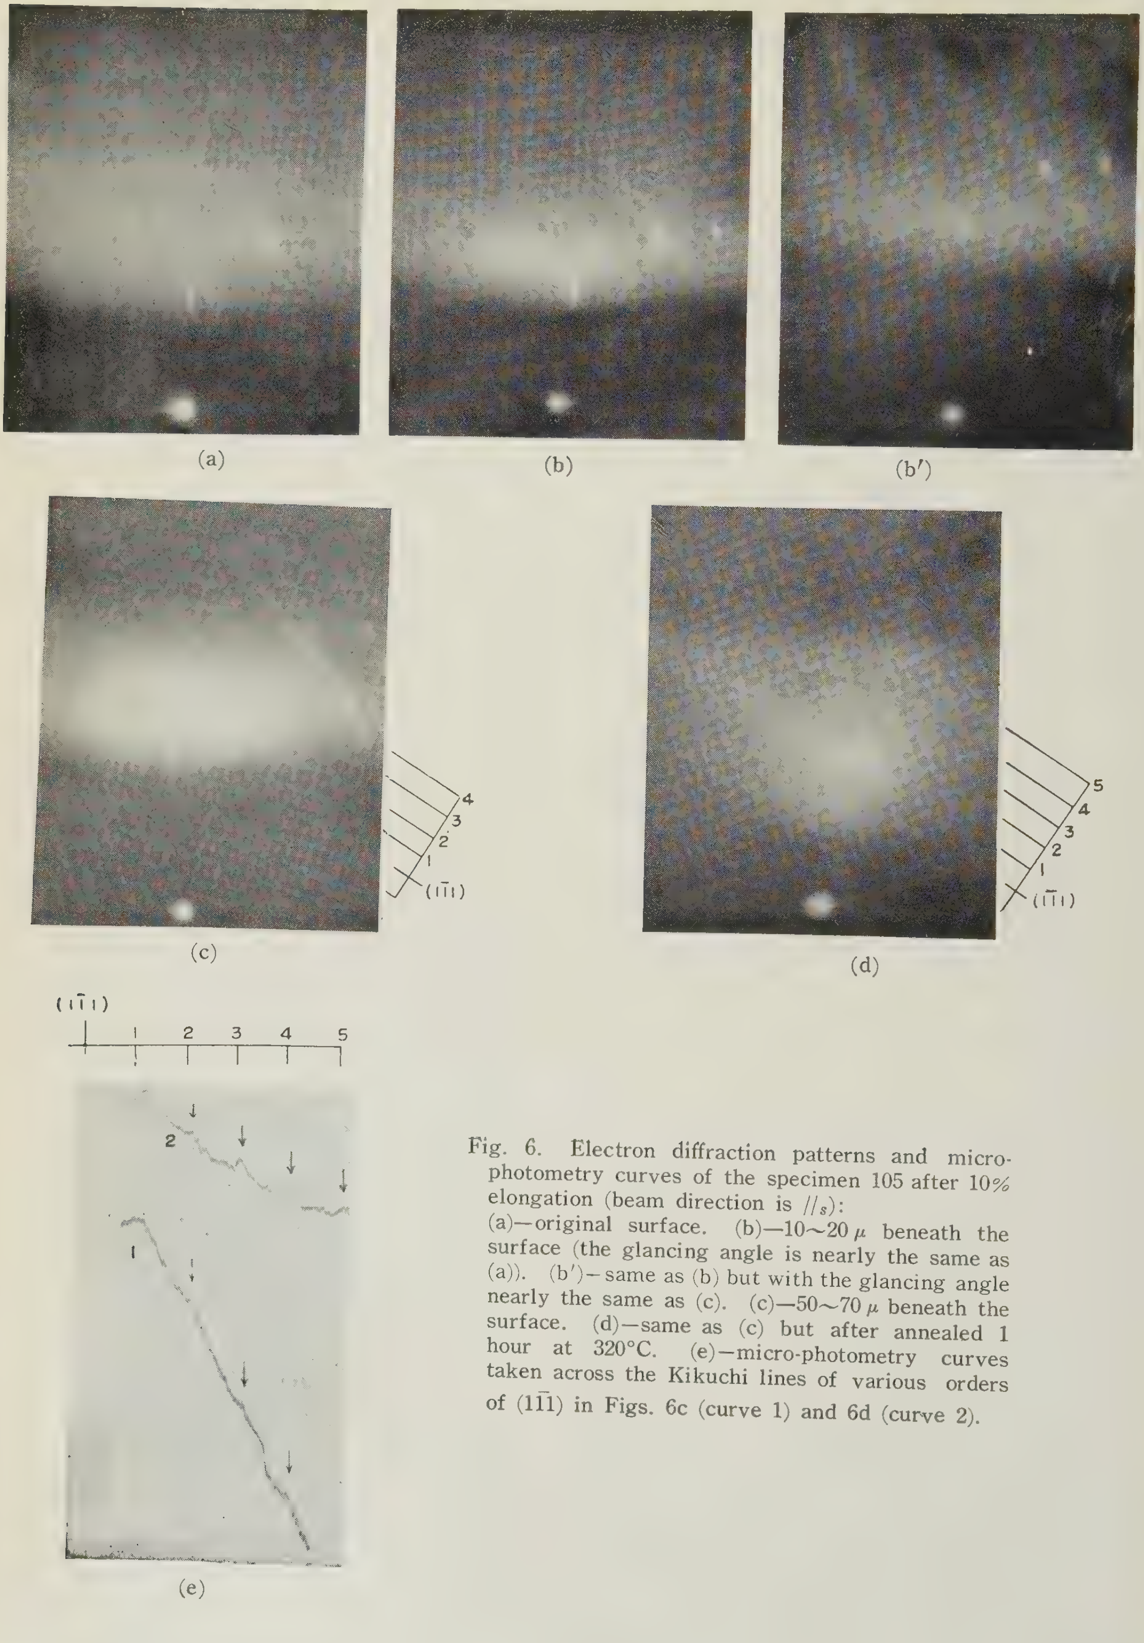
### (b) *Electron Diffraction*

Before and after the mechanical testing, all the specimens were subjected to the electron diffraction study. A diffraction camera with a 309 mm. camera length and the electron beam about 100 $\mu$ in diameter at the specimen, accelerated by finely stabilized high voltage of 50 KV (common with the electron microscope), were employed. The glancing angle of the incident beam was 2∼3° as usual. In consequence, an elliptical domain with its major axis of about 1 mm. long and minor axis of about 0.1 mm. long was illuminated on the surface of the specimen and the crystal near the surface was traversed by the beam to a depth of several 10 Å. This is of great importance in comparing the results of electron diffraction with those of the microscopes.

Before any deformation had occured in the crystal, the reflection pattern consisted of sharp Laue spots and Kikuchi lines as are seen in Figs. 7a, 8a, 8c and 10a. The Laue spots were always small and distinct but stretched towards the shadow edge presumably due to the refraction effect. It was therefore concluded that the crystal surface was feebly undulating but otherwise perfect and flat, so the diffraction pattern was substantially of the reflection type, not arising by transmission of the electron beam through any kind of ragged protuberance. Kikuchi lines were superimposed on a background originating from incoherent scattering in the crystal and more or less in the surface oxide layer. Kikuchi envelopes and Kikuchi bands were also observed in some cases, the latter being of singnificance in this study.

In the preliminary test, two kinds of nasty disturbances were encountered at times; one was narrow splitting of Kikuchi lines showing existence of a small angle crystal boundary likely introduced during the preparation of the specimen, and the other was a high background indicating that the surface finishing by electropolishing had been failed and fairly thick oxide film (probably more than 20 Å) existed on the surface. These unfavourable cases were, of course, excluded as much as possible.

Since at first sight the results of electron diffraction on the plastically deformed crystals were various and rather unsystematic, it seems difficult to give an outline of them in the first



(a) (b) (b′)

(c) (d)

(e)

Fig. 6. Electron diffraction patterns and micro-photometry curves of the specimen 105 after 10% elongation (beam direction is $//_s$): (a)—original surface. (b)—10∼20 $\mu$ beneath the surface (the glancing angle is nearly the same as (a)). (b′)—same as (b) but with the glancing angle nearly the same as (c). (c)—50∼70 $\mu$ beneath the surface. (d)—same as (c) but after annealed 1 hour at 320°C. (e)—micro-photometry curves taken across the Kikuchi lines of various orders of (1$\bar{1}$1) in Figs. 6c (curve 1) and 6d (curve 2).

place. It may rather be adequate to begin by describing individually the results obtained from each specimen, then to have a general aspet therefrom.

The specimen 105 was first deformed to 10% elongation. When the incident beam was nearly parallel to the slip traces, the background considerably increased, Laue spots were generally broadened, and Kikuchi lines extremely diffused as in Fig. 6a. When the beam was normal to the slip traces, the changes of the diffraction pattern due to tensile deformation were not essentially different from the above case, although slightly clearer patterns were obtained.

From these incipient results some conjectures were made as follows: There might be many local distortions, presumably due to the deformation bands, in the crystal, which are responsible for the severe changes of the diffraction pattern, for instance, such that splitting of spots and disappearance of Kikuchi lines. If, therefore, the incident beam favourably gets in a region which does not contain the strongly distorted places, the diffraction pattern will suffer less disturbance, as actually obtained by chance. The fact that Laue spots generally split into a few and the corresponding misorientations in the crystal were of the order of 1° seemed to support these conjectures, since the area illuminated by the incident beam on the crystal surface was of such an order as to accommodate a few deformation bands in usual situations and the misorientation between two crystal portions bounded by a deformation band was likely to fit the observed value. In order to ascertain these, more systematic observations were made on the other specimens; for instance, the crystal surface was scanned with the electron beam, azimuth of the beam was taken to be parallel and normal to the traces of the deformation bands, the specimen without appreciable deformation bands was examined, etc. The results thus obtained were exactly such as what should be expected, which will be mentioned respectively in the following.

A further investigation was intended on the specimen 105 to elucidate whether the state of plastic deformation in the interior of the crystal appreciably differs from that near the surface. The surface which produced the obscure patterns as in Fig. 6a was electropolished for about 5 minutes in the Jaquet electrolyte which was kept below 10°C; this caused removal of metal $10\sim20\,\mu$ thick from the surface, the velocity of dissolution of aluminium by this method being in thickness about $3\,\mu$/min. Then, the diffraction pattern appeared to become clear slightly, irrespective of the beam direction, as in Figs. 6b and 6b′ (Fig. 6b should be compared with Fig. 6a because of nearly the same glancing angle). Further electropolishing was done to expose the interior of the crystal to the depth of $50\sim70\,\mu$, and the pattern became undoubtedly sharper than the former ones, as in Fig.6c,(which should be compared with Fig. 6b′) in which the sharp Laue spots, Kikuchi lines (especially lines of various orders of $(1\bar{1}1)$) and Kikuchi bands can be seen. It was feared that there might have been produced any annealing effect on the crystal near the dissolving surface during electropolishing. So, the crystal suffering removal of the surface to a depth of $50\sim70\mu$ was actually annealed 1 hour at 120°C *in vacuo* and then very slightly electroplished. Although this heat treatment was thought to be more effective than that conceivable in electropolishing in the prior treatment, no changes on the diffraction pattern were presented. Whereas, the stronger annealing, 1 hour at 320°C *in vacuo*, additionally imposed upon the same specimen clearly raised further restoration of Kikuchi lines, as shown in the diffraction pattern of Fig. 6d and the microphotometry curves of Fig. 6e. Consequently, the annealing effect by electropolishing seemed to be improbable, and it was supposed that the deeper the crystal part from the surface of the deformed specimen the more perfect it became and correspondingly the clearer the diffraction pattern appeared.

The specimens 100A and 100B having a common crystallographic orientation given in Fig. 1 were submitted to more precise examinations. For the former specimen, four beam directions were chosen as follows; parallel to slip traces, normal to slip traces, parallel to deformation bands and normal to deformation bands, which we shall denote by $//_s$, $\perp_s$, $//_d$ and $\perp_d$ respectively. The results of the diffraction tests in these four cases are given in the following:

(1) $//_s$. Owing to the unsuitable orienta-

tion, Laue spots were not observed whether before or after the tensile deformation. After the deformation Kikuchi lines from those crystal planes which were nearly perpendicular to slip planes were barely observable, while those of the other kinds were absent.

(2) $\perp_s$. Most of the spots split, showing discrete relative rotations of various parts of the crystal. Very weak Kikuchi lines were also observable.

(3) $//_a$. The spots were multiple, but some regions produced single spots during scanning of the surface with the electron beam. This fact, together with the result obtained from the specimen 105, suggested that multiplication of Laue spots would not be caused by the relative rotations in activated slip planes but produced by another kind of rotations in a larger scale, probably due to deformation bands as illustrated in Fig. 5. The angle of the rotation was again of about 1°. The Kikuchi lines were diffuse even when accompanied with the single Laue spots, but they were not weak.

(4) $\perp_a$. The spots generally broadened and split as well. The spots from the crystal planes with certain indices, however, did not exhibit appreciable splitting, so that the corresponding rotations should be confined to a certain kind, say, the rotation about some definite axis. According to the concept that these splittings are due to the relative rotations or bendings between the crystal parts sectioned by the roughly parallel deformation bands, the axis of rotation most conceivable is [211] which is in the slip plane $(\bar{1}11)$ and the plane of deformation band $(0\bar{1}1)$ and consequently perpendicular to the slip direction $[0\bar{1}1]$ as shown in Fig. 4. No Kikuchi lines were visible presumably due to the screening effect of surface undulation provoked by the deformation bands; as presented in Fig. 5, slipped but otherwise perfect regions between deformation bands are generally screened from the incident beam by the wavecrests where the deformation bands exist, so that the greater part of the beam will illuminate the highly distorted parts of the crystal and produce the exceedingly diffuse Kikuchi lines difficult to observe unless the incident beam is more or less parallel to the deformation bands. This screening effect of the deformation band was found to be a general tendency, so it should possibly be rejected if the effect of crystal imperfections produced by the simple slip mechanism on Kikuchi lines is to be investigated.

From this point of view, the specimen 100 B which was stretched to only 1% elongation was examined to elucidate to what extent the Kikuchi lines will be affected by the pure laminar plastic flow. As already stated, the specimen in reality had laminar slip lines and no remarkable undulation, i.e. no appreciable deformation bands. Laue spots after the deformation did not exhibit any detectable change as expected. Hence, the concept that

| Specimen 105 (10% elong.) | | Specimen 100 A (5% elong.) | |
|---|---|---|---|
| Depth | General aspect of diffraction pattern | Depth | General aspect of diffraction pattern |
| 0 $\mu$ (surface) | Obscured pattern with a high background, Kikuchi lines extremely diffuse and Laue spots diffuse. | 0 $\mu$ | Obscured pattern. |
| | | 1 $\mu$ | Much the same obscured pattern. |
| 10–20 $\mu$ | Slight recovery of Kikuchi lines and Kikuchi bands and decrease of background. | 11 $\mu$ | Very slight recovery of some Kikuchi lines. Fairly clear Kikuchi bands. |
| 50–70 $\mu$ | Clearer change of Kikuchi lines and Kikuchi bands. Sharp Laue spots. | 25 $\mu$ | Recovery of many Kikuchi lines.<br>Clear Kikuchi bands.<br>A weak background. |
| | | 42 $\mu$ | Considerable sharpening of Kikuchi lines. Clear Kikuchi bands.<br>Sharp spots. |
| | | 62 $\mu$ | A slight further recovery. |
| | | 99 $\mu$ | No more appreciable improvement. |

the splitting of Laue spots is due to deformation bands seemed more rigidly confirmed. On the other hand, a close inspection revealed slight broadening and weakening of Kikuchi lines as well as slight increase of the background. Both diffraction patterns before and after the deformation are to be compared in Figs. 7a and 7b. It may, therefore, be stated that in general the diffraction pattern is partly affected by macroscopic local distortions such as deformation bands and partly by somewhat uniformly distributed crystal imperfections associated with the formation of laminar slip lines, the effect of the former being some times so preponderant as to thoroughly cover that of the latter. We shall call the latter effect the intrinsic effect of slip lines on the diffraction pattern, and this is one of the subjects of the greatest significance in the present study.

The state of plastic deformation in the interior of the crystal was investigated on the specimen 100 A by means of electron diffraction like the specimen 105 but more precisely: Careful electropolishings were repeatedly imposed upon the specimen to expose crystal parts at various depths from the surface, each depth being measured with a micrometer with the error of the order of a few microns. The result was much similar to that of the specimen 105; i.e., when the depth of about 20 $\mu$ was reached, the diffraction pattern visibly recovered irrespective of the direction of the incident beam, and the deeper the crystal, the sharper the diffraction pattern until the depth of about 50 $\mu$ was reached. However, the patterns obtained at the depths of 62 $\mu$ and 99 $\mu$ were not appreciably different from each other; it might follow from this that the situation of deformation does no longer undergo a sensible change below the depth of about 50 $\mu$ in contrast with the considerable change taking place at 10$\sim$20 $\mu$. The results of both specimens are summarized in Table II.

The specimens 108 A, 108 B and 108 C which were extended respectively to 7%, 20% and 55% elongations as cited in Table I were examined in the next place, particular attentions being concentrated upon the intrinsic effect of slip on the electron diffraction pattern in respect to the amount of tensile deformation. The surface structure, resembling foregoing ones, consisted of single slip lines as in Fig. 3 and almost parallel deformation bands intersecting them. On the specimen 108 C, however, deformation bands were no longer parallel but randomly intersecting one another as a result of the rotation of their own in various degrees which had taken place during the large deformation. The results of electron diffraction obtained from these crystals were analogous to those already given in this paragraph, and such effects as above-mentioned were confirmed. In the following is their brief explanation:

In general, the Laue spots from the crystal planes related nearly to the (211) plane, which, was perpendicular to the active slip plane $(\bar{1}11)$ and containing the slip direction $[01\bar{1}]$, were less multiple, and the Kikuchi lines from these planes correspondingly remained com-

Fig. 8. Electron diffraction patterns of the specimen 108 A: (a)—$\perp_s$, before deformation. (b)—$\perp_s$, after 7% elongation. (c)—$//_a$, before deformation. (d)—$//_a$, after 7% elongation.

paratively sharp. So that, the relative rotations of various parts most probable in the crystal are those produced by deformation bands which are the rotations about the [211] axis. On the other hand, there existed no signs in the diffraction pattern attributable to the rotations in the active slip planes or about the [$\bar{1}$11] axis.

When the direction of incident beam was chosen as $//_a$ and less distorted crystal parts between the deformation bands were illuminated, the screening effect due to the deformation band could be avoided to a great extent; for instance, Laue spots barely split, Kikuchi lines and Kikuchi bands were fairly sharp even if they were from the crystal planes necessarily bent by the [211] rotations. Such appearances will be recognizable from comparison between diffraction photographs of Fig. 8 taken before and after deformation for two beam directions, where the pattern for $//_a$ remains considerably sharp after 7% elongation. Presumably for such reason, the specimen 108 B could produce broadened single spots and some faint Kikuchi lines in spite of the large amount of tensile deformation, provided that the condition of the incident beam was just as desired. For the specimen 108 C, there seemed no preferential beam direction in producing the diffraction pattern with tolerable distinctness. The diffraction pattern was composed of the blurred Laue spots and very high background as shown in Fig. 9. It should be noted, however, that the beam direction of $//_s$ appeared to give the pattern with a slightly better contrast than other directions, and even a certain contrast which might be referred to Kikuchi lines or Kikuchi bands was observed in this case. It follows from this that if the screening effect of deformation bands were sufficiently excluded in higher stages of deformation in the present method of investigation, fairly sharp Kikuchi bands and Kikuchi lines would be obtained and the intrinsic effect of slip lines on the diffraction pattern would be estimated to some extent.

By removing metal of various thicknesses from the surfaces of these specimens, electron diffraction tests to clarify the state of deformation in the interiors were repeated; the results obtained from the specimens 108 A and 108 B were much similar to those from the specimens 105 and 100 A, but from the specimen 108 C no conclusive result was obtained.

(a) (b)

Fig. 10. Electron diffraction patterns of the specimen 109 before ((a), left) and after ((b), right) 10% elongation. Beam direction is //s.

The specimen 109 was examined in the last place to elucidate the effect of plastic deformation in case of operation of many slip systems in complicated manner, as its structure of deformation was the slip-clusters as mentioned in the preceding paragraph. The incident beam was made to hit a seemingly nonslipped region, in which slip was almost suppressed even after 10% elongation and very small undulation was observed by using the phase-contrast microscope. By means of electron microscope, however, it was realized that in this region more than one slip system were actually activated and mutually interacted, from place to place, producing extremely fine slip lines in various directions. The electron diffraction patterns before and after deformation are presented in Figs. 10a and 10b, there being broadened weak spots, a high background and no Kikuchi lines in the latter. It may be concluded from this result that when many slip systems strongly interact with one another, the effect of plastic deformation on the diffraction is strong. It is worth noticing that the diffraction pattern did not yield any noticeable change even after removal of a layer of 90 $\mu$ thick from the surface of the specimen, in other words, the states of plastic deformation near the surface and in the interior of this crystal were barely different from each other in contrast with the considerable difference between both states in the other crystals as far as electron diffraction could perceive.

A general aspect of the effects of plastic deformation on the diffraction patterns which was established by the above experiments is summarized below:

1. With increasing plastic deformation Laue spots generally become broad and weak, showing increase of imperfections of the crystal presumably such as relative rotations and bendings of various parts of the crystal which occur in a minute scale. This is only remarkable at fairly high deformation, say, several per cent elongation. The other type of change of Laue spots associated with deformation, that is splitting or multiplication, is very frequently observed as well. However, it can be regarded as due to deformation bands, where slip is almost arrested and sharp bending of crystal occurs, not due to slip lines themselves, from the following facts; single spots can be obtained when the incident beam favourably illuminates a region between deformation bands, the crystals without appreciable deformation bands do never produce multiple Laue spots, and the splitting manner actually observed is not such that produced by $[\bar{1}11]$ rotations most likely occurring in active slip planes but such that expected from [211] rotations or bendings taking place at deformation bands.

2. In appearence, Kikuchi lines are very sensitive to plastic deformation; for instance, only a few per cent tensile deformation can sometimes extinguish whole Kikuchi lines. However, this phenomenon undoubtedly results from the screening effect of deformation bands and cannot be referred to the intrinsic effect of slip lines. In reality, Kikuchi lines are visible even after 20% tensile deformation when the electron beam is directed so as to avoid possibly the disturbance produced by deformation bands. Of course, Kikuchi lines become increasingly diffuse and weak with increasing deformation even though accompanied with single Laue spots, and we named this the intrinsic effect of slip lines on the Kikuchi lines.

3. Kikuchi bands behave in parallel with Kikuchi lines but somewhat less markedly in regard to the sensitivity to plastic deformation. The background always increases with increasing deformation, so that Kikuchi lines, Kikuchi bands and weak spots generally dissolve into it at higher stage of deformation.

4. It is, therefore, concluded that the electron diffraction pattern is fairly distinct when obtained from a crystal part deformed with a single slip system but otherwise perfect, and is very obscure when obtained from a highly distorted crystal part such as in the vicinity of deformation bands or deformed with many slip systems mutually interacting.

5. Except highly distorted crystals, clearer patterns are obtained by removing metal progressively from the surface as much as about $100\,\mu$; this indicates that the deeper the crystal part the more perfect it becomes. In particular a noticeable change appears to take place at the depth between 10 and $20\,\mu$, and there is no longer appreciable change below $60\,\mu$.

## § 4. Discussion

The observation carried out by Heidenreich and Shockley[1] that the slip bands spaced a few microns apart can be resolved into clusters of finer lines with the slip distances of about 2000 Å and separated by distances of about 200 Å seems nowadays difficult to consider as a general representation of the structure of slip bands on the surfaces of pure metals not affected by any kind of surface cold-working. All recent studies seem to advance that the surface structures of deformed pure metals are somewhat finer and more irregular than the above as shown in Fig. 3. It should be noted that the local distortions caused by the deformation bands were inevitable for such crystals and played a very important rôle in producing various electron diffraction patterns; this fact had perhaps been overlooked by Heidenreich and Shockley. Their opinions on the effect of plastic deformation on the diffraction patterns such that, Kikuchi lines are so sensitive to slip that they can be extinguished by only a few per cent tensile deformation, and such that rotational components of slips possibly produced in active slip planes are responsible for multiple Laue spots, have so far been admitted. Nevertheless, according to the present study, these effects are thoroughly attributable to the deformation bands as stated in the preceding paragraph. It is quite interesting that Kimoto[2] *et al*. have recently found that when a convergent electron micro-beam was used, considerably different diffraction patterns were obtained from aluminium single crystals plastically deformed. That is, the patterns from the laminar slip regions were so sharp as to be indistinguishable from those produced by the undeformed crystal, they suddenly become blurred when the incident beam entered a highly distorted region where a deformation band most likely existed, and a discrete jump of the pattern occurred when such a region was traversed by the beam, indicating a relative rotation of two crystal parts bounded by this region. Their result appears to correspond with the demonstration of Gay and Honeycombe[8] using an X-ray micro-beam that asterisms were not obtained unless the beam straddled a deformation band. Such results, we consider, substantially accord with that of the present study. Reconsideration should be needed at this point for the widely acknowledged opinion of Heidenreich and Shockley. The effect of deformation bands is remarkable in our experimental results, and its intuitive but convincing explanation may be given in terms of the dislocation model in which only the edge dislocations are of significance. On the other hand, the effect of slip lines or the intrinsic effect is less evident both in the experimental results and in their interpretation with dislocation model. In general, slip lines are considered to be not only mere traces but actually containing dislocations piling up and anchored against obstacles or without obstacles to cause hardening of the crystal. If such dislocations are almost of the edge type, subsequent crystal distortions around them will be bendings more or less similar to the case of deformation bands. Hence, the axis of rotations or bendings should be [211]. On the contrary, if screw dislocations are very predominant, the distortions will be represented by the rotations in active slip planes, the axis of which should be $[\bar{1}11]$. At the present stage of study of plastic flow, it seems difficult to decide which state is more essential, although this is a very important and urgent problem. In principle, the electron diffraction study should be able to reveal this as Heidenreich and Shockley[1] suggested. That is, apart from the effect of deformation bands, if Kikuchi lines from those crystal planes which orient near to $(\bar{1}11)$ were sharper than those from otherwise orienting planes (this means comparative sharpness of the diffraction pattern of $//_s$), comparative perfectness of the $(\bar{1}11)$ planes would be indicated and, therefore, $[\bar{1}11]$ rotations in active slip planes or piling up of only screw dislocations would be verified. While, if only Kikuchi lines from crystal planes of (211) and near kinds remained sharp, bendings of active slip planes around [211] and, in consequence, piling up of edge dislocations would be demonstrated. In actual observations, however, it is scarcely possible to determine which of the two representations is more correct as far as the present method of investigation is employed, because the screening effect of deformation bands is very intense as already stated. Our experimental results could only give some evidence for the existence of the intrinsic effect of slip lines but no further information. It will be noticed that Heidenreich and Shockley[1] have emphasized in their report that the diffraction pattern of $//_s$ was clearer than that of $\perp_s$, by which $[\bar{1}11]$ rotations were indicated as well as by the multiple Laue spots. In view of the consideration of the present investigation, however, we believe that the result obtained by them was rather accidental and seems inadequate to regard as indicating a general feature of diffraction patterns affected by cold-working. It is of particular importance that Kimoto[2] showed that the intrinsic effect was very little in the case of convergent-beam electron diffraction. In order to give a clear-cut explanation for these outwardly contradicted results, it would be necessary to have such kind of experiments further repeated under various circumstances. Although we have above-described the change of diffraction patterns associated with plastic deformation in terms of local rotations of certain kinds introduced in the crystal, there might be still other possible imperfections capable of accounting for the diffusing of electron diffraction patterns than the rotations or bends; for instance, such that the metal is broken up into small crystallites $10^{-6}\sim10^{-7}$ cm in diameters and such that the lattice parameter changes from place to place in the crystal. These other types of imperfections may be sometimes expected to play a principal part at higher stages of deformation, but it seems very unlikely that either of them is of any importance as far as the simply stretched single crystals are concerned.

Another important problem, i.e., whether or not the state of plastic deformation in the interior of the crystal sensibly differs from that in the vicinity of the original surface, appears to be somewhat clear in the present experimental results as already mentioned. Nevertheless, a little further consideration seems to be necessary for the conclusive discussion, because there can be some other causes to produce the increase of sharpness of the diffraction patterns with the increasing depth:

(1) One of the possible causes is annealing associated with the stepwise electro-polishing to remove metal from the surface, which has however been found to be ineffective as stated in the preceding paragraph. The other annealing effect due to the incident beam is also unprofitable to induce recovery of metal, as known from the fact that the diffraction patterns from the deformed crystals were not alterd even after fairly long exposure of the specimens to the incident beam.

(2) Difference between the surface topological structures of the deformed crystal just prior to and after electro-polishing might cause the difference in sharpness of the diffraction patterns, the surface after electro-polishing being lacking in the stepwise structure due to the slip lines. However this is very unlikely as well from the fact that after a slight electro-polishing of the first stage removing only about 1 $\mu$ of metal from the original surface but sufficient to extinguish the stepwise structure, the diffraction pattern exhibited no appreciable change as shown in Table II.

(3) It does not seem unreasonable to expect that the surface unevenness brought about by the deformation bands is smoothed to some extent by electropolishing, and, if so, the diminished screening effect of deformation bands will permit the clearer pattern to appear after a proper electro-polishing. The interferometer-microscope, however, revealed that such unevenness could not be reduced so strikingly as to decrease the screening effect even after an electro-polishing removing metal of as much as 100 $\mu$. Moreover, even when the beam direction was taken to be parallel to the deformation bands in order to avoid highly distorted regions, the general tendency above-mentioned was not altered. So that, it is clear that change of surface unevenness can not be considered as the cause of the phenomenon in question.

Consequences of the above considerations thus give support to the conclusion stated in the preceding paragraph that the observed increasing sharpness of the diffraction patterns with increasing depth is originated from no other than the variation of internal structures produced by plastic deformation.

In regard to this point, there have been some notable predictions mainly from theoretical point of view as follows: Hollomon[9]) has pointed out that the dislocation lines terminating at the free surface can behave just like the Frank-Read sources twice the length of themselves when they are subjected to the applied stress, so it may be expected that much more slips can be initiated at the surface of the crystal than the interior. H. Suzuki[10]) has postulated that the dislocation lines forming fairly regular plane networks in the crystal should be unknitted in the vicinity of the free surface to sustain the mechanical balance between the dislocation segments themselves and thus long dislocation lines terminating at the free surface should already exist in the unstretched crystal, and they will give many slips near the surface. Kuhlmann-Wilsdorf[5]) has also considered a certain type of sources of slip situated at the free surface and she has attributed the elementary structure to these surface sources. The present experimental results appear to be verifying these predictions that the distribution of slip lines should be much finer in the vicinity of the free surface than in the interior of the crystal, but the question how such difference of deformation structures results in the observed difference of sharpness in the diffraction patterns still remains open.

Another apparently possible explanation for this phenomenon is that an oxide thin film presumably formed during electropolishing prior to deformation might prevent a part of the dislocations produced in the body of the crystal from comming up to the surface and therefore might cause the excess piling up of the dislocations near the surface; this will have an intense effect on the electron diffraction pattern, if actually happens. However, it is scarcely conceivable at least in the present experiment, for the oxide film in this case is considered as too thin (probably less than 30 Å) to arrest sufficiently the dislocations. In order to elucidate this point, a crystal with a suitable orientation was subjected to anodic oxidation to form a surface oxide film a few hundred Å thick and was stretched to several per cent, but the diffraction study was unsuccessful because of miscarriage of subsequent electropolishings to remove metal together with the oxide film from the surface.

## § 5. Summary

The suitably oriented single crystals of aluminium subjected to the tensile deformation of various amounts were investigated by electron diffraction together with the ordinary microscope, interferometer microscope and electron microscope. The outstanding results are as follows:

1. Slip distances vary continuosly from less than 30 Å to more than 1000 Å, and spacings of the slip lines are several hundred Å. Hence, the stepwise structure of such sizes is produced on the crystal surface. Further, the deformation bands cause the local high distortions and the surface undulation with spacings of 0.1∼1 mm.

2. The deformation bands strongly affect the diffraction patterns by themselves and by screening the laminar slip regions; for instance, Kikuchi lines are extremely diffused and extinguished, a high background is produced and Laue spots are split as a result of existence of the deformation bands.

3. From the splitting manner of the Laue sports and variations of diffusing of the Kikuchi lines it is concluded that the discontinuous bending about the [211] axis to the angle of the order of 1° should occur at each deformation band.

4. The intrinsic effect of slip lines other than deformation bands on the diffraction pattern is also indisputable from diffusing of patterns in the absence of deformation bands. Especially this effect is remarkable in the case of the simultaneous operations of more than one slip system. However, rotations of crystal parts about the $[\bar{1}11]$ axis or in the active slip planes can not be distinguished.

5. From the increasing sharpness of the diffraction patterns with increasing depth of the crystal parts examined it is strongly suggested that the state of plastic deformation in the vicinity of the crystal surface may be quite different from that in the interior, a plausible interpretation being possible based on some theoretical predictions.

The authors wish to express their hearty thanks to Prof. R. Uyeda of Nagoya University for his valuable discussions and advices.

# Intersections of {301}, {101} Twin Bands in Tin

By Saiyu MARUYAMA
*Department of Physics, Osaka Women's University*
and Hiroshi KIHO
*Department of Physics, Kyoyo-bu, Kyoto University*

(Received September 14, 1955)

In the course of impact tests on single crystals of β-Sn, we found twin bands of the type {301} and its reciprocal {101}, intersecting each other. The intersections were investigated with reflecting microscope, and it was observed that crossing twins were accompanied by at least one of the three types of additional twinning process, namely, secondary twin, bouncing twni, and the broadening or narrowing of crossed twin. Here are given our interpretation for the mechanisms of these additional twinning processes obtained from the results of shear strain measurements around intersections. Several photographs are added with explanations in detail.

## § 1. Introduction

The mechanical twin plane {301} in β-Sn is well-known[1]. The twin plane {101}, other than the well-known twin plane {301}, was recently found by several investigators[2][3]. The twin plane, and the second undistorted plane are usually denoted by $K_1$ and $K_2$. The direction of the twinning shear, and the intersect of $K_2$ on the shear plane are denoted by $\eta_1$ and $\eta_2$ respectively. When $K_1$ and $\eta_2$ of a twin are found to have the same indices as $K_2$ and $\eta_1$ of the other twin, the twins are said to be "reciprocal"[4]. In the case of β-Sn, $\eta_1, \eta_2$ and $K_2$ of (301) twin are $[\bar{1}03]$, [101] and $(\bar{1}01)$, while those of $(\bar{1}01)$ twin are [101], $[\bar{1}03]$ and (301). Therefore, $(\bar{1}01)$ twin is the reciprocal twin of (301) twin, although the reciprocal twin is rarely found in metals. The atom movements are similar in both {301} and {101} twins. The magnitude of the twinning shear strain is 0.119 in either case.

The {101} twin bands are hardly produced by the usual impact tests, while {301} twins are easily produced. But when {301} twins were prevented from further broadening by external constraint, {101} twin can be produced usually in a form of narrow band.

In our work, normal impact stress was applied on a single crystal of tin constrained in a glass tube, in order to produce {101} twins as many as possible. The numerous {301} and {101} twin bands thus produced were scarcely broader than 0.1 mm and they intersected each other. At these intersections various additional twins were produced. These intersections attracted our attention, and we tried to interpret their mechanisms.

For Bi and As, Gough and Cox[5][6] demonstrated photographs of the intersections of twin bands and the secondary twins; and for Neumann bands in Fe, Smith, Dee, and Young did the same[7].

Recently, R. W. Cahn[4], in his excellent paper on "Plastic Deformation of α-Uranium", mentioned the two necessary conditions for secondary twin formations, as follows:

1. The traces of $A$ and $C$ in the $K_1$ plane of $B$ must be parallel to each other.
2. The direction, magnitude and sense of shear must be identical in $A$ and $C$.

Note: $A$, $B$ and $C$ show, respectively, crossing, crossed and secondary twins.

In our work on β-Sn, as might be easily seen crystallographically, none of the secondary twins in β-Sn has the shear direction indentical with that of the incident one. Therefore, Cahn's first condition holds good, but the second does not. Our methods of treating all the additional twinning processes at twin intersection are given in the following.

After Cahn's work, P. L. Pratt examined the twin intersections in single crystals of zinc[8], and found that there were secondary twins which did not satisfy even Cahn's first condition.

## § 2. Experimental Methods

Rod single crystals of tin, about 4~5 mm in diameter, were prepared in glass tubes following a method similar to Czochralski's. A seed single crystal, X-rayed in advance and covered in a glass tube, was put in the melt. The lower end of the crystal was immersed in it, while the upper end was cooled by water continuously. Then the system was raised slowly from the melt, producing rod single crystal with the same orientation of the seed. As the glass tube was constricted, the narrowest diameter being about 1 mm, and bent at some angle, the crystal below the constricted part took the orientation different from that of the seed. By this means, we prepared specimens with any desired orientations suitable for our experiment. Fig. 1 shows these orientations determined by light figure or X-ray methods, which varied within about 5° from specimen to specimen.

Leaving each specimen in the glass tube, impact shocks were applied. The glass tube was dissolved in hydrofluoric acid and the specimen was etched chemically. Then it was observed that {301} twins had been prevented from broadening, {101} had been stimulated and intersections of these twins had been produced. The twin lamellae were so narrow that the conventional X-ray method failed in verifying twin relations. But, by measuring the angles of twin traces on the specimen surface with respect to a system of coordinates of specimen, the indices of twin planes were determined without confusion, because there are wide differences in orientations (at least 30°) between any types of twin planes.

The intersections of these twin traces were photographed by reflecting microscope with oblique illumination. The photographs are magnified about 70 times.

## § 3. Results of Observation and Discussion

In these photographs, we observe various additional twins generated from the intersections. These are classified into the following three types.

*Type* I). *Secondary Twin*: In the crossed twin band, the secondary twin succeeds the crossing one (as shown in Plates 5, 6 and 8).

*Type* II). *Bouncing Twin*: Starting from the intersection, the bouncing twin is reflected in the matrix region (as shown in Plates 1, 2, 3 and 5).

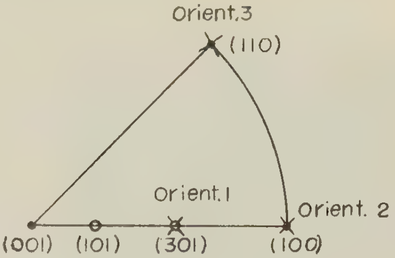

Fig. 1. Orientations of specimen axes.
○ pole of twin plane
× direction of specimen axis.

*Type* III). *Narrowing or Broadening of the Crossed Twin*: Narrowing or broadening of the crossed twin is promoted on either side of the intersection, as a result of for- or backward boundary movement (as shown in every Plate).

As is seen in every plate, the intersection of twin bands is not composed of only two bands, as in the case of slip bands, but of several more twin bands which start from there. Sometimes each twin band has sides keeping parallel up to the intersection (as shown in Plates 1, 4 and 5, and under part of Plate 2), while sometimes it takes the lenticular or tapering shape in the vicinity of the intersection (as shown in upper part of Plate 2, and Plates 3, 6, 7 and 8). These complicated figures of the intersections may be interpreted as follows. A crossing twin band impinges upon a crossed twin. Here, the former carries the macroscopic twinning shear strain into the intersection, and promotes the various deformations by which the strain may be accomodated, e. g. generation of new twin bands, broadening or narrowing of the crossed twin, (we may call them additional twinning processes), slipping, kinking, cracking, etc. When crossing twin band tapers in front of crossed twin, the strain carried by the former is not accomodated perfectly at the intersection, but has been accomodated gradually before crossing, accompanying presumably slipping, or kinking. We attended to the case in which each twin band has sides keeping parallel up to the intersection, and tried to estimate the degree of accomodation which is made only by additional twinning processes.

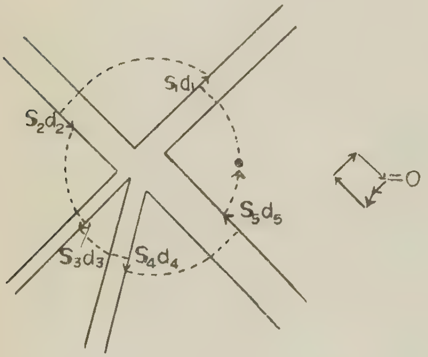

Fig. 3. Twinning shear vectors around intersection referring to Eq. (1).

the intersection is represented by vector sum

$$\sum_i S_i d_i \ ,$$

where $S_i$ denotes the shear displacement per unit thickness of $i$-th twin band. Its sense is the one which appears when we encircle the intersection in one sense, as illustrated in Fig. 3, and the magnitude $S$ in {301} and {101} twins is 0.119 in either case. Next, $d_i$ denotes the thickness of the $i$-th band. In the case where the twin plane is not perpendicular to the specimen surface (e. g. Plate 4, 5, 6 and 7), we calculate the true thickness $d_i$ from the apparent one $d_i'$ on the specimen surface by the following relationship:

$$d_i = d_i' \frac{\sin\theta}{\sin\theta'} \ ,$$

where $\theta$ represents the angle between the specimen axis and the twin plane, and $\theta'$ between the specimen axis and the twin trace on the plate (as shown in Fig. 2).

The values of $\sum S_i d_i$ are listed in Table I. Subcolumns in each twin plane show the values of $d_i$ in both parts of the intersections. *Residual* means the magnitude of $\sum S_i d_i$ around the intersection, which is very small considering that the shear displacement carried into the intersection is of macroscopic scale. It may be worth noting that the residual always increased when we tried to neglect any one of the additional twins.

As a result, when the sides of each twin band were parallel, we found that the shear strains carried by the twins were nearly perfectly accomodated around the intersections, only by additional twins without accompanying any other deformations.

The net shear displacement takes the form, different from the above mentioned, including the Burgers vectors of twin dislocations[9),

$$\sum_i S_i d_i = \sum_i n_i b_i \ ,$$

where $n_i$ denotes the total number of twin dislocations carried in the $i$-th band. Following the above result, the residual twin dislocations in the intersection are rare, or even if they remain, the total vector sum of the Burgers vectors piled up in the intersection is very small.

From the above result, we may proceed to interpret the mechanism of additional twinning processes. A twin band is crossed by another. For the reduction of $S_i d_i$ brought about by the latter around the intersection, one of additional twins which implies shear strain $S$ holding the relation

$$(S_i S) < 0 \ ,$$

may be expected to generate. Here again the

** Additional twin plane indirectly seen from the offset of crossing twin.

sense of the shear strains is assigned as before. This relation corresponds to Cahn's second condition which does not hold in our case.

The shear strain carried by the crossing twin would not be accomodated only by the above single additional twin, without any other ones. These other additional twins should accomodate not only the strain carried by the crossing twin, but also the strain carried by the additional twin already generated. Therefore, some additional twins might be generated which satisfy the relation $(\boldsymbol{S}_i\boldsymbol{S})=0$ in the limiting case.

## § 4. Interpretation of Photographs

Taking the two conditions described above into account, the additional twin planes in the specimens of orientation 1 or 2 in Fig. 1 are selected and are listed in Table II. Of course, only simultaneous inversions of signs of indices in each row from $\{h0l\}$ to $\{\bar{h}0l\}$ are admitted. By the way, (031), $(0\bar{3}1)$, (011) and $(0\bar{1}1)$ twin bands are not found in these specimens, because (1) the normal impact stress has not the component in the twinning shear directions on these twin planes, and (2) any twin planes having these indices do not satisfy the first condition in the cases listed in Table II, and cannot be produced by additional twinning processes. All additional twinning processes shown in Plates 1 to 5 having the specimen axes of orientation 1 are consistently interpreted using Table II.

In Plate 1, ($\bar{3}$01) twin crosses (301) twin, reflecting (101) twin in mother crystal, generating $(101)_t$ secondary twin in crossed twin (here subscript $t$ means that the indices should be taken with respect to the crossed twin orientation), and causing forward movement of the left part of (301) twin boundary. Further, $(101)_t$ twin in crossed twin generate again ($\bar{3}$01) secondary twin in mother crystal (which is twin region with respect to (301) twin band), and cause backward movement of the left part of (301) twin boundary. As a result, the left part of (301) twin band gets narrowing relative to the right.

In Plate 3, two ($\bar{3}$01) twins impinge upon the opposite sides of (101) twin, reflecting (301) twins and promoting (101) boundary movements. Consequently, the section of (101) between both intersections becomes narrower and narrower and gets finally out of sight. (We observed the quite similar configuration to Plate 3, except that the section of (101) twin was just disappearing.)

Secondary twins in Column 4 of Table II are often indistinct, but we can find some of them by slightly changing the direction of the illumination, and confirm without fail their existence by the offset of one twin just before and after crossing over another. It should be noted that this offset is due to the secondary twin formation in crossed twin, and is not due to the stress concentration "without any true secondary twin" as cited in the book by E. O. Hall⁽¹⁰⁾. Here, for reference, we show Plate 5 (orientation 1 in Fig. 1), 6 (orientation 3) and 8 (orientation missed), in which secondary twins are clearly seen in the crossed twins.

It is unsuccessful to find that the crossing twin dislocations are resolved into or composed by new additional twin dislocations produced at the intersection. It seems better to consider that new twin dislocations independent of transported ones are produced at the intersections by the aid of shear stress of crossing twin.

We express our cordial thanks to Prof. Kenzo Tanaka, Kyôto University, for his constant interest in and encouragement to our work, and to A. Aitani, Y. Mitsunari, T. Takahashi and E. Zen, students of Osaka Women's Univ., for their helpful assistances in the present experiment. This work was performed by a grant-in-aid of the Ministry of Education.

# Electron Microscopic Study on the Structure of Mosaic Boundaries in Ni–Mn Single Crystal

By Tadami TAOKA and Shoichiro AOYAGI

*Institute of Science and Technology, University of Tokyo*

(Received February 6, 1956)

For the purpose of studing the structure of mosaic boundaries in an alloy, observation of etching pits on the (110) plane of a Ni–Mn single crystal has been made by an electron microscope. The results obtained are summarized as follows: i) Mosaic boundary is composed of a set of parallel edge dislocations which are regularly spaced on a crystal lattice plane, as shown by Burgers, model. ii) These edge dislocations are along <112> crystallographic direction with Burgers vector $a/2\langle 110\rangle$, or along <100> direction with Burgers vector $\boldsymbol{a}\,\langle 100\rangle$ as suggested by Frank. iii) The dislocations are regularly spaced on {110} or {100} plane respectively which are perpendicular to its Burgers vector.

## § 1. Introduction

The structure of real single crystals, either metals or minerals, is very different from the ideal one in which the lattice planes have the same orientation in all parts of the crystal. The microscopic studies as well as the examinations by *X*-ray diffraction method have shown that real crystals are composed of small blocks with slightly different orientations. This structure is called the "mosaic structure", and the boundaries between the small blocks are called the "mosaic boundary" or "low angle boundary". Up to the present, the structure of the mosaic boundaries have been represented by the transition layers between two neighbouring crystal blocks inclined at small angles to each other, which may be possible by considering a suitable array of dislocations which is dealt with in this paper.

Models of grain boundaries in terms of dislocations were first proposed by Burgers¹⁾ and Bragg²⁾. Read and Schockley³⁾ have later developed the model in detail and derived the expression for the relationships between the boundary energy and the angle between the axes of two crystals. The experimental results of Aust and Chalmers for lead⁴⁾ and tin⁵⁾ are found to be in good agreement with their theory not only at low angles, but also at large angles where the theory is less reliable.

According to the model, the boundary consists of a sheet of parallel edge dislocations of the same sign, parallel to the $z$ axis and are spaced at intervals $h=b/\theta$ along the $y$ axis as shown in Fig. 1, where $b$ is the appropriate lattice transition vector and $\theta$ is the angle between the two crystals. In advance, this was demonstrated in the two-dimensional crystals of bubbles by Bragg and Nye⁶⁾. Some evidence for supporting this model has been offered, chiefly in the observations on the etching pits formed on a surface of single crystals⁷⁾⁸⁾. Recently, Vogel and his collaborators⁹⁾ succeeded to show directly the clear-cut correlation between $h$ and $\theta$, on the basis of microscopic and *X*-ray studies carried out on germanium single crystals.

The present work aims to study the structure of the mosaic boundaries, especially to find the crystallographic directions of the dislocation arrays within the transition layers by the electron microscopic observations on the etching pits formed on the surface of Ni-Mn single crystal.

## § 2. Specimen and Experimental Procedure

Single crystals of Ni-Mn alloy were prepared by solidifying slowly the melt of electrolytic nickel and metallic manganese in vacuum. The sample was then annealed at 1200°C for 20 hours. A specimen was cut to obtain a surface approximately parallel to (100) plane with an area of about 2 cm². After deep etching, this was annealed at 900°C for 3 hours, and then slowly cooled to room temperature, especially very slowly in the temperature range from 700°C to 300°C for 12 days within pure hydrogen atmosphere. After this heat treatment the alloy was chemically analysed and was found to contain 22.0 atomic percent Mn. Low specific electrical resistance of this specimen was considered to be an evidence that Ni and Mn atoms were in ordered state. The diffuseness of Laue spots, taken by back reflection, showed that the specimen was composed of mosaic blocks with the maximum deviation of their orientations 2∼3 degrees.

The procedure finally adopted as a standard preparation for the electron micrography of this alloy is as follows:

1. Carefull polish using conventional metallographic technique.
2. Electropolish with a current of 2.0 amp. /cm² at 40°C for 2 minutes in an electrolyte containing 100-cc phosphoric acid and 100-cc ethylalcohol. The cathode is a copper plate of large area.
3. Wash specimen in distilled water, rinse in ethylalcohol and dry rapidly. The surface of the specimen which is nearly parallel to (110) plane, is then ready for the preparation of a replica after the method developed by Fukami[10].
4. Formation of the collodion replica film using a solution of 0.5% collodion in amylacetate.
5. Formation of the reinfore film using a solution of 2% Ethocel in trichlorethylene.
6. Striping the replica film in hot water at 60°C.
7. Shadow casting by paradium.
8. Dissolving of backed Ethocel film in trichlorethylene.
9. After volatilization of the solvent the collodion reprlica films, ahered to a mesh, are ready for examination.

Observations have been made on the whole area of the specimen using one replica film. Some examples of the electron micrographs thus obtained, as well as the interpretation of their patterns will be given in the next section.

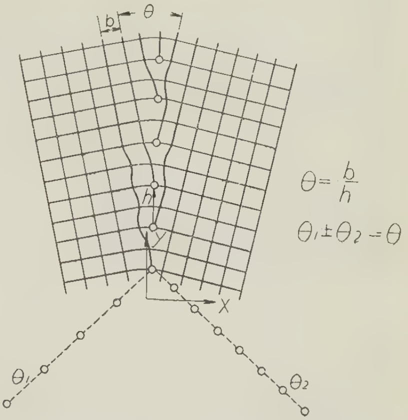

Fig. 1. A simple set of three low angle boundaries passed through one point which is composed of parallel edge dislocations.

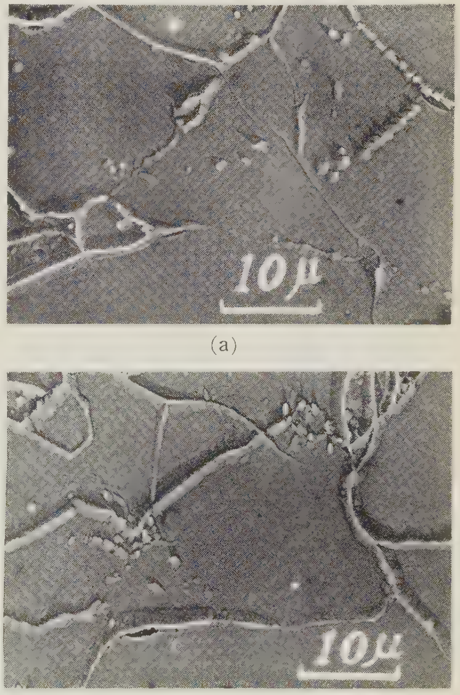

(a)

(b)

Fig. 2. Examples of electron micrographs of mosaic boundaries at low magnification.

## § 3. Observation and Discussion

Some examples of the electron micrographs of low magnification are shown in Fig. 2 (a), (b) which show that the single crystal is composed of small blocks with dimensions of the order of 1∼50 $\mu$. The boundaries between blocks consist of straight arrays of pits or ridges with fine structure, which can clearly be seen in the micrographs of high magnification as shown in Fig. 3 (a), (b) and (c). The individual pits which compose the boundaries are of sharp conical form, as shown in Fig. 3 (a), (b), and they are regularly spaced along straight lines. The ridge is seen to be composed of closely overlapping conical pits, as shown in Fig. 3 (c). In view of the tendency that etching pits will be formed around crystal defects such as dislocations, these observations

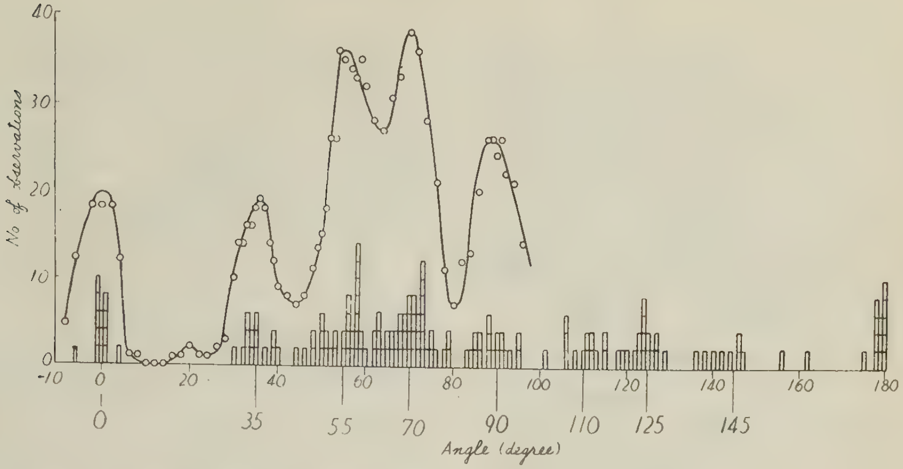

Fig. 5. Distribution of observed values of angles subtended between mosaic boundaries on (110) plane.

suggest that the mosaic boundaries are arrays of parallel edge dislocations which may be regularly spaced on some crystallographic plane. This possibility will be confirmed from the experimental fact that the maximum orientation diference between neighbouring crystal-blocks calculated from *X*-ray measurement (about 2∼3 degrees) is in good agreement with the estimation from the separation of pits, as already described in § 2.

Next, we will concentrate our attention on the values of angles subtended between mosaic boundary lines which meet at one point on the observed plane.

Some examples of electron micrographs are represented in Fig. 4 (a), (b), (c), (d) and (e). In Fig. 4 (a), two boundaries at the right side are almost parallel, while the angle between the two left boundaries is 57 degrees. Fig. 4 (b) shows three parallel boundaries and two of them change their directions with same angle 57 degrees. Fig. 4 (c) shows the micrograph near the intersecting point of two boundaries. The angle between these boundaries is 114 degrees and the transition from one to the other is not smooth but zigzag. Fig. 4 (d) shows three mosaïc boundaries intersecting at one point with angles of 68, 113 and 179 degrees. Fig. 4 (e) shows a triangle composed of three boundaries which intersect with angles of 73, 57 and 50 degrees respectively.

The angles subtended between two linear boundaries have been observed in 170 cases, and the result is plotted in Fig. 5 where a small rectangle represents one observation which corresponds to the angle represented by the abscissa. It seems that the observed values are not distributed at random, but make groups around several particular values. For the purpose of making the situation more clear, the angles from 90 to 180 degrees are replaced by their supplementary angles. Each small circle shown in the figure represents the number of observations, in which angles are contained within the range of ±5 degrees of the value specified by the absissa. The graph shows five peaks at 0, 35, 55, 70 and 90 degrees.

Interpretation of these five peaks would be given as follows: We may consider that dislocations are in the most stable state after prolonged annealing, especially after the annealing for the formation of superlattice. Frank[11] has given a simple criterion for the possibility of a dislocation-formation on the basis of the assumption that the energy of a dislocation is proportional to the square of its Burgers vector. The shortest lattice vector in a face-centered cubic lattice is $a/2\ \langle 110\rangle$ where $\boldsymbol{a}$ is lattice constant. The next shortest vector, $\boldsymbol{a}\ \langle 100\rangle$, can be decomposed into two shortest vector, $\boldsymbol{a}/2\ \langle 110\rangle$, but there is no gain of energy when this occurs. Then the Burgers vector of a stable perfect edge dislocation may be a lattice vector $a/2\ \langle 110\rangle$ or $\boldsymbol{a}\ \langle 100\rangle$.

Let us assume, as shown in Fig. 6 (a), that the dislocations along the direction $\langle 112\rangle$ with Burgers vector $a/2\ [\bar{1}10]$ on (111) plane are

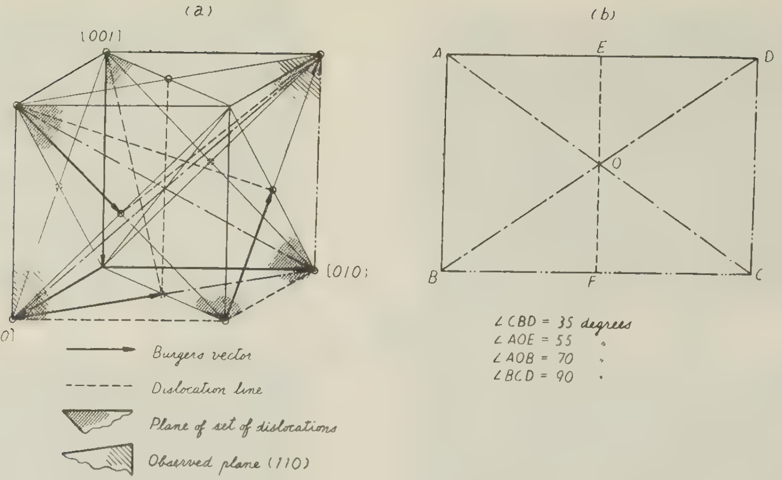

Fig. 6. Stable dislocations and boundaries composed of parallel edge dislocations (a), and patterns of boundaries on (110) plane (b) in face-centered cubic crystal.

stable and are regularly spaced on $(\bar{1}10)$ plane which is perpendicular to Burgers vector $a/2$ $[\bar{1}10]$ and (111) plane. The pits of a set of parallel dislocations on the observed plane (110) should be represented on the intersection of $(\bar{1}10)$ and (110) plane. i. e., EF as shown in Fig. 6 (b). In the same way, the pits of sets of parallel dislocations along $\langle 121\rangle$ with Burgers vector $a/2$ $[\bar{1}01]$ and $\langle 211\rangle$ with Burgers vector $a/2$ $[01\bar{1}]$ appear along AC and DB respectively on the observed plane. Moreover, if we assume that the dislocations along [100] or [010] with Burgers vector $\boldsymbol{a}$ $[00\bar{1}]$ are regularly spaced on the (001) plane, the pits of these parallel dislocations on the observed plane are represented along BC which is the intersection of (001) and (110) plane. In the same way, the pits of set of parallel dislocations along $\langle 100\rangle$ with Burgers vector $\boldsymbol{a}$ [010] appear along DC on the observed plane. Thus the mosaic boundaries composed of stable parallel dislocations may be observed along only EF (DC), AC, DB and BC on the (110) plane, as shown in Fig. 6 (b). Thus the angles subtended between any two among four kinds of boundaries are 0, 35, 55, 70, 90 degrees and their supplementary angles which really correspond to five peaks as shown in Fig. 5.

The plausibility of this interpretation can be confirmed by checking the relation among the three orientation differences of crystals on both sides of the three boundaries, passed through one point as shown in Fig. 1. The dislocations shown by the pits along DB and AC intersect the observed plane (110) with the same angle 35 degrees and have the same appropriate transition vector. Then the relation $\theta_1\pm\theta_2=\theta$ should be satisfied among three orientation differences of crystals on both sides of three boundaries along DB and AC, as seen in Fig. 4 (d). The relation has been checked by measuring the pits spacings on the boundaries. The result is in agreement with this expectation within a experimental error, as listed in Table I.

## § 4. Conclusions and Acknowledgement

The electron microscopic studies on the mosaic boundaries in a Ni-Mn single crystal lead to the following conclusions. i) The mosaic boundary is composed of a set of parallel edge dislocations which are regularly spaced on some crystal lattice planes, as shown by Burgers, model. ii) The edge dislocations comprised in the mosaic boundary are stable in the crystal, as suggested by Frank. iii) The dislocations are regulary spaced on the plane which is perpendicular to the Burgers vector.

We wish to express our hearty thanks to Prof. S. Kaya for his kind guidance throughout this work. We also wish to thanks Messrs H. Noda, A. Fukami and S. Sakata for their suggestions and guidance in the electron microscopic technique.

# Low Temperature Specimen Method for Electron Diffraction and Electron Microscopy

By Goro Honjo, Norihisa Kitamura, Kohji Shimaoka
*Tokyo Institute of Technology, Oh-okayama, Tokyo, Japan*
and Kazuhiro Mihama
*Japan Electron Optics Laboratory, Ltd., Kami-renjyaku Mitaka, Tokyo*

(Received February 18, 1956)

Techniques of low temperature specimen method for electron diffraction and electron microscopy were developed. Convenient low temperature specimen holders were constructed with a sufficient number of freedoms to adjust specimen settings for various observations. The temperature of specimen support could be varied within a range from liquid nitrogen temperature to +200°C. Contaminations of specimen caused by condensation of residual vapours, which usually occur considerably below −80°C, were practically eliminated by improving the vacuum of the apparatus and by the use of a special shield around specimen.

Results of preliminary studies on ice and mercury were briefly described: For ice, the contribution of hydrogen atoms to the diffraction pattern of ice was recognized; for mercury, the solid-liquid phase transition was studied by electron diffraction and the growth of hair-like mercury crystallites was observed by electron microscopy.

## § 1. Introduction

The application of electron diffraction method to specimens at low temperatures was reported by Gen et al. and other workers[1]. By this method, for example, the cubic modification of ice was discovered by König[2]. However, as yet the low temperature method of electron diffraction is not in as general use as the low temperature method of *X*-ray diffraction. Until recently no report has been

Table I.

| Mode of movement | Mechanism | Range |
|---|---|---|

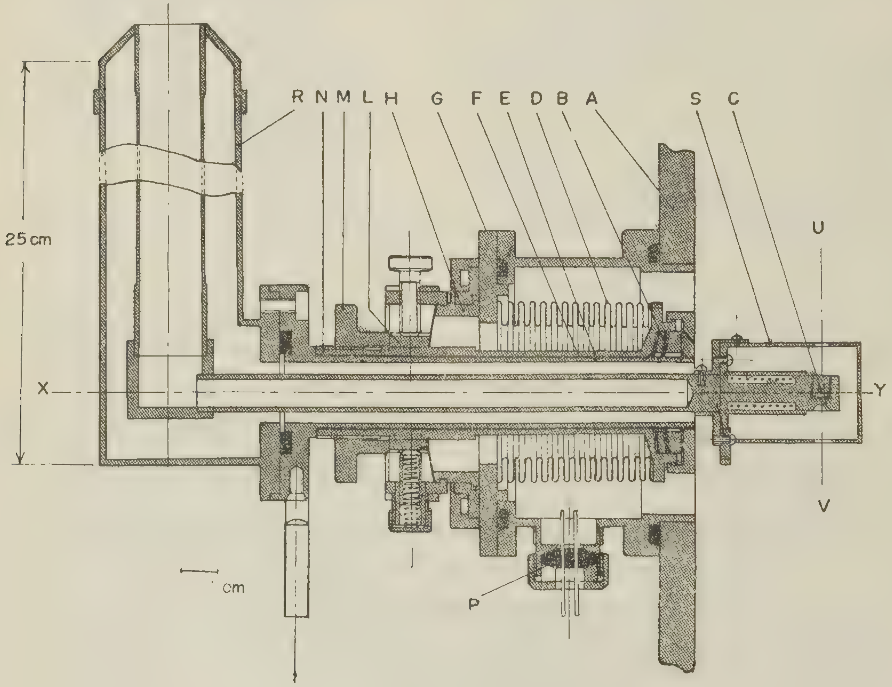

Fig. 1.

published concerning a similar method for electron microscopy.

The present authors have constructed convenient low temperature specimen holders for electron diffraction and electron microscopy and have applied the low temperature method to the studies on ice and mercury. Details of the techniques and preliminary results of these studies are reported here.

## § 2. Specimen Holder

One of the difficulties in constructing low temperature specimen holders is the requirement that the holder must carry a refrigerant reservoir of considerable size. Because of this difficulty, previous workers have designed only transmission specimen holders with restricted freedoms to adjust settings of specimen. Since the reflexion method also was required for our study, a holder was constructed which could work for both methods.

Photo. 1 shows arragement in the specimen chamber and Fig. 1 gives the detailed construction of our holder. *R* is the refrigerant reservoir to be filled with liquid nitrogen or other refrigerants. The reservoir is essencially a vessel of double walls, the space between the walls to be evacuated as well as the specimen chamber. The vertical inner and outer walls were made of brass tubes of thickness 0.5 and 1 mm, respectively, and they are as long as about 25 cm. Thus the vessel is provided with a sufficient capacity (about 60 cc.) and good thermal insulation (see, § 4). Wilson vacuum seal *B* and sylphon bellow *D* give allowance for the specimen movements as tabulated in Table I.

The range of the rotation 3 is sufficient to change the glancing angle of a reflexion specimen and the range of rotation 4 is sufficient to change the azimuthal angle of a reflexion specimen.

Detail of the part around specimen *C* are shown in Fig. 2 and Photo. 2. *S* is a cylindrical shield against radiation and contamination (Cf. § 3). Shutter *W* with throats *T* and *T′* can be rotated around shield *S* by a loosely coupled hook *K* which can be controled from the outside of the specimen chamber by nob *Q* (Photo. 1). During observation the windows of the shield are opened for the electron beam, while the windows can be closed (see, § 3) by turning the throats to positions as indicated by dotted line in Fig. 2b. Part *d* in Fig. 2a is the support of reflexion specimen and *e* is an additional shield. For transmission specimen, *d* and *e* of Fig. 2a are replaced by *d* and *e* of Fig. 2c. Heating coil *h* has a power about 20 Watts. A copper-constantan thermocouple is attached to *e*. The lead-wires for the heater and the couple are connected to terminals such as *P* in Fig. 1 through tunnels *a* and *b*.

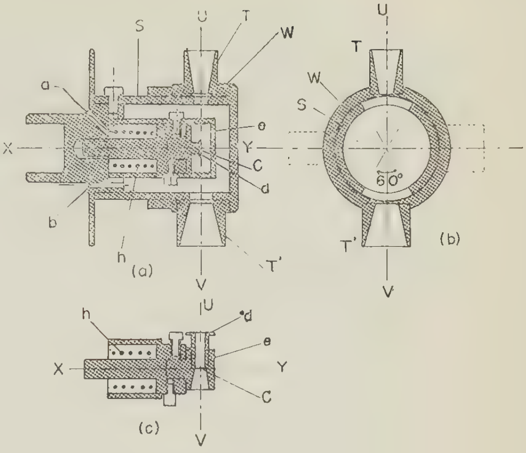

Fig. 2. Arrangement around specimen.

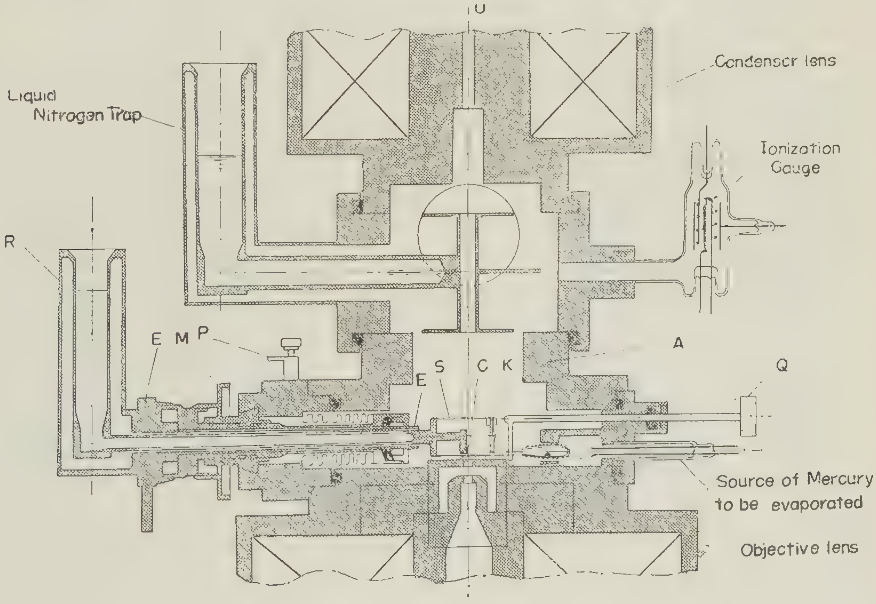

Fig. 3.

The specimen holder for electron microscopy* (Fig. 3) is similar to that for electron diffraction but much more compact since the stage *L* of Fig. 1 is omitted. Thus the rotation 3 of specimen (Table I) is not possible. Boiling of a refrigerant such as liquid nitrogen caused irregular specimen vibration of amplitude of about 1 $\mu$. To eliminate the vibration, the part connected to the specimen was clamped to *E* by a piece of cork. In this way electron micrographs of electron optical magnification

---

* This was designed for use in E. M. type 5 of Japan Electron Optics Laboratory, Ltd. in which the object plane is in a position about 4 mm above the top of objective pole piece. With slight modification, it can be also used in any electron microscope of conventional type in which a specimen is inserted into the throat of objective pole piece.

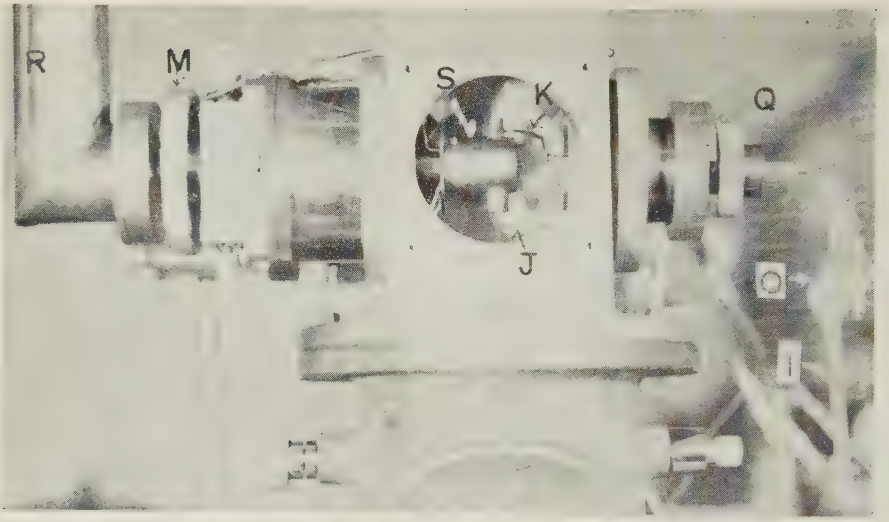

Photo. 1. Specimen chamber arrangement for low temperature method of electron diffraction.

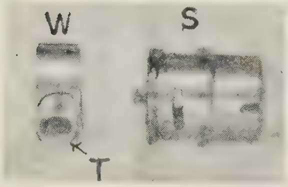

Photo. 2. Shield around specimen.

as high as 10,000 can be taken without much difficulty.

## § 3. Contamination of Specimen

One of principal difficulties of the low temperature method which must be overcome is the contamination of specimens due to materials condensing from residual vapours.

In preliminary experiments carried out under conventional vacuum of $5\times10^{-4}\sim1\times10^{-5}$mmHg of electron diffraction camera and electron microscope, we found that the condensed materials were negligible above $-80\sim-100$°C but below these temperatures we found them to be considerable to the extend that within several minutes they cover the specimen surface so thickly that the diffraction pattern due to specimen is concealed behind the pattern of the condensed material (Photo. 3).

Oily vapour has been considered the main source of contamination, but water vapour may be more likely, because the larger part of residual vapours is usually water vapour. The above mentioned findings correspond to the fact that dew points of water vapour of pressures $4\times10^{-4}$ and $1\times10^{-5}$ mmHg are at $-80\sim-100°C$. König identified the condensed material with cubic ice and we have confirmed his identification (Photo. 3b and see, § 5(a)).

By the use of the kinetic theory of gas, the number of water molecules impinging onto the specimen through the windows of shield is calculated as

$$n\approx3\times p\cdot\alpha\times10^{22}$$

molecules per cm² per minute

at room temperature, where $p$ is the pressure of the water vapour in mmHg. and $\alpha$ is given by $\alpha=\sin\Theta$, $\Theta$ being the effective semi-aperture angle of the windows. If all the molecules were condensed on the specimen at low temperatures, it would result in a deposition of ice at a rate of thickness increase given by

$$dh/dt=n\cdot m/\rho\approx1\times p\cdot\alpha \quad \text{cm per minute.}$$

(The mass $m$ of a water molecule is $3.0\times10^{-23}$ gr. and the density $\rho$ of ice at $-100$°C is 0.92 gr./cm³.) When $\alpha$ is the order of 1/10, as it was in our experiment, $dh/dt$ is 5,000∼100Å/min. for $p$ of $5\times10^{-4}\sim1\times10^{-5}$mmHg. and thus it seems natural that contamination occurs as rapidly as stated above.

Contamination of another nature occurred in our preliminary electron microscopic experiments. Although this contamination also became remarkable below $-80\sim-100$°C, it remains on the specimen even when it is rewarmed up to $+200°C$ in the apparatus (Photo. 4). It was proved that this contamination is caused by electron irradiation and that

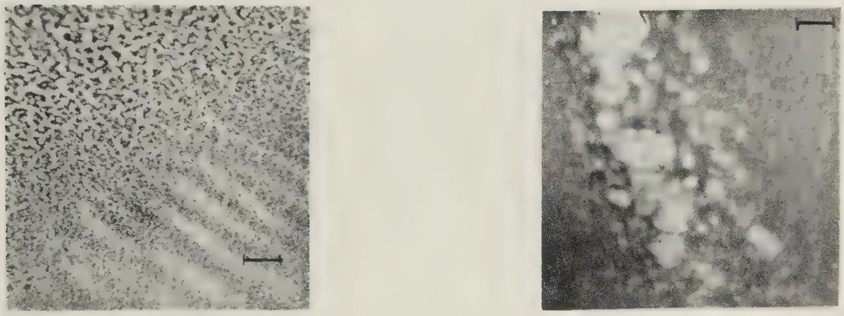
Photo. 3. Micrographs and diffraction patterns of ice condensed from residual vapours of pressure of the order of $1\times10^{-4}$ mmHg. Micrographs were taken at electron optical magnification of ×5,000 with exposures of about 5 seconds. Diffraction patterns were taken by the method of three-stage microscope.

(a) Zinc oxide smoke covered by ice within several minutes after the charge of liquid nitrogen at −80°C.

(b) Ice condensed on collodion film at −80°C (The temperature was measured at the specimen support. Thickness and radius of the film were 400Å and 5 $\mu$, respectively).

Diffraction patterns (c) and (d) correspond to (a) and (b), respectively. All the rings can be indexed by the structure of cubic ice found by König.



(a) (b)

Photo. 4. Contamination on collodion films produced by electron irradiation for several minutes at liquid nitrogen temperature in conventional vacuum of the order of $1\times10^{-4}$ mmHg. These micrographs were taken after the films were rewarmed upto +200°C.

the amount of deposit depends on dosage of electron irradiation. It produces an electron diffraction pattern of only two diffuse halos at $\sin\theta/\lambda=0.24$ and 0.44Å$^{-1}$. The origin and nature of this product have not yet been studied, but it is very likely that this contamination is similar to that which occurs in ordinary electron microscopy and which is considered as a product of hydrocarbon vapour decomposed by electrons$^{3)}$. The rate of deposition seems to be considerably accelerated below −80∼−100°C by the condensing water vapour.

In order to reduce contaminations, we can minimize $\alpha$ down to 1/100. Since, however, a larger aperture of the order of $\alpha\sim1/10$ is desirable in practice for the sake of wider freedom of observation, we tried to reduce the contamination by (i) shutting out the contaminating vapour from specimen by keeping the windows of shield around specimen closed except during observation, and especially during the procedure of cooling down the specimen to desired temperatures, and (ii) with special precautions, improving the working vacuum as far as possible. The actual procedure of the experiment was as follows:

First, the apparatus is evacuated up to 1∼2

$\times 10^{-5}$mmHg*. Next, a liquid nitrogen trap is charged. For electron diffraction camera the trap is attached to the top of the pumping system and for electron microscope (Fig. 3) it is attached just above the specimen part. Then, after the window shutters are closed, refrigerant is poured into the reservoir to cool down the specimen. At this stage the vacuum of the specimen chamber becomes about 1~2 $\times 10^{-6}$mmHg. Finally the shield is bombarded by the electron beam for several minutes and then the shutter are opened to the electron beam.

This procedure efficiently reduced contami-

---

* It was possible to attain to this vacuum within one-half hour after each recharge of photographic plates. The pumping system utilized in our experiments was a 3-inch oil diffusion pump backed by a phosphorus pentoxide trap and a 150$l$/min. oil rotary pump. Inside walls of all parts of the apparatus were throughly cleaned and baked before assembling them. Only well-dried air was let into the apparatus when the vacuum was broken. Photographic plates were well-dried beforehand in another vacuum system.

Table II.

| Index of ring | $\sin\theta/\lambda$ (in Å$^{-1}$) | | Relative intensity* | |
|---|---|---|---|---|
| | Al | Ice | Al | Ice |
| 111 | 0.214 | 0.136 | 100 | 38 |
| 200 | 0.247 | — | 37 | — |
| 220 | 0.350 | 0.222 | 15 | 18 |
| 311 | 0.410 | 0.261 | 14 | 6 |

* The intensity was calculated by the formula $I=k\cdot d/v^2\cdot q\cdot F_{hkl}/(\sin\theta/\lambda)^6$, where $k$ is a constant, $d$; the thickness of the film, $q$; the multiplicity factor and $v$; the unit cell volume. For the structure factor for cubic ice, see § 5.

nations. Photo. 5(a) and (b) reproduce electron diffraction patterns produced from an aluminium film of thickness of about 200Å; (a) was taken before cooling at room temperature and (b) at liquid nitrogen temperature after a continual observation for 30 minutes. Curve (A) of Fig. 4 gives the intensity plot obtained by photometry of the pattern Photo. 5 (b). Calculated relative intensity and values of $\sin\theta/\lambda$ of Debye rings are tabulated in Table II for aluminium and cubic ice films of the same thickness.

The intensity peaks of curve (A) in Fig. 4 can be analysed into curve (B). The intensity peak of (111)-reflexion of ice does not exceed one-half that of (200)-reflexion of aluminium. We can safely say, therefore, that deposition of ice on the aluminium film was less than 100 Å and, according to the above estimation of the rate of deposition of ice, the pressure of residual water vapour must have been as low as a fraction of $1\times10^{-6}$mmHg.

Since in practice the necessary observation time is less than 30 minutes, the contamination is quite negligible.

Photo. 6 (*a*) and (b) reproduce electron diffraction patterns from a cleavage face of zinc blende; (*a*) was taken before cooling at room temperature and (b) at liquid nitrogen temperature after a continual observation of 10 minutes. In these patterns no appreciable effect of contamination is found. It may be worth noting here that the contaminating effect on diffraction patterns should be nearly the same for reflexion specimens as for transmission specimens, because in the reflexion method the aperture of the shield is inclined towards the specimen surface and consequently the rate of deposition is reduced by the factor by which the effect of contaminations is multiplied.

Photo. 7 (a) and (b) show a pair of electron micrographs of a collodion film of about 400 Å thick; (a) taken before cooling at room temperature and (b) at liquid nitrogen temperature after a continual observation of 45 minutes. There is no appreciable change in the contrast between the film itself and the holes, proving that contaminations were completely eliminated.

## § 4. Temperature of Specimen

The temperature of the specimen support *e* (Fig. 2) can be varied within a range from

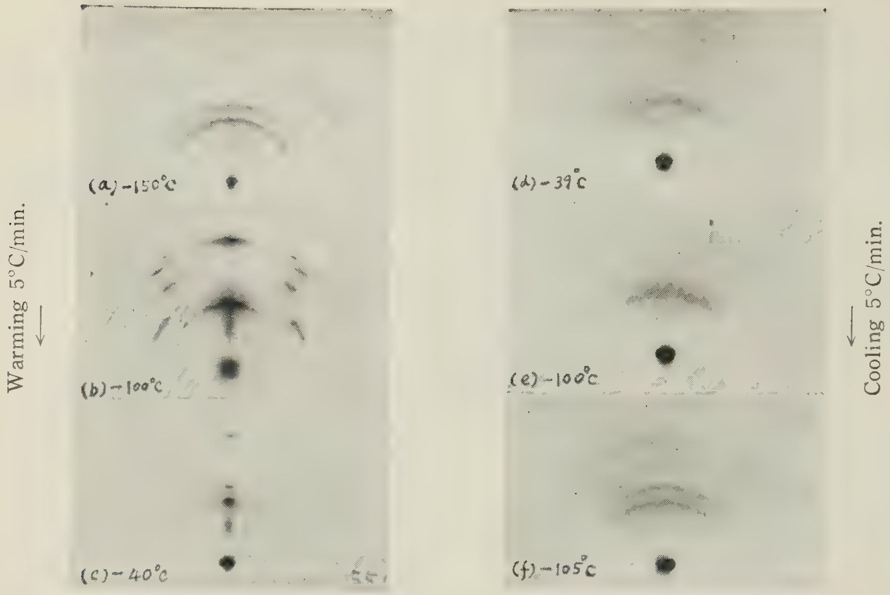

Photo. 9. Electron diffraction patterns from mercury at various temperatures.

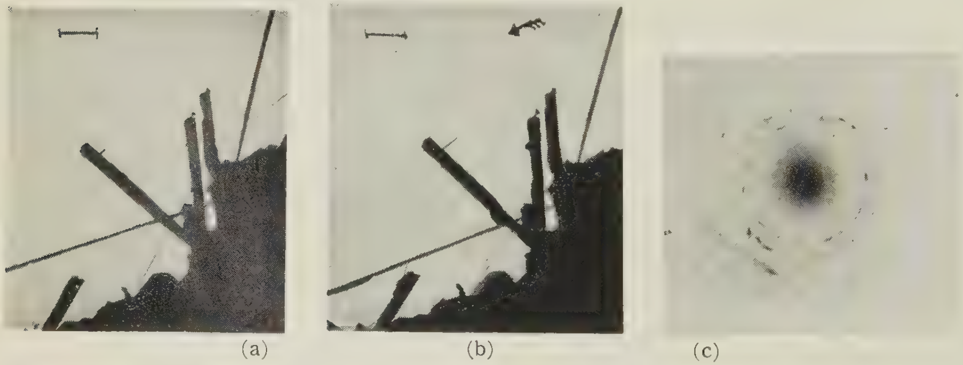

Photo. 10. Micrographs and diffraction pattern of hair-like crystals of mercury.
(a) Hair-like crystals formed by condensing mercury vapour at about −100°C.
(b) Two minutes after (a). The crystal indicated by the arrow completed its growth within a fraction of a second.
(c) Diffraction pattern corresponding to (b), taken by three-stage method.

(a) Liquid state, (b) Solid state, crystallized at about −100°C. Pay attention to polygonization in (b).

the temperature of liquid nitrogen to +200°C. The lowest temperature can be maintained for 20 minutes by one charge of liquid nitrogen without further supply. It is not difficult to maintain a desired temperature within a fluctuation less than a few degrees for an observation period of as long as an hour.

The electron irradiation, however, produces a temperature difference between specimen and the specimen support. Although an exact estimation of the temperature difference is difficult to make, the following discussion may be valuable.

As already noted, it was observed by electron microscope that water vapour condenses on a specimen surface when it is in a coarse vacuum. By this phenomenon we were able to prove that the temperature rise due to electron irradiation is not so large as that predicted by Borries and Glaser[4]. They gave a formula to calculate the temperature $t$ at the centre of a film spanning on a circular aperture of radius $r$ for a given temperature $t_0$ of the support and for a given specific specimen load (Objektbelastung) $\Delta n_0$. According to their formula, the calculated temperature $t$ turns out as high as $-40°\mathrm{C}$ for a collodion film of thickness 400 Å and $r=50\,\mu$, provided $t_0=-80°\mathrm{C}$ and and $\Delta n_0=0.05$ Watt/cm$^2$. The values of thickness and radius adopted here are those of our experiments (Photo. 3b). Although the specific load is difficult to estimate, the value 0.05 Watt/cm$^2$ adopted here is the lowest possible value for electron microscopic observations according to Borries and Glaser. If the calculated temperature is actually the real one, no ice would be deposited on our collodion film at $t_0=-80°\mathrm{C}$. However, we did observe the deposition at $t_0=-80°\mathrm{C}$ (Photo. 3b) under a moderate irradiation (Photo. 3b). This discrepancy may be due either to failure in estimation of specific load or to some change in thermal conductivity of the film because of irradiation. In any event, our observation proves that the specimen temperature must be kept very low contrary to the openion of Borries and Glaser.

In ordinary electron diffraction, the specific load is more than one hundred times less than that in electron microscopy. For example, for the former the load is $5\times10^{-4}$Watt/cm$^2$ (total current$\sim1\times10^{-10}$Amp. for specimenn area$\sim(0.1\,\mathrm{mm})^2$[5]). Thus, even according to Borries and Glaser, the temperature rise is only a fraction of a degree at $t_0=-200°\mathrm{C}$ for collodion film of the same thickness and radius as above (400Å; $r=50\,\mu$).

## § 5. Application of the Low Temperature Method

Some results of preliminary studies on ice and mercury are briefly described below.

(a) *Study on ice*

As mentioned before, König identified the material condensed from residual vapour as ice of new modification of a diamond-type structure with the lattice constant $a=6.36$ Å. This structure is closely related to the well-known hexagonal structure of ice ($a=4.50$ and $c=7.34$Å; the relation is similar to that between cristobalite and tridimite.

Since in our experiment the condensation of residual vopour was eliminated, the vapour was supplied from a prepared source to form ice. In the glass tube $I$ in Photo. 1 we enclosed small pieces of silica gel which had absorbed a suitable amount of water vapour. By opening the cock $O$ the water vapour from the gel was ejected from the jet $J$ onto collodion film at low temperatures.

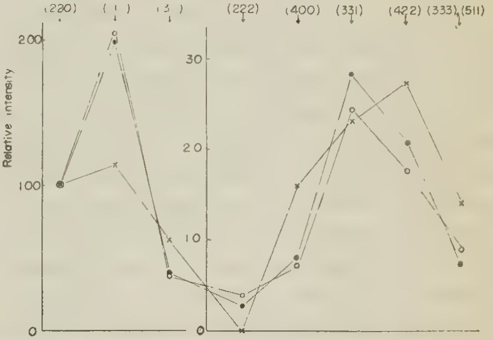

Fig. 5. Comparison of the observed and calculat- intensities of cubic ice. Plain circles, black circles and crosses represent, the observed intensity, the calculated intensity taking account of hydrogen atoms and the calculated intensity neglecting the hydrogen atoms, respectively.

Photo. 8 (a) and (b) reproduce electron diffraction diagrams produced from ice; (a) was produced from ice formed above $-80°\mathrm{C}$ and then cooled down to $-150°\mathrm{C}$ and (b) from ice formed at $-150°\mathrm{C}$. Diagrams (a) and (b) can well be indexed, respectively, by hexagonal and cubic structures of ice. The ice formed below $-160°\mathrm{C}$ was found to produce only diffuse halos, indicating that the crystal growth is poor at these temperatures. When the specimen was warmed up to $-150°\mathrm{C}$, the halos developed rapidly into sharp rings appropriate for cubic structure.

Although König could not detect (222)-reflexion from cubic ice, we were able to find the reflexion and the corresponding reflexion (00,4) for hexagonal ice. If the scattering of electron by hydrogen atoms were negligible as supposed by König, these reflexions would not appear. Actually, electrons are scattered appreciablely by hydrogen atoms⁶⁾, and the observed intensity of our diffraction diagrams deviates considerably from the value calculated by neglecting the scattering by hydrogen atoms (Fig. 5). If, however, the scattering by hydrogen atoms is taken into account, the observed intensity agrees very well with the calculated value (Fig. 5). In the calculation we assumed Pauling's positions for hydrogen atoms⁷⁾ and adopted Weinstein's scattering power⁶⁾. Further studies concerning the structure of ice is now in progress.

(b) *Study on mercury*

Liquid and solid states of mercury were studied by electron diffraction and electron microscopy. Our interest was directed to this study by the following reasons: ( i ) Previous electron diffraction studies which belong to earlier dates of the developement of electron diffraction method gave results contradicting to each other even about the types of diffraction patterns⁸⁾. (ii) The characteristic crystal growth "whiskers" has been suggested for mercury by Sears⁹⁾. (iii) It was expected that the temperature rise of specimen caused by electron irradiation could be checked by observing the liquid-solid phase transition.

Mercury evaporated onto a rigid substrate such as cleavage face of crystal produced clear electron diffraction patterns of solid and liquid phases without ambiguities as reported by previous observers.

Photo. 9 reproduces a series of diffraction patterns of mercury at various temperatures; Pattern (a) is ordinary Debye-rings of solid mercury. When the specimen warmed, the ring pattern changed to pattern (b) of fibrous orientation at about −100°C. Degrees of orientation were improved at higher temperatures as shown by pattern (c). Pattern (c) changed to halo pattern (d) exactly at the melting point −39°C. When the specimen was cooled, the halo pattern remained down to as low as −100°C (e), indicating a remarkable supercooling, and changed to ordinary Debye-rings (f) at lower temperatures. Solid patterns showed sometimes fine structures (Photo. 10c), suggesting the characteristic crystal growth.

Electron micrographs revealed a conspicuous hair-like growth of mercury crystals (Photo. 10). It was noteworthy that the growth of hair-like crystallites completed themselves within a fraction of a second as could be observed on the fluorescent screen. The thickness and length of crystallites differed considerably according to the temperature and supply rate of mercury vapour.

The two micrographs in Photo. 11 show that a droplet of liquid mercury was polygonized through crystallization at about −100°C.

Unless electron irradiation was made unnecessarily heavy, the solid state of mercury could be maintained under electron microscopy up to $t_0 \sim -40°\mathrm{C}$ without appreciable effect of the irradiation. Thus, for the reflexion specimens of above observations, the temperature rise due to electron irradiation was not significant. If mercury particles were dispersed on collodion film well-separated from each other, the temperature rise might be considerable. But we could not prepare such mercury specimen and could not check the temperature rise for this more interesting case.

In conclusion, the authors express their sincere appreciation to Professors Shizuo Miyake and Ryozi Uyeda for their interest and helpfull suggestions. Credit is due Mr. Kenzi Kazato, Dr. Kazuo Ito and technical staffs of Japan Electron Optics Laboratory, Ltd. for providing facilities used in this research.

# Magnetic After-Effect in $Ni_3Mn$ Alloy

By Tadami TAOKA

*Institute of Science and Technology, University of Tokyo*

(Received January 10, 1956)

In nickel-manganese alloy with stoichiometric composition $Ni_3Mn$, very remarkable magnetic after-effect has been found. The after-effect (i) is large at the intermediate state of order of the alloy, (ii) is most noticeable at the steepest part of the magnetization curve, (iii) is comparatively temperature insensitive, and (iv) is not affected by mechanical deformation. The experimental formula of the phenomenon is well expressed by an analytical form derived by Street and Woolley on the basis of the concept of thermal activation process of single domain particles. It has been confirmed by electron microscopic study that the alloy with remarkable magnetic after-effect is composed of innumerable number of small particles of prolate ellipsoidal form embedded in matrix. The dimension of these particles is of such a order of magnitude that is occupied by only single magnetic domain.

## § 1. Introduction

In our previous paper[1] on $Ni_3Mn$ alloy, we have reported some preliminary observations on the anomalously large and long magnetic "after-effect" or "viscosity" which was observed in the alloy having intermediate state of order, but the mechanism of this anomalous effect has remained unsolved.

Formal theories have been developed to express the various types of the phenomena observed on many materials since Preisach[2] and Richter[3]. Recently, some investigators have proposed various hypotheses concerning the physical origin of the phenomena.

Snoek[4] has assumed that the magnetic viscosity is due to the retarded rearrangement of impurity atoms following the movement of domain walls. This theory has been recently extended by Néel[5], and further, Snoek and independently Tomono[6] have confirmed the theory by experiments carried out on low carbon steel.

There are another types of magnetic after-effect which was called "irreversible after-effect" by Néel[7]. He has proposed two kinds of mechanisms to interpret this category of after-effect. Firstly, he[8] has investigated the magnetic properties of fine powders which are small enough for each one to contain only a single elementary Weiss domain. In his theory, he takes account not only of the usual rotations of the domain orientations produced by the application of magnetic field against the different forces of anisotropy: anisotropy of form, magnetocrystalline anisotropy etc···, but the spontaneous rotations due to thermal fluctuations which provoke a kind of magnetic Brownian motion. This concept has been applied to the interpretation of the thermoremanent magnetization of lavas and clays. Secondary, Néel[9] has considered the magnetic after-effect due to the thermal activation of domain walls. On activation, the domain boundary wall sweeps through a certain volume which corresponds to a Barkhausen discontinuity. He applied this theory to the results obtained by Barbier[10] on an Alnico specimen.

Street and Woolley[11] have carried out a mathematical treatment on magnetic viscosity based on activation energy concepts, and applied the results thus obtained to the phenomenon occuring in materials in which bulk magnetization proceeds by the rotation of each single domains. Experiments have been made in detail on specimens of Alnico maintained at various temperatures and its results have been shown to be in agreement with the theoretical analysis.

In spite of these extensive investigations, there appears to be no experiment which leads to an unambiguious confirmation of the underlying physical origin except for the case in which the after-effect is caused by diffusion of impurity atoms. The observed phenomena on different materials may probably be attributed to the different mechanism.

In this paper the magnetic after-effect

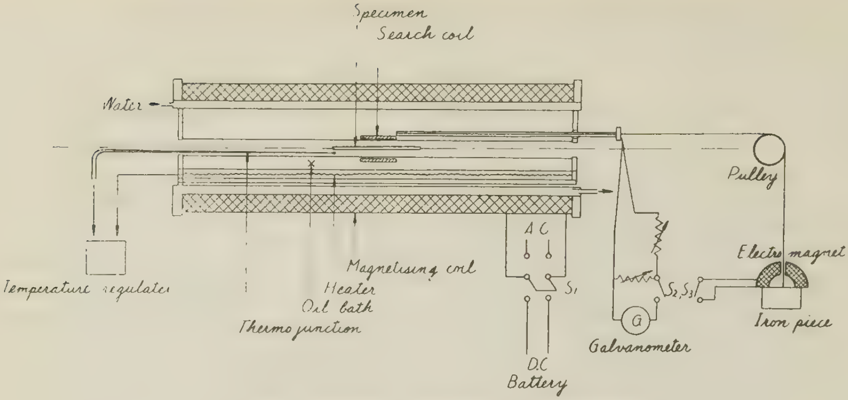

Fig. 1. Schematic diagram of apparatus.

observed on the virgin magnetization curve of $Ni_3Mn$ alloy is reported in detail. The phenomenon is affected by the strength of the applied field, the temperature and especially the degree of the material.

The present observations will be compared with the previous experiment results, as well as with the results expected from the theories described above. Finally, a physical mechanism is proposed in connection with the stages of development of ordered phase within the alloy, which have been comfirmed by the electron microscopic study.

## § 2. Specimen, Apparatus and Method

The specimen used in this study was a rod of $Ni_3Mn$ alloy of length 214 *mm*. and diameter 1.5 *mm* with the demagnetizing factor $D=0.00251$. This is the same specimen described in the previous paper.

The heat treatments necessary for the formation of the superlattice of appropriate degrees of order have been made after the suggestion described in the paper put forwarded by S. Kaya²⁾. Different states of order were obtained by quenching the specimen, in the course of slow cooling from 700°C (disorder), 530°C, 520°C, 500°C, 480°C, 420°C and room temperature (perfect order) respectively. The dependence of the saturation induction on quenching temperature has been shown in Fig. 2 of the previous paper.

The arrangement of the apparatus is shown in the schematic diagram of Fig. 1. The specimen was placed inside a search coil in an oil bath which could be maintained at any constant temperature between 10°C and 100°C within about 1°C during measurement. External magnetic field was applied by means of solenoid of length 90 *cm*, of which temperature could be maintained constant by supplying water of constant temperature. The required stability of the magnetic field (about 0.2%) could only be obtained by supplying the current to the solenoid from a 12 V battery of large capacity. The search coil of 4100 turns was connected, through a suitable variable resistance, to be ballistic galvanometer of period 10 sec. The galvanometer deflection was 1.0 *mm* when the intensity of magnetization of the specimen changed by about 2.0 gauss.

In order to keep the temperature of the specimen exactly constant during the very long course of measurements, minute precaution has been added to the procedure of the measurement. At first, a constant magnetizing current of desired strength was supplied to the solenoid for a long time until a thermal equilibrium was established between specimen and its environment. The procedure from hereon was as follows:

The battery circuit was opened and the specimen was carefully demagnetized in alternating field. Then the field of previous strength was again applied through the battery circuit. After a desired interval of time, the circuit of the electromagnet, by which a weight was suspended, was suddenly opened, immediately after the galvanometer circuit was closed. Then the search coil was consequently pulled out by the dropping weight from the specimen, and the galvanometer made a deflection, which corresponds to the induction of the specimen at this instant. This measurement of induction was repeated at

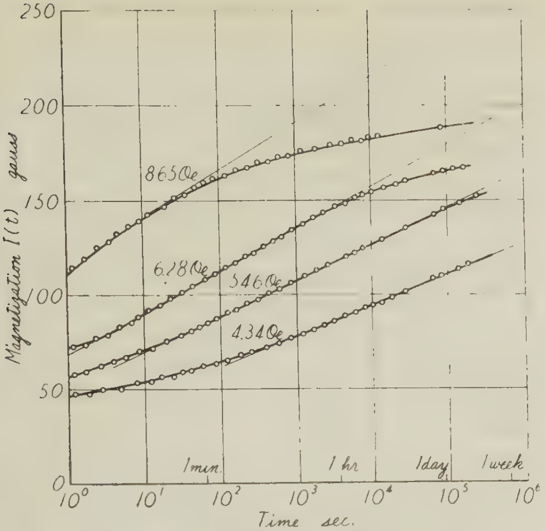

Fig. 2. Variation of magnetization as a logarithmic functions of time at 50°C for the specimen quenched from 500°C. The applied external fields are indicated on the curves.

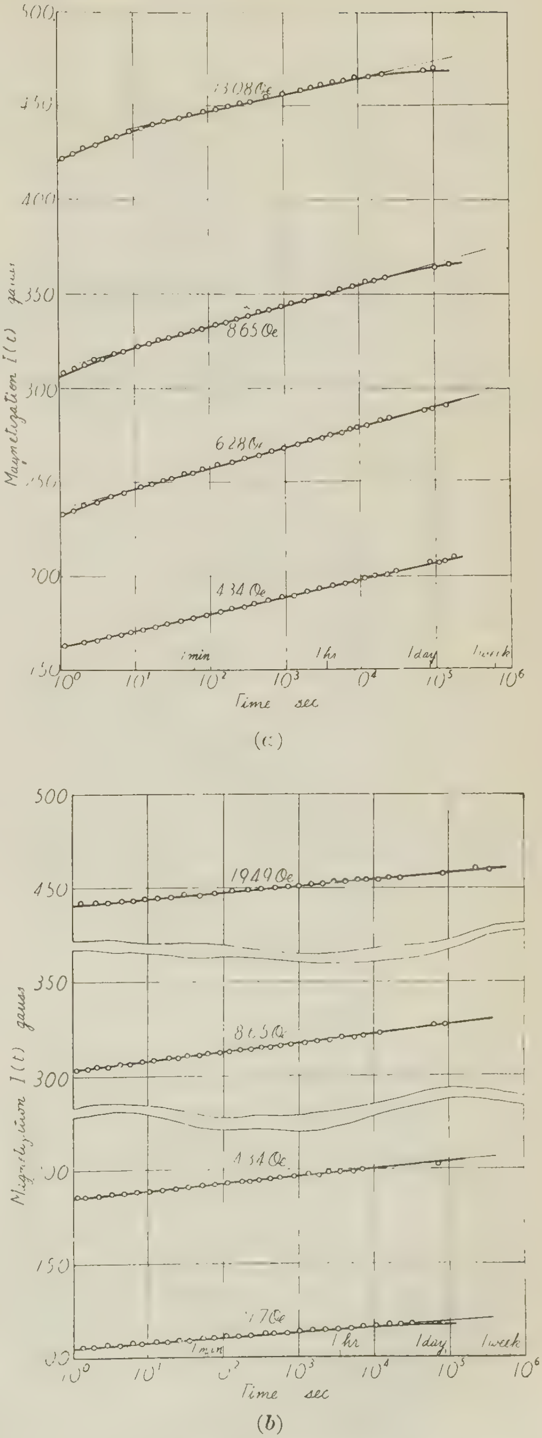
various interval of time after the application of the magnetic field. Thus the intensity of magnetization of the specimen was observed as a function of time after application of the field, from 1 sec. up to one day or week. Special attention was paid to the construction of the apparatus and the arrangement of the circuit, in order to avoid mechanical and magnetic shock, which would be added to the specimen during the measurement.

## § 3. Experimental Results

The experimental results so far obtained are as follows:

i) Magnetic after-effect curves

A typical result from a set of measurements is shown in Fig. 2, which represents the variation of magnetization as a logarithmic function of time $t$ measured from an instant of application of external field of various strength (the "magnetic after-effect curve"). The measurement were made at 50°C for the specimen quenched from 500°C. The main parts of these curves can be represented by straight lines with different inclinations. Similar after-effect curves at 20°C for the specimen quenched from 460°C are shown in Fig. 3 (*a*) and for the specimen with perfect order in Fig. 3 (*b*). As can be seen in these figures, the length of the linear portion depends on the strength of applied field, temperature and the degree of order of the specimen.



(*a*)

(*b*)

Fig. 3. Variation of magnetization as a logarithmic function of time, (*a*), for the specimen quenched from 460°C, and (*b*), for the specimen with perfect order which are measured at 20°C. The applied external fields are indicated on the curves.

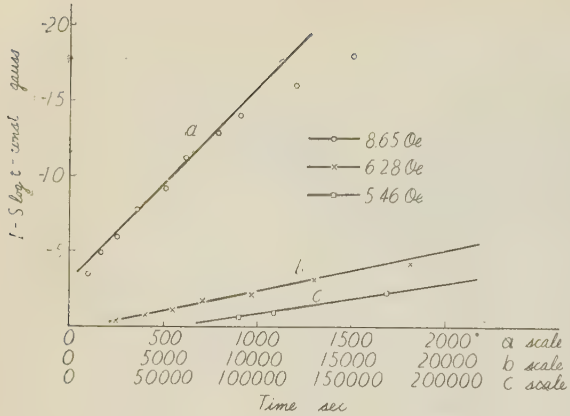


Fig. 4. Variation of $I$- $S\log t$- const. as a function of time $t$.

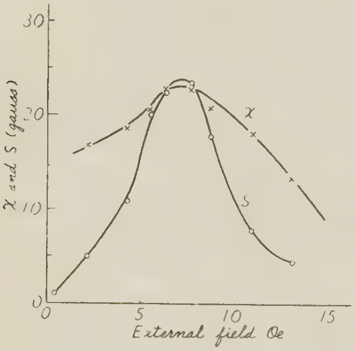

Fig. 5. Variation of $S$ and $\chi$ as a function of applied field at 50°C for the specimen quenched from 500°C.

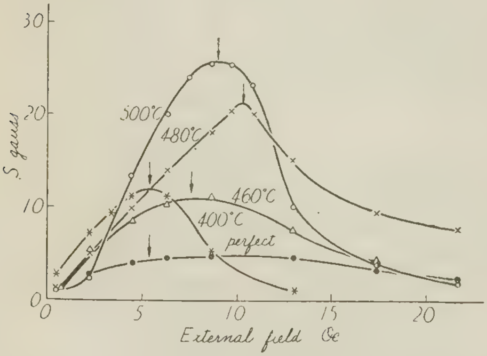

Fig. 6. Variation of $S$ as a function of applied field at 20°C for the specimen with various degrees of order. The quenching temperatures are indicated on the curves and the arrows on each curves represent the field correspond to maximum value of $\chi$.

Generally speaking, the regions of straight lines have a tendency to extend longer with a decrease of applied field, as well as with the decrease of temperature and the formation of the superlattice.

In general, these curves can be expressed fairly well by

$$I(t)=S\,log\,t-\gamma t+\text{const}\,. \qquad (1)$$

where $S$ and $\gamma$ are independent of time but depend on the intensity of applied field, temperature and the degree of order of the specimen. In order to examine the experimental formula (1), the variation of $I(t)-S\log t$ $-$const. as a function of time $t$ is show in Fig. 4, referred to the curves represented in Fig. 2. Linear relationship over a wide range of time, as shown in this figure, indicates that the observed curves are represented well by equation (1), except for short time intervals between $t=1\sim10$ sec.

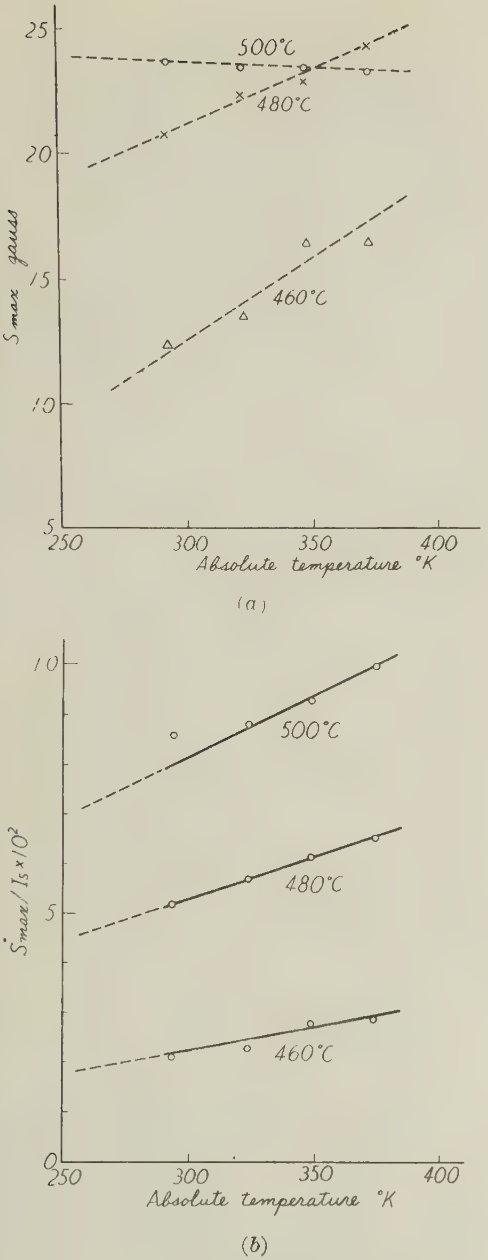
Both parameters $S$ and $\gamma$ are to be considered as important characteristic factors for the after-effect studied here. Firstly we will study how $S$ is affected by the variation of experimental conditions.

### ii) Effect of applied field

The dependence of $S$ on the intensity of applied field is shown in Fig. 5 for the same specimen as in Fig. 2. The susceptiblity $\chi$ is also plotted on this same figure against the field, and it will be seen that the maximum value of $S$ occurs within the experimental error where $\chi$ has the greatest value. Similar variations of $S$ against the external field are shown in Fig. 6 which was measured at 20°C for the specimens with various degrees of order. It shows that the maxima of $S$ and $\chi$ are reached on the same field irrespective to the change of conditions in case of measurements.

### iii) Effect of temperature

The temperature dependence of $S$ will be shown quite simply by the relation between the maximum value of $S$ shown in Fig. 5 and 6 and temperature. Fig. 7($a$) is a plot of $S_{\max}$ as a function of the absolute temperature for the specimens with various degrees of order. It shows that $S_{\max}$ is represented approximately as linear function of the temperature, and also that the inclinations of the lines change its sign from negative to positive with the formation of the superlattice. In order to take into account the dependence of the saturation magnetization on temperature, as well as on degree of order, the maximum value of $S$ was replaced by $S_{\max}/I_s$ where $I_s$ is the saturation magnetization. Fig. 7($b$) shows a plot of $S_{\max}/I_s$ against the absolute



(a)

(b)

Fig. 7. Variation of (a) $S$ and (b) $S_{\max}/I_s$ as a function of absolute temperature. The quenching temperatures are indicated on the curves.

temperature for the specimens with various states of order. The fact, that the straight lines roughly pass through the origin of temperature axis, shows that $S_{\max}/I_s$ is proportional to the absolute temperature for the various states of order. The value of the inclination of the line decreases with the formation of superlattice.

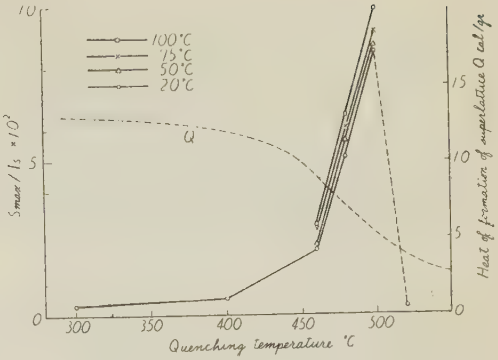


Fig. 8. Variation of $S_{\max}/I_s$ and formation heat of superlattice as a function of quenching temperatures.

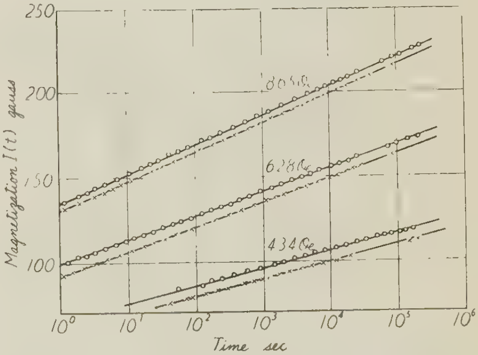

Fig. 9. Variation of magnetization as a logarithmic function of time at 20°C for the specimen quenched from 480°C. The applied external fields are indicated on the curves.
- • - • - without longitudinal tension.
- x - x - with longitudinal tension.

### iv) Effect of degree of order

The dependence of $S_{\max}/I_s$ on the quenching temperature is shown in Fig. 8, together with the change of heat of formation of the superlattice with quenching temperature measured by Kaya and Nakayama[12]. The values of $S_{\max}/I_s$ decrease rapidly with the decrease of quenching temperature. It can be seen that the after-effect is closely related to the formation of superlattice and become most remarkable at the intermeniate state of order.

### v) Effect of mechanical deformation

In order to study the dependence of the after-effect on mechanical deformation, studies have been carried out for the specimen which had been streched by a tension of the strength 2.1 $Kg/mm^2$ for 24 hours before the measurements. This strength of the tension will be considered to be on the transition point from $\alpha$ region to $\beta$ in the initial creep rate curves. The result obtained for the specimen quenched from 480°C, measured at 20°C, is shown in Fig. 9. It can be seen that the values of $S$ and the range of linearity are independent of the mechanical deformation. However, a slight parallel displacement of the curves to lower field can be acknowledged as the consequence of the deformation.

## § 4. Discussion

We can summarize here the experimental results thus obtained as follow:

i ) In general, the magnetic after-effect curves can be well expressed by the experimental formula (1).

ii ) The maximum value of $S$ occures at the magnetic field where $\chi$ has the greatest value.

iii) $S_{\max}/I_s$ is always protortional to the absolute temperature for every states of order.

iv) This phonomenon is closely related to the formation of superlattice and is most remarkable at the intermediate state of order.

v ) Mechanical deformation has no sensible influence on this phenomenon.

These five facts, especially iv), must be explained by assuming a reasonable physical model. One of the mechanisms by which a quantitative explanation has been given on the magnetic after-effect is the diffusion of the impurity atoms such as carbon or nitrogen in iron. However Richter's measurements seem to indicate that the variation of $S$ with temperature in soft iron is essentially different from that shown in the results iii). In the former case, $S$ appears to be substantially independent on temperature. Moreover, the crystal structure of $Ni_3Mn$ alloy is different from that of iron, and the magnetostriction, the existence of which is the cause of rearrangement of impurity atoms in case of change of magnetization, is very small[1] in this alloy. This mechanism, therefore, may not be applied in the case of $Ni_3Mn$ alloy. As was described in the previous section, Néel has proposed two mechanisms for the irreversible magnetic after-effect: the one is the rotation of the magnetization in isolated single domain and the other is the displacement of the domain walls, both of which are to be activated by thermal fluctuation. In these cases, the analytical forms are expressed by $S$ *log* $t$, same as the first term of the equation (1). In the former, $S$ is proportional to $T$ in the first approximation within a certain range of time, but in the latter $S$ is proportional to $\chi_i T^{1/2}$ where $\chi_i$ is the irreversible differential susceptibility at the temperature concerned. A precise comparison between Néel's theories and the present results may be difficult because of the ambiguity on the assumption in the theory as well as of the lack of data of $\chi_i$. Moreover, both mechanisms suggested by Néel can not be applied to our results, because the 2nd term $-\gamma t$, whose existence is clearly comfirmed by our experiment, could not be derived from his treatments unless some auxiliary assumption will be introduced on the distribution of activation energy of single domains or walls.

Street and Woolley have also treated the isolated single domain model and derived the analytical form similar to the experimental formula (1). They assume that fine particles, the dimention of which are smaller than the critical value for the formation of domain walls, are embedded in a less ferromagnetic matrix.

Thus, at time $t$ after the sudden application of fiield, let the number of particles assigned by activation energies lying between $E$ and $E+dE$ be $f(E)\,dE$. The time rate of change of $f(E)\,dE$ due to thermal activation at constant temperature will be given by

$$\frac{df(E)}{dt}=-Cf(E)dE\exp(-E/kT) \qquad (2)$$

assuming that successive activations do not produce additional states in the same range of $E$. If at time $t=0$, the value of $f(E)$ is a constant $p$ within the energy range from 0 to $E_0$ and is equal to zero outside this range, the required formula is given by

$$I(t)=ipkT(\log t-\lambda_0 t)+\text{const.} \qquad (3)$$

where $i$ is an average component of the magnetization of the particles in the direction of applied field, and

$$\lambda_0=C\exp(-E_0/kT) \qquad (4)$$

The equation (3) is identical with the experimental formula, if we put

$$S=ipkT \qquad (5)$$

and

$$\gamma=\lambda_0 S \qquad (6)$$

Table I.

| quenching temp. C | 500 | | | 480 | | 460 |
|---|---|---|---|---|---|---|
| external field, *Oe.* | 5.46 | 6.28 | 8.65 | 6.28 | 8.65 | 8.65 |
| $E_0$ $10^{12}$ *erg* | 1.6 | 1.6 | 1.4 | 1.25 | 1.37 | 0.58 |
| $\log_{10} C$ | 10.0 | 11.1 | 10.1 | 6.4 | 8.7 | 2. |
| $S$ gauss at 50°C | 19.9 | 22.4 | 30.0 | 17.5 | 22.3 | 11.6 |

Prior to the comparison of this theory with the experimental results, we must consider the influence of the changes of the effective magnetic field while the experiments are made using specimens with demagnetizing factor other than zero, since the effective field acting in the specimen varies continuously with time under the constant value of the external field. Street and Woolley have given, semi-experimentally, the variation of $S$ for the same material having different demagnetizing factor $D$ by

$$\frac{1}{S}=\frac{1}{S_0}+\left(\frac{g}{kT}+\frac{\chi_{\mathrm{rev}}}{S_0}\right) \qquad (7)$$

where $S_0$ is the value of $S$ in the case $D=0$, $g$ is the proportional factor, with which the domain activation energy changes proportionally with changes of field strength, and $\chi_{\mathrm{rev}}$ is the reversible susceptibility concerned. When $D$ is small, the influence of changes of effective field will be small. If the numerical values in the present measurements are substituted in the expression, the difference of $S$ and $S_0$ will be shown to be less than a few percent, and may be neglected in the following discussions without considerable error.

Thus the comparison of the experimental results with equation (3) may be summarized as follows:

1) The magnetic after-effect curves, except for short time interval immediately after the application of extarnal field, can be well expressed by equation (3), which includs the 2nd term, the existence of which was not comfirmed in case of Alnico *V*.

2) $S_{\max}/I_s$, if it is replaced by $S$, is proportional to the absolute temperature as expected from equation (5), and shown in Fig. 7 (b).

3) The relations between $\log \lambda_0$ and $1/T$ within the range of observed temperature from 20°C to 100°C measured under constant field are shown in Fig. 10 for the specimen quenched from 480°C. The slopes of these straight lines give, according to the equation (4), the maximum values $E_0$ of activation energies of the small particles.

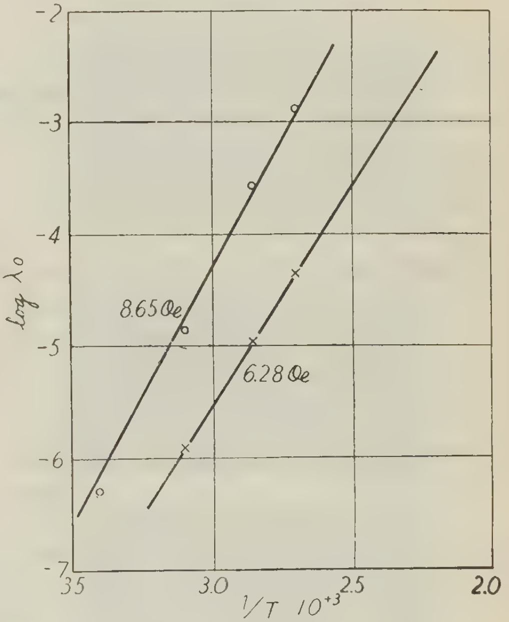

Fig. 10. Variation of $S_{\max}/I_s$ as a function of $1/T$. The applied fields are indicated on the lines.

The numerical values of $E_0$, $\log C$ and $S$ are summarized in Table I which shows slight decrease of $E_0$ and rapid decrease of $C$ with the formation of superlattice.

Thus the experimental results seem to be well explained by Street and Woolley's theory using the isolated single domain model. If we assume the existence of such particles contributing to the magnetic after-effect in Ni$_3$Mn alloy, the maximum volume of these particles can be estimated as follows. The energy required to reverse the magnetization of single domain of volume $v$ would be roughly expressed by

$$E_0=I_sH_cv \qquad (8)$$

where $H_c$ is the coercive force. Putting $I_s=270$ gauss, $H_c=12.5$ *Oe* and $E_0=1.6\times10^{-12}$ *ergs* which are the observed values of the specimen quenched from 500°C, we obtained $v=4.7\times10^{-16}cm^3$ and the linear dimension $d=1\times10^{-5}$ $cm$, assuming a spherical shape.

On the other hand, in a material with a low magnetic anisotropy, we can estimate the critical diameter $d_s$ of the single domain of uniform spontanious magnetization by the following expression derived by Néel[8)]

$$d_s^2=\frac{3Na}{2k}\left(\log\frac{ds}{a}-0.307\right) \qquad (9)$$

where $N$ is the coefficient of the molecular field (36,000 for $Ni_3Mn$) and $a$ is the distance between magnetically active neighbours. For the same specimen, we obtain $d_s=1\times10^{-5}\,cm$ in agreement with the above estimated value.

In case of Alnico *V*, it has been concluded by Heidenreich and Nesbitt[13)] from electron metallographic study that the high values of both coercive force and anisotropy are caused by very finely divided precipitation produced by the permanent heat treatment. If we take these fine precipitates into consideration, the influence of heat treatment on the magnetic viscosity in Alnico *V* investigated by Street, Woolley and Smith[14)] can easily be understood.

Now, in the $Ni_3Mn$ alloy, question will be raised as to the existence of single domain particles such as those in Alnico *V*. In this alloy, the ferromagnetic Curie point increases with the formation of superlattice, and more ordered phase has more stronger intensity of magnetization. It seems plausible that small particles of more ordered phase are embedded in a less ordered matrix. Two kinds of studies have been carried out directly to examine the above hypothesis.

One of them was the domain pattern observation on the alloy with various degrees of order using the technique developed by H. J. Williams and his collaborators[15)]. In the perfect ordered state, large, simple domains were observed, whereas the size of domains decreases with the decrease of degree of order, and in the intermediate state of order at which the magnetic after-effect was most remarkable, the fine colloid particles of magnetite were distributed at random, showing no distinct figure.

The other was the electron microscopic study, carried out on six specimens with various ordered states. The electron microscopic observation was made on the surface of the disks of the polycrystalline $Mi_3Mn$ alloy.

The procedure finally adopted is as follows:

1) Careful abrade by usual metallographic technique.

2) Electropolish for about one min. with current density 1 $amp/cm^2$ in an electrolyte containing one part of phosphoric acid and one part of ethylalcohol at about 40°C.

3) Rinsing in distilled water and ethylalcohol, and rapid drying.

4) Preparation of the negative Pd-shadowed collodion replica using the technique developed by Fukami[16)].

The replica thus obtained have been examined under electron microscope. Some examples of the electron micrographs are shown in Fig. 11. As can be seen in the photograph (*a*), no speciality exists in perfectly disordered state, while the photograph (*c*) for the specimen quenched from 500°C clearly shows that there exists the ordered phase of elliptical form, the dimension of which is less than about 750Å for the short axis and 3500 Å for the long axis, which is the same order of magnitude estimated from equation (8). In the course of superlattice formation, these ellipsoids are gradually formed, and again become undistinguishable in the perfect ordered state.

For the purpose of examining the relation between the highly preferred orientation of the ellipsoids and crystal axes, the same electron microscopic observations have been made on the (**110**) plane of a single crystal of Ni-Mn alloy. Unfortunnately, the specimen was richer in Ni content than the alloy of stoichometric composition of $Ni_3Mn$ by 3 percent. In this alloy, the ordered phases can easily be distinguished from the disordered region after chemical etching for about 5 minutes in a mixture containing 10 $gr.$ ferric chloride, 30-cc concentrated HCl and 120-cc distilled water at room temperature. This will be ascribed to the difference of composition in the ordered and disordered phases. The replicas were made after quenching the same specimen from different temperatures. The electron micrographs show in Fig. 12 illustrate the change of the structure with the formation of superlattice.

The following conclusions are drawn from these results:

1) As can be seen in Fig. 12 (*b*), the elongated ordered phases exhibited themselves at

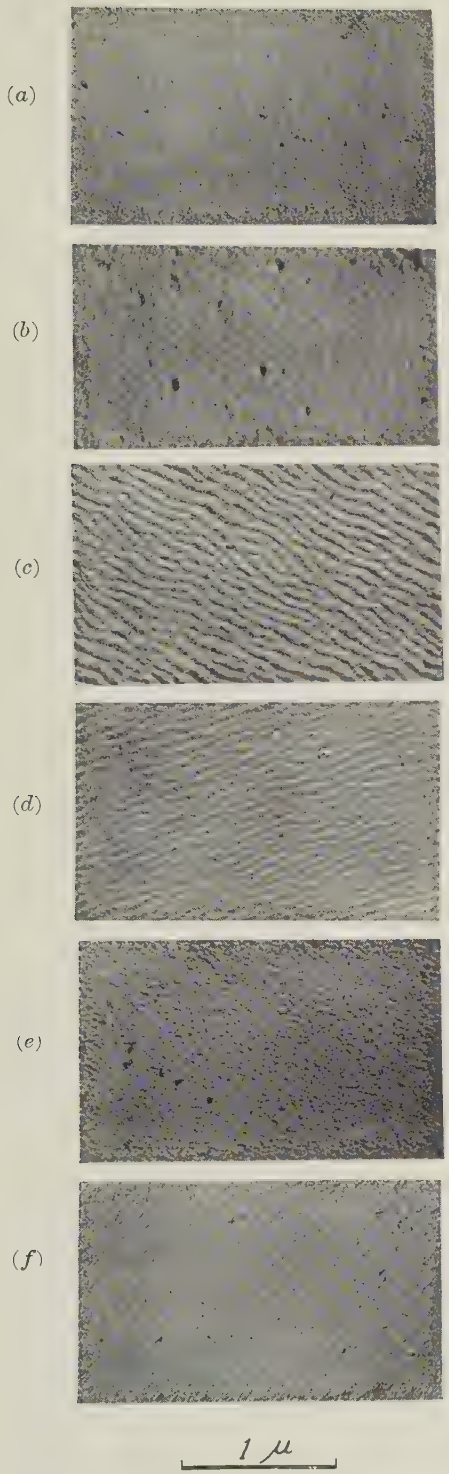

Fig. 11. Electron micrographs of Pd-shadowed collodion replica of Ni$_3$Mn alloy quenched from (*a*) 700°C, (*b*) 520°C, (*c*) 500°C, (*d*) 460°C, (*e*) 400°C and (*f*) room temperature.

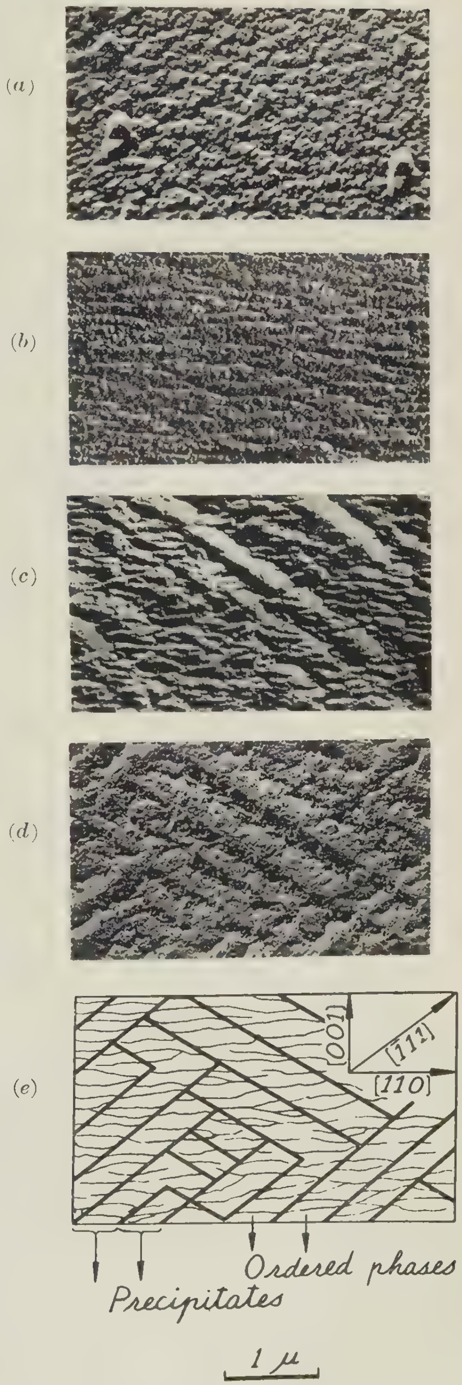

Fig. 12. Electron micrographs of Pd-shadowed replica on (**110**) plane of single crystal of Ni–Mn alloy, which contains 22 atomic percent Mn, quenched from (*a*) 700°C, (*b*) 510°C, (*c*) 360°C, (*d*) room temperature and (*e*) its interpretation.

intermediate state of order and their long axes are parallel to ⟨**110**⟩ directions as illustrated in Fig. 12(*e*).

2) The ordered phases become undistinguishable when the superlattice formation made progress, and mutually parallel valleys along two ⟨**111**⟩ directions in (**110**) plane gradually appear, as shown in Fig. 11(*c*). In the perfectly ordered state, rod-like structure, the dimension of which is about $0.55\,\mu\times 2\sim 5\mu$, can be clearly observed as shown in Fig. 11 (*d*). It seems that the precipitates are elongated to the ⟨**111**⟩ directions. Quite similar phenomena was found by Nesbitt, Williams and Bozorth[17].

Moreover the measurements of magnetic anisotropy[18] carried out by using the disk of the single crystal of the alloy have showed that the anisotropy energy has the same order of magnitude as the magnetostatic energy caused by free poles of the ordered phase within the specimen, which can be expressed by

$$E_m=(1/2)N(\Delta I_s)^2V(1-V) \qquad (10)$$

Where $N$ is the demagnetizing factor of the ordered phase, $\Delta I_s$ is the difference of the magnetization of ordered phase and matrix, and $V$ is the volume proportion of the ordered phase. If the values $I_s=300$ gauss, $V=0.9$, $N=0.75$ which is estimated from the photograph, we obtain an anisotropy energy of about $3\times 10^3\,erg/cm^3$ which is in agreement with the observed value.

## § 5. Summary and Acknowledgement

Now, it can be concluded that the after-effect observed in $Ni_3Mn$ alloy with intermediate state of order is ascribed to the thermal activation process, which causes relaxed rotation of magnetization of the ordered phase of ellipsoidal form from the direction having an obtuse angle with the applied field to one having an acute angle. The experimental results can be explained as follows:

i ) The assumptions to derive the equation (3) are that number of particles per unit energy range is a constant within some energy range and successive activations do not produce additional states in the same range. The second assumption is understood plainly on the proposed mechanism. The first one could not be accepted after the above experimental results, however, unless $f(E)$ at $t=0$ varies as steeply with $E$ as does $\exp(-\lambda T)$, the logarithmic form of $t$ at equation (3) cannot be profoundly affected where $\lambda=C\exp(-E/kT)$. The existence of maximum activation energy $E_0$ is ascribed to the critical size of the single magnetic domain.

ii ) The relation of $\chi$ and $S$ is reasonable.

iii) The value of $S_{\max}/I_skT$ which is proportional to the volume of one of domains contributing to the after-effect is not affected by the temperature.

iv) It was pointed out by the electron microscopic study, that the most distinguished magnetic viscosity is associated with the formation of small ordered region of ellipsoidal form within the matrix of disordered phase.

v ) The absence of the influence of mechanical deformation on the phenomenon is also reasonable, because the direction of magnetization in the ordered phase cannot be changed easily by longitudinal tension.

The author wishes to express his hearty thanks to Prof. S. Kaya for his kind guidance, to Mr. Y. Tomono for his kind discussion throughout the course of this research. He also wishes to thank Prof. Y. Tani and Mr. A. Fukami for their guidance, and Messrs. S. Sakata and S. Aoyagi for their assistance on the techniques of the electron microscopic study.

# Note on the Paramagnetic Susceptibility and the Gyromagnetic Ratio in Metals

By Ryogo KUBO and Yukio OBATA

*Department of Physics, University of Tokyo*

(Received February 17, 1956)

Although the orbital magnetic moments of the electrons in metals are "quenched" by the crystal field, their contribution to the paramagnetic susceptibility for partly filled degenerate bands is shown to be of the same order of magnitude as the Pauli spin paramagnetism. This contribution corresponds to the so-called "temperature independent high frequency term" in the theory of the paramagnetic susceptibility of atoms. Due to this contribution, the gyromagnetic ratio is reduced by an appreciable amount.

## § 1. Introduction

In the usual treatment of the susceptibility of non-forromagnetic metals, paramagnetism has been considered to be entirely due to the unpaired spins of electrons. The contribution of the orbital magnetic moments to paramagnetism has been neglected for the reason that they are queched by the crystal field. Pauli's expression is used for theoretical estimation, and the discrepancy between theory and experiment is attributed to the exchange and correlation effects.

The purpose of the present note is to point out that, for metals with partly filled non-*s* bands, the orbital magnetic moment contributes to the paramagnetic susceptibility through the second order perturbation, the order of which is in general not negligibly small compared with the Pauli spin paramagnetism. In connection with this, it is shown that the gyromagnetic ratio, $g'$, of non-ferromagnetic metals is smaller than 2 by an appreciable amount.

The reasoning to the above conclusion is as follows: In the case of paramagnetic salts, where the magnetic electrons are well localized, the orbital contribution* through the second order perturbation is of the order of $\mu^2/\Delta$, where $\mu$ is the Bohr magneton and $\Delta$ is the mean separation of the energy levels connected by the orbital angular momentum. This is negligibly small compared with the spin contribution, which is of the order $\mu^2/kT$ at room temperatures. In the case of metals, however, the spin paramagnetism is *reduced*** by the factor $T/T_0$, where $T_0$ is the degeneracy temperature. The orbital magnetic moment is also partly quenched by an effective crystal field which comes from the itenerant character of the electrons. The orbital paramagnetism of free atoms will thus be reduced in the metal to the fraction $T/T_0$, that is, the ratio of the thermal and the hopping energy. Therefore the orbital paramagnetism in metals with degenerate bands can be an appreciable part of the total paramagnetism. This is only because the spin part is greatly reduced. As an illustration of this idea, an estimation of the effect is given in § 3 for a much simplified $p$-band model, which is followed by some discussions in § 4.

---

* Apart from the first order term $\mu^2\lambda/kT\Delta$ through the spin-orbit coupling.

** For rare earth metals, the $4f$ electrons are localized rather than itinerant, so this reduction does not take place.

## § 2. General Expressions for the Susceptibility and the Gyromagnetic Ratio

Throughout the present paper we shall use the one-electron approximation. For a single electron in a metal subject to an external magnetic field $\boldsymbol{H}$, represented by the vector potential $\boldsymbol{A}$, the Hamiltonian may be written in the form,

$$\mathscr{H}=-\frac{\hbar^2}{2m}\Delta+V(\boldsymbol{r})+\Lambda+\frac{e^2}{2mc^2}A^2 -\frac{ie\hbar}{mc}\boldsymbol{A}\cdot\boldsymbol{\nabla}+\frac{e\hbar}{mc}\boldsymbol{H}\cdot\boldsymbol{S}\,, \qquad (1)$$

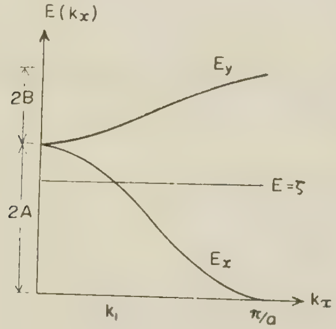

Fig. 1.

where $V$ is the electrostatic potential in the metal and $\Lambda$ is the spin-orbit coupling operator. We shall divide this Hamiltonian into two parts

$$\mathscr{H}=\mathscr{H}_0+\mathscr{H}_1\,,$$

where

$$\mathscr{H}_0=-\frac{\hbar^2}{2m}\Delta+V(\boldsymbol{r})+\Lambda+\frac{e^2}{2mc^2}A^2\,, \qquad (1\text{ a})$$

$$\mathscr{H}_1=-\frac{ie\hbar}{mc}\boldsymbol{A}\cdot\boldsymbol{\nabla}+\frac{e\hbar}{mc}\boldsymbol{H}\cdot\boldsymbol{S}$$

$$=\mu\boldsymbol{H}(\boldsymbol{L}+2\boldsymbol{S})\,, \qquad (1\text{ b})$$

in which the usual gauge $\boldsymbol{A}=(\boldsymbol{H}\times\boldsymbol{r})/2$ is used.

$\boldsymbol{A}$ is linear in electron coordinate and is not a small perturbation in the usual sense. Using Peierls' technique[1)2)], however, we can get rid of this difficulty.

The susceptibility of the metal is given by

$$\chi=-\left(\frac{\partial^2F}{\partial H^2}\right)_{\zeta=\text{const},\,H\to0}, \qquad (2)$$

$$F=N\zeta+\text{Tr}\,g(\mathscr{H})\,, \qquad (3)$$

where

$$g(\mathscr{H})=-kT\log(1+\exp(\zeta-\mathscr{H})/kT)\,. \quad (4)$$

Since $\mathscr{H}_1$ is digonal in the wave vector $\boldsymbol{k}$ in the tight binding approximation[2)], $\text{Tr}\,g(\mathscr{H})$ may be expanded in powers of $\mathscr{H}_1$ as follows;

$$\text{Tr}\,g(\mathscr{H}_0+\mathscr{H}_1)=\text{Tr}\,g(\mathscr{H}_0)+\sum_m g'(E_m)\langle m|\mathscr{H}_1|m\rangle$$

$$+\frac{1}{2}\sum_m\sum_{m'}\frac{g'(E_m)-g'(E_{m'})}{E_m-E_{m'}}|\langle m|\mathscr{H}_1|m'\rangle|^2+\cdots\,, \qquad (5)$$

where the representation in which $\mathscr{H}_0$ is diagonal is used. The first term in the right-hand side of the Eq. (5) was discussed by Peierls for a single-band case. The contribution from this term to the susceptibility* will be denoted by $\chi_d$. The second term vanishes except for ferromagnetic metals. From the third term the paramagnetic susceptibility $\chi_p$ is obtained. Since we are interested in the terms of the order of $H^2$, we can substitute for $E_m$ the value in the absence of $\boldsymbol{H}$. Thus, the susceptibility is given by

$$\chi=\chi_d+\chi_p\,,$$

with

$$\chi_p=\mu^2\sum_{nn'}\int\frac{dk}{(2\pi)^3}\frac{f(E_n(\boldsymbol{k}))-f(E_{n'}(\boldsymbol{k}))}{E_{n'}(\boldsymbol{k})-E_n(\boldsymbol{k})}\langle n\boldsymbol{k}|\boldsymbol{L}+2\boldsymbol{S}|n'\boldsymbol{k}\rangle\langle n'\boldsymbol{k}|\boldsymbol{L}+2\boldsymbol{S}|n\boldsymbol{k}\rangle\,, \qquad (6)$$

where

$$f(x)\equiv g'(x)$$

$$=\{\exp(x-\zeta)/kT+1\}^{-1}\,, \qquad (7)$$

is the Fermi distribution function.

$\chi_p$ consists of three contributions:

---

* In the presence of the spin-orbit coupling, the expression given by Peierls may be modified. In this paper, however, we shall not discuss this point in detail.

i) $$\chi_S=\mu^2\sum_{nn'}\int\frac{d\boldsymbol{k}}{(2\pi)^3}\frac{f(E_n(\boldsymbol{k}))-f(E_{n'}(\boldsymbol{k}))}{E_{n'}(\boldsymbol{k})-E_n(\boldsymbol{k})}\langle n\boldsymbol{k}|2\boldsymbol{S}|n'\boldsymbol{k}\rangle\langle n'\boldsymbol{k}|2\boldsymbol{S}|n\boldsymbol{k}\rangle\simeq 2\mu^2 n(\zeta)\,, \tag{8}$$

where $n(\zeta)$ is the state density at the Fermi surface. This is the well-known Pauli spin paramagnetism.

ii) $$\chi_{S0}=\mu^2\sum_{nn'}\int\frac{d\boldsymbol{k}}{(2\pi)^3}\frac{f(E_n(\boldsymbol{k}))-f(E_{n'}(\boldsymbol{k}))}{E_{n'}(\boldsymbol{k})-E_n(\boldsymbol{k}))}\{\langle n\boldsymbol{k}|\boldsymbol{L}|n'\boldsymbol{k}\rangle\langle n'\boldsymbol{k}|2\boldsymbol{S}|n\boldsymbol{k}\rangle + \langle n\boldsymbol{k}|2\boldsymbol{S}|n'\boldsymbol{k}\rangle\langle n'\boldsymbol{k}|\boldsymbol{L}|n\boldsymbol{k}\rangle\}\,. \tag{9}$$

This term is smaller than $\chi_S$ by the factor of $\lambda/\Delta$, where $\lambda$ is the spin-orbit energy and $\Delta$ is the mean band width. This is usually unimportant.

iii) $$\chi_0=\mu^2\sum_{nn'}\int\frac{d\boldsymbol{k}}{(2\pi)^3}\frac{f(E_n(\boldsymbol{k}))-f(E_{n'}(\boldsymbol{k}))}{E_{n'}(\boldsymbol{k})-E_n(\boldsymbol{k})}\langle n\boldsymbol{k}|\boldsymbol{L}|n'\boldsymbol{k}\rangle\langle n'\boldsymbol{k}|\boldsymbol{L}|n\boldsymbol{k}\rangle\,. \tag{10}$$

This is the term which comes from the second-order effect of the orbital angular momentum. It is a polarization effect and is always paramagnetic. The magnitude of this term is of the order $\mu^2/\Delta$.

The expression for the gyromagnetic ratio $g'$ is given by

$$\begin{aligned} g'&=\frac{\sum_{nn'}\int\frac{d\boldsymbol{k}}{(2\pi)^3}\frac{f(E_n(\boldsymbol{k}))-f(E_{n'}(\boldsymbol{k}))}{E_{n'}(\boldsymbol{k})-E_n(\boldsymbol{k})}\langle n\boldsymbol{k}|\boldsymbol{L}+2\boldsymbol{S}|n'\boldsymbol{k}\rangle\langle n'\boldsymbol{k}|\boldsymbol{L}+2\boldsymbol{S}|n\boldsymbol{k}\rangle}{\sum_{nn'}\int\frac{d\boldsymbol{k}}{(2\pi)^3}\frac{f(E_n(\boldsymbol{k}))-f(E_{n'}(\boldsymbol{k}))}{E_{n'}(\boldsymbol{k})-E_n(\boldsymbol{k})}\langle n\boldsymbol{k}|\boldsymbol{L}+2\boldsymbol{S}|n'\boldsymbol{k}\rangle\langle n'\boldsymbol{k}|\boldsymbol{L}+\boldsymbol{S}|n\boldsymbol{k}\rangle}\\ &=\frac{\chi_S+\chi_{S0}+\chi_0}{\frac{1}{2}\chi_S+\frac{3}{4}\chi_{S0}+\chi_0}\\ &=\frac{2(1+\chi_{S0}/\chi_S+\chi_0/\chi_S)}{1+3\chi_{S0}/2\chi_S+2\chi_0/\chi_S}\sim\frac{2(1+\chi_0/\chi_S)}{1+2\chi_0/\chi_S}\,. \end{aligned}\tag{11}$$

Thus it is clear from the above expression (11) that $2-g'$ can become quite appreciable in those metals which have partly filled degenerate bands.

It should be noted that orbital paramagnetism, represented by $\chi_0$, has little to do with the deviation of the spectroscopic splitting factor, $g$, from 2, since $g$ is determined by the first order Zeeman effect. Therefore, for paramagnetic metals* the following inequality is generally valid,

$$g-2<2-g'\,.$$

## § 3. Simple Model

For the numerical estimation of $\chi_0$, detailed knowledges of the band structure and wave functions are necessary. Even when these are at hand, calculation for actual metals would be laborious. So, in this section, we shall consider a much simplified model.

For a rather fictitious case of $p$ electrons in a simple cubic lattice, without spin-orbit coupling, we can give a little more explicit forms for $\chi_S$ and $\chi_0$. In this case, the matrix element of $\boldsymbol{L}$ and $\boldsymbol{S}$ are independent of $\boldsymbol{k}$, so the expression (10) is greatly simplified. If the magnetic field is applied in the $z$ direction, we have

$$\chi_S=2\mu^2 n(\zeta)\,, \tag{12}$$

and

$$\chi_0=2\mu^2\int\frac{d\boldsymbol{k}}{(2\pi)^3}\frac{f(E_x(\boldsymbol{k}))-f(E_y(\boldsymbol{k}))}{E_y(\boldsymbol{k})-E_x(\boldsymbol{k})}\,, \tag{13}$$

where $E_x(\boldsymbol{k})$, $E_y(\boldsymbol{k})$ are given in the usual text-books[3)].

Even in this case, the numerical calculation would be tedious. As seen from Eqs. (11), (12) and (13), we get the following relations

$$g'=2\frac{1+\xi}{1+2\xi}\,, \tag{14}$$

$$\xi=\chi_0/\chi_S \simeq\frac{1}{\Delta}\Big/n(\zeta)\sim 1\,. \tag{15}$$

Let us simplify the above model further, and consider one-dimensional case (which corresponds to (100) cut in the $\boldsymbol{k}$ space). The band energy will be written in the form

---

* Of course, the statement made here does not apply to the ferromagnetic substances.

$$E_x = A(1+\cos k_x a)\ ,$$
$$E_y = 2A + B(1-\cos k_x a)\ .$$

In this case, as easily calculated, the susceptibility is given by

$$\chi_S = 2\mu^2 \left| \frac{1}{\pi a A \sin k_1 a} \right| , \tag{16}$$

and

$$\chi_0 = 2\mu^2 \frac{1}{2\pi a(A+B)} \cot \frac{k_1 a}{2} , \tag{17}$$

where

$$\zeta = E_x(k_1)\ .$$

The ratio of the two contributions is given by

$$\xi = \frac{\chi_0}{\chi_S} = \frac{A}{A+B}(1+\cos k_1 a)\ .$$

Since $A$ is much greater than $B$, we have

$$\xi \simeq 1 + \cos k_1 a\ .$$

## § 4. Discussions

Although the model in the preceding section is too much simplified, it is an illustration of the importance of $\chi_0$ when the distribution of electrons is given by the Fermi distribution function. Therefore, if one wishes to calculate the absolute value of the paramagnetic susceptibility or gyromagnetic ratio for paramagnetic metals, one should, except for alkali metals where electrons are almost $s$-like take into account the orbital contribution besides the corrections due to exchange and correlation effects. The exchange and correlation effects usually almost cancel each other. Their effects on $\chi_0$ are also expected to be small.

If the experimental data of the electron spin resonance, static susceptibility, $g$ and $g'$ of a metal are at hand, we can get a measure of each of the three contributions to the paramagnetic susceptibility, $\chi_S$, $\chi_{S0}$ and $\chi_0$. Therefore, it is highly desirable that measurements on the electron spin resonance and gyromagnetic ratio are carried out for paramagnetic metals.

Often the experimental value of the paramagnetic part of the susceptibility is larger than the calculated $\chi_S$, using the state density obtained by some other kinds of experimental data. In such cases the contribution of the orbital paramagnetism may be important.

The interband contribution to the susceptibility has already been considered by A. H. Wilson[4] and N. E. Adams[5]. Wilson obtained for the susceptibility the expression (35) of his paper, beside the Peierls susceptibility. If the Fermi distribution is used instead of Boltzmann's, it may be written in the form

$$\chi = \frac{m^2\mu^2}{\hbar^2} \int \frac{d\boldsymbol{k}}{(2\pi)^3} g[E_n(\boldsymbol{k})] \int_{\text{unit cell}} \left( \frac{\partial^2 u_{\boldsymbol{k}n}{}^*}{\partial k_x{}^2} \frac{\partial^2 u_{\boldsymbol{k}n}}{\partial k_y{}^2} + \frac{\partial^2 u_{\boldsymbol{k}n}{}^*}{\partial k_y{}^2} \frac{\partial^2 u_{\boldsymbol{k}n}}{\partial k_x{}^2} - 2 \frac{\partial^2 u_{\boldsymbol{k}n}{}^*}{\partial k_x \partial k_y} \frac{\partial^2 u_{\boldsymbol{k}n}}{\partial k_x \partial k_y} \right) d\tau_0\ .$$

In the case of tight-binding this term represents the difference of gauge factor for ajacent atomic functions and becomes zero in the limit of isolated atoms. The physical meaning of this term is not clear.

Adams obtained a paramagnetic term

$$\chi_A = \frac{1}{4} \mu^2 n(\zeta) \langle (l^{xy} - l^{yx})^2 \rangle ,$$

which is connected to the presence of the orbital angular momentun. This is, however, different from the effect we considered. This is important only for the case in which orbital momentum has nonvanishing diagonal elements.

In both Wilson's and Adams' calculations, the orbital contribution is not fully taken into account.

# Study of Magnetic Annealing on $Ni_3Fe$ Single Crystal

By Sōshin CHIKAZUMI

*Department of Physics and Chemistry, Gakushuin University,*
*Mejiro, Tokyo, Japan*

(Received at February 17, 1956)

Magnetic anisotropy induced by magnetic annealing was measured for $Ni_3Fe$ single crystal by means of a high temperature-torque magnetometer. It was found that the magnitude of anisotropy depends upon the crystallographic direction of the field which is applied during annealing. It was largest for <111>, next for <110> and smallest for <100>. It was also found that the minimum of the anisotropy energy lies not in just the same direction as that of annealing field, but in the direction nearer to the neighboring <111>. These facts could be explained qualitatively by Néel-Taniguchi-Yamamoto's formula. Quantitative discrepancy between them could be attributed to the nature of face-centred cubic lattice that some of the nearest neighbors of one atom are also in nearest neighbors of one another. Influence of ordinary order was also investigated.

## § 1. Introduction

It was first found by Kelsall[1] that the presence of a magnetic field during heat treatment of the iron-nickel alloys causes a large increase in maximum permeability. This phenomenon can be interpreted as a result of appearance of the magnetic anisotropy, which has its stable direction parallel to the annealing field. Many investigators have studied the mechanism of this anisotropy, to which reference was made in the foregoing paper[2].

The author has investigated this phenomenon on a single crystal of $Ni_3Fe$ for the purpose of studying the details of this anisotropy. A part of this result has been referred by S. Kaya[3] in his report. Recently L. Néel[4] and independently S. Taniguchi and M. Yamamoto[5] carried out the detailed calculations on this anisotropy and showed that their result is in good agreement with the observation of the present author.

In this paper the author will give a full report on the details of the experiment and will make a comparison with the theory.

## § 2. Apparatus and Specimen

Measurement of magnetic anisotropy was carried out by means of the torque magnetometer as shown in Fig. 1, which was specially constructed for the purpose of this investigation. This apparatus is characterized by a high sensitivity and high temperature uses. Specimen **O** mounted to a quartz disk **Q** is suspended freely under the elastic string **P** without any mechanical bearing for the purpose of avoiding any frictional forces. The horizontal displacement of the specimen could be avoided by using the generallized Helmholtz coil **C**, which is designed to produce an accurately uniform field. The coil constant of this coil is 107.4 Oe/amp. The current is

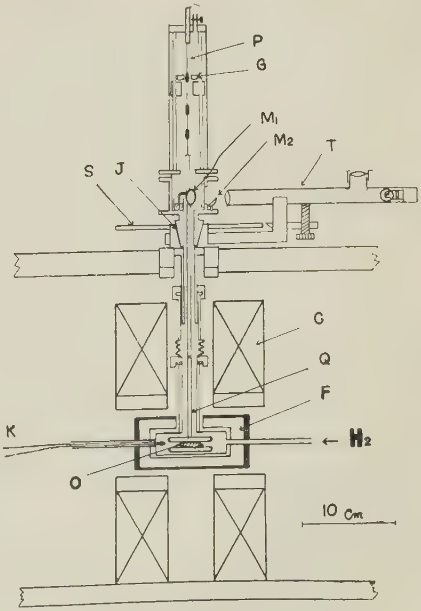

Fig. 1. Construction of high temperature torque magnetometer. **P**: elastic string, **G**: grip for fixing the top of P, $\mathbf{M}_1, \mathbf{M}_2$: mirrors, **T**: autocollimation telescope, **S**: circular scale, **J**: metal joint, **C**: large Helmholtz coil, **F**: electric furnace, **Q**: specimen holder, **O**: specimen, **K**: junction.

limited within 6 amp. By using a small electric furnace **F** set in this coil, the specimen could be heat-treated under the presence of a magnetic field. This furnace is also useful for the measurement of torque curve at elevated temperature. In order to protect the specimen from oxidation, the specimen together with the suspended system is confined in a hydrogen atmosphere.

The upper part of the apparatus, separated from the lower part at a ground metal joint **J**, is rotatable around vertical axis together with the suspended system. The orientation of the specimen can be determined by the mirror $\mathbf{M}_1$, which is attached to the suspended system. The torque exerted on the specimen can also be determined by the twisted angle of elastic string **P**, which is equal to the angle between $\mathbf{M}_1$ and $\mathbf{M}_2$, the latter being the mirror attached at a rotatable part. Both mirrors were previously adjusted to be parallel when no torque exerted on the specimen. The direction of the mirror was determined by means of the autocollimation telescope **T**, which is movable around the circular scale **S**. Accuracy of the measurement of the angle was about ±0.05°. The sensitivity of the elastic string can be altered by changing the fixing point of the string by means of the grip **G**, which is movable vertically along the elastic string by the externally controlled action of mechanism. The sensitivity for each grip was 11.3, 27.9, 91.8 and 341 dyne-cm /degree respectively.

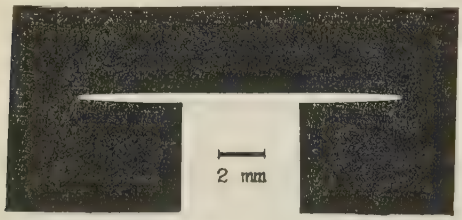

Fig. 2. The profile-projection of the specimen disk.

The specimen used was an oblate of $Ni_3Fe$ single crystal having a surface parallel to (110). On account of the low intensity of the magnetic field, a demagnetizing factor of specimen must be limited within the value smaller than 0.3. Moreover, since the anisotropy in question is as small as $10^2$erg/cc, specimen must be made in an accurate shape, otherwise a slight deviation would cause a disturbing anisotropy.

The preparation of the specimen in such a thin and accurate shape was the most difficult task in this experiment. Various methods were tried on twelve specimens. The method finally adopted was as follows: The crystal was firstly cut into an accurate circular plate, the size of which was 0.445±0.001 mm in thickness and 14.005±0.001 mm in diameter. This shaping was made by means of a small grinder lathe. This plate was then attached by magnetic means to a rotatable axis made of M. K. magnet and was electropolished with about 20 amp (40 volt) by dipping an under half of the plate into the electrolyte and by rotating it with a high speed of 2000~4000 r.p.m. Sometimes the plate was reset to an optical projector and its profile was compared with a standard elliptic form. The depth of the dipping was sometimes altered so as to fit its shape to a required one. This operation, however, need not be very delicate, because the shape of the plate tends to approach to a nearly ellipsoidal form, if it is done without careful adjustment. The rotational motion must be maintained at high speed, because it was found that a low speed polishing results in a slightly deviated shape having a cyrstallographic symmetry. When the speed was lowered down to 100~200 r.p.m., the resulting fluctuation of diameter was about 1 %, which is large enough to arise the anisotropy $0.5 \times 10^2$ erg/cc. The reason why a high speed rotation has a good effect is not clear, but it may be related to the following fact: When the speed is increased, it is found that the electrode resistance increases and the electrolytic efficiency is largely decreased. Accordingly the voltage difference between electrodes could be largely increased, while maintaining the current within relatively small value.

The final shape of the specimen was 13.698±0.005 mm in diameter and 0.452 mm in thickness at the center. The projection is shown in Fig. 2. A calculated demagnetizing factor was 0.288.

## § 3. Details of the Experimental Method

After the specimen was set in a torque meter, the heat treatments and torque measurements were repeated without removing the specimen from the apparatus.

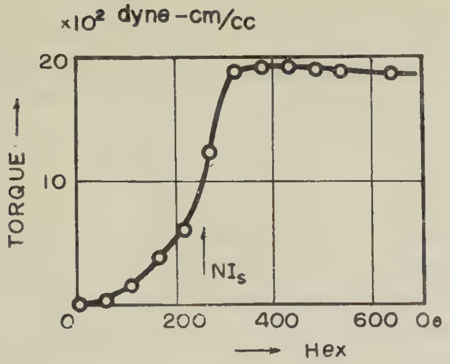

Fig. 3. Dependence of the torque upon intensity of a magnetic field.

The process of the magnetic annealing is as follows: Firstly the specimen is heated up to 650°C and annealed for 30 min., then it is cooled at a controlled rate down to room temperature in a magnetic field. The intensity of the field is 320∼430 Oe, which is large enough to magnetize the specimen parallel to the field. During this treatment the suspended system is fixed by the grip **G** and the orientation of the specimen relative to the field is accurately determined by using the mirror $\mathbf{M}_1$ and the telescope.

After cooling the torque curve is measured at room temperature. The intensity of the magnetic field in this case is 430 Oe, which is also large enough to induce the saturated intensity of the torque. The dependence of the torque upon intensity of the field is shown in Fig. 3 for the present specimen. It is seen in this figure that the torque saturates at about 300 Oe, which is nearly equal to the calculated intensity of the demagnetizing field $NIs=260$ Oe. If the specimen were in a shape of circular plate, as is usually the case, the torque would increase gradually with an increase of the field intensity. In such a case the true torque value must be determined by the extrapolation to $H_{ex}=2\pi I_s$. It was, however, unnecessary for the present specimen.

It should be added here that a very small change in the torque (positive or negative) was observed in the high field region. The magnitude and the sign of this change depend upon the crystallographic direction of the field. In the case of Fig. 3 it was negative. In other words, there is a small field-dependent anisotropy, whose curve form is different from the fundamental one. Since this anomalous anisotropy can be reduced by the

thermal treatment, it may be caused by the residual strain. After annealing it becomes smaller than 50 dyne cm/cc, which was negligibly small as compared to the fundamental one.

## § 4. Experimental Results

Some of the torque curves obtained after cooling in a magnetic field are shown in Fig. 4 for various crystallographic directions of annealing field. In order to make the interpretation easier, the torque curves were converted to energy curves as shown in Fig. 5 by integrating the torque values with respect to the angle. The integration was made by summing the torque values at each five degrees, the calculation of which introduces the error less than 0.1%.

It will be natural to consider that the anisotropy energy thus obtained consists of the usual crystal anisotropy $E_k$ and the uniaxial anisotropy $E_u$ induced by magnetic annealing. The anisotropy energy in (110) plane will then be given by

$$\begin{aligned} E &= E_k + E_u \\ &= K_1(\sin^4\theta/4+\sin^2\theta\cos^2\theta)+K_2\sin^4\theta\cos^2\theta/4 \\ &\quad -K_u\cos^2(\theta-\theta_0)\,, \qquad (1) \end{aligned}$$

where $K_1$ and $K_2$ are the usual constants of crystal anisotropy, $K_u$ is the constant of uniaxial anisotropy and $\theta$ is the direction of intrinsic magnetization as measured from ⟨100⟩ direction.

The experimental curves in Fig 5 could be analyzed into several terms in Eq. (1) by means of the Fourier analysis. This calculation was easily carried out by summing up the products of energy values and $\sin 2\theta$, $\cos 2\theta$, $\sin 4\theta$, $\cos 4\theta$, $\sin 6\theta$ or $\cos 6\theta$ at every 15 degrees in $\theta$, where the values of sin or cos at these angles are limited into one of 1.00, 0.866, 0.500 or 0.00. For the present specimen the $K_2$ term was found to be less than 1% of $K_1$ term, so $K_2$ term can be reasonably neglected. $E_k$ and $E_u$ terms thus analyzed are shown in Fig. 5, together with sum of these terms (shown by circles), which agrees well with original curves.

By comparing the $E_u$ curves, in Fig. 5 one may find that the depthes of the minimum, namely $K_u$, are considerably different with one another. It is noticed, further, that when the direction of the annealing field does not coinside with the principal crystallographic directions (Cf. Fig. 5 (d)), the minimum in $E_u$ lies not in just the same direction as that of the annealing field, but in the direction nearer to the neighboring ⟨111⟩ direction. The angle of deviation will be denoted by $\Delta\theta$ hereafter, which is given by

$$\Delta\theta=\theta_0-\theta_t\ , \qquad (2)$$

where $\theta_t$ is the direction of annealing field.

The values of $K_1, K_u$ and $\Delta\theta$ are plotted as a function $\theta_t$ in Figs. 6 and 7 for various cooling rate.

It is seen in Fig. 6 that $K_u$ depends upon the crystallographic direction of the annealing field, being largest at ⟨111⟩, second at ⟨110⟩ and smallest at ⟨100⟩, while the $K_1$ is fixed at a constant value. The value of $K_1$ increases with decrease of cooling rate as seen in the same figure. This is due to the development of ordinary order. Since the development of the ordinary order means a decrease of B–B pairs, the $K_1$ value can be interpreted as an indication of a decrease of B–B pairs. ($K_1$ is negligibly small at disordered state for the present composition Cf. Fig. 10). On the other hand, since $K_u$ can be interpreted as resulting from the unbalanced distribution of B–B pairs Cf. § 5), we can regard $K_u$ versus $K_1$ curve as indicating the variation of the unbalanced B–B pairs as a function of total number of B–B pairs. Fig. 8 shows such a variation of $K_u$ as a function of $K_1$, together with the variation of $\Delta\theta$. In this case the direction of the annealing field, $\theta_t$, was fixed at 13.5°, where $\Delta\theta$ takes the maximum value as seen in Fig. 7. It is seen that $K_u$ increases at first with order formation, but it decreases with an approach to perfect order. It is quite natural that the unbalancing of B–B pairs vanishes with vanishing of B–B pairs. The variation of $\Delta\theta$ will be interpreted in § 5.

## § 5. Interpretation of the Result

Néel[4] and independently Taniguchi and Yamamoto[5] carried out the calculation on the anisotropy induced by magnetic annealing in terms of directional order and dipole coupling between atom pairs. They showed that their result is in good agreement with the preliminary result[3] of the present author. The same mechanism has independently been considered by the present author[2] in order to interprete the variation of $K_u$ with composition of iron-nickel system.

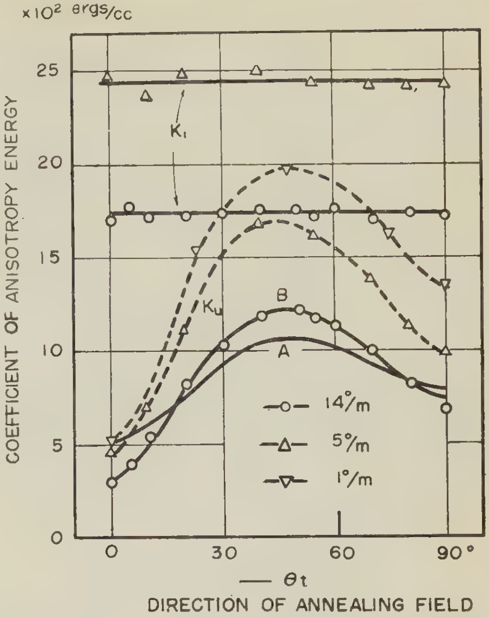

Fig. 6. $K_u$ and $K_1$ as a function of $\theta_t$ (direction of annealing field). A: Neel-Taniguchi-Yamamoto's formula, B: Experimental formula with $k_2/k_1=8.5$.

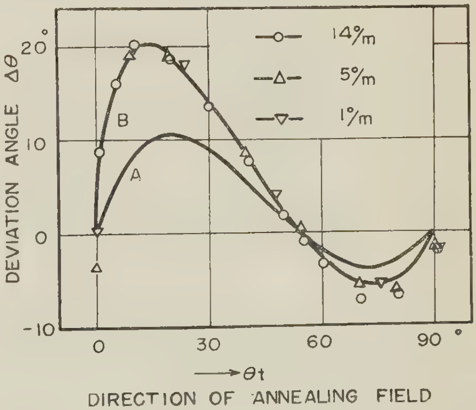

Fig. 7. $\Delta\theta$ (deviation of minimum direction $\theta_0$ from $\theta_t$) as a function of $\theta_t$. A: Néel-Taniguchi-Yamamoto's formula, B: Experimental formula with $k_2/k_1=8.5$.

Now we shall briefly follow their calculation: Firstly it is assumed that in binary alloy of A–B system the dipole-dipole interactions between neighboring atoms are different between different sorts of atom pairs A–A, B–B and A–B. Since the distribution of A–A or B–B pairs are necessarily determined by the distribution of B–B pairs, we may keep our attention exclusively on B–B pair by regarding it as having the energy

$$\omega_k=(l_{AA}+l_{BB}-2l_{AB})\cos^2\varphi_k$$
$$=l\cos^2\varphi_k\ , \qquad (3)$$

where $l_{AA}$, $l_{BB}$ and $l_{AB}$ are the coefficients of dipole-dipole interaction of A–A, B–B and A–B pairs and $\varphi_k$ is the angle between $k$-th bond direction and the intrinsic magnetization. When the alloy is annealed in a magnetic field, since the energy of B–B pair depends upon its bond direction relative to the field, the number of B–B pairs having $k$-th bond direction, $N_k$, will be proportional to the Boltzman factor $\exp(-w_k/kT)$. After the alloy is cooled down to room temperature, such an unbalanced distribution of B–B pairs (called directional order) shoud give rise to the anisotropy energy, which is given by

$$E_u=\sum_k N_k\omega_k'$$
$$=\left(\frac{N_0}{z}\right)\sum_k \exp(-\omega_k/kT)\omega_k'\ , \qquad (4)$$

where $\omega_k'$ is the energy after cooling, $N_0$ is the total number B–B pair contained in 1 cc and $z$ is the number of nearest neighbors. Putting Eq. (3) and

$$\omega_k'=l'\cos\varphi_k'\ . \qquad (5)$$

into Eq. (4), we have approximately

$$E_u=-\frac{N_0ll'}{zkT}\sum_k \cos^2\varphi_k\cos^2\varphi_k'\ . \qquad (6)$$

After summing up over all bond directions, we have

$$E_u=-\frac{N_0ll'}{kT}\left(k_1\sum_i \beta_i\gamma_i+k_2\sum_{i>j}\beta_i\beta_j\gamma_i\gamma_j\right) \qquad (7)$$

where $\beta_i$ and $\gamma_i$ are the direction cosines of intrinsic magnetization and the annealing field. The values of $k_1$ and $k_2$ are given in Tab. I for various crystal type.

Table I.

| crystal type | $k_1$ | $k_2$ |
|---|---|---|
| face-centred cubic | 1/12 | 4/12 |
| body-centred cubic | 0 | 4/9 |
| simple cubic | 1/3 | 0 |

We shall call the formula (7) together with Tab. I as Néel-Taniguchi Yamamoto's formula (N.T.Y.). When the intrinsic magnetization lies in (110) plane, Eq. (7) becomes

$$E_u=-K_u\cos^2(\theta-\theta_0)\ , \qquad (8)$$

where

$$K_u^2=K^2(p_0+p_1\cos 2\theta_t+p_2\cos^2 2\theta_t) \qquad (9)$$

with

$$p_0=\frac{1}{64}(4k_1^2+4k_1k_2+17k_2^2)$$
$$p_1=\frac{1}{32}(12\,k_1^2-4\,k_1k_2-k_2^2)$$
$$p_2=\frac{3}{64}(12\,k_1^2+4\,k_1k_2-5k_2^2)\ , \qquad (10)$$

and

$$\cot 2\theta_0'=q_1\operatorname{cosec} 2\theta_t+q_2\cot 2\theta_t \qquad (11)$$

with

$$q_1=\frac{1}{2}-\frac{k_2}{4k_1}$$
$$q_2=\frac{3}{2}+\frac{k_2}{4k_1}\ . \qquad (12)$$

By using the values of $k_1$ and $k_2$ for face-centred cubic lattice (Tab. I), we can have the theoretical relations $K_u(\theta_t)$ and $\Delta\theta(\theta_t)$ from Eqs. (9) and (11). They are graphically shown as curve A in Figs. 6 and 7. It is seen that qualitative features of the experimental curve can be well explained by these theoretical curves.

Now we shall determine the values of $k_1$ and $k_2$ so as to fit the formula (7) with experiment. By analysing the experimental curves of Figs. 6 and 7 by Fourier analysis and comparing it with Eqs. (9) and (11), we have the values

$$p_0K^2=147.6\times10^4,\qquad p_1K^2=-22.6\times10^4,$$
$$p_2K^2=-115.6\times10^4;$$
$$q_1=-0.191,\qquad q_2=0.427 \qquad (13)$$

for the case of cooling rate 14°/min. From these values we can easily have

$$k_1K=2.8_1\times10^2,\qquad k_2K=23.8\times10^2\ . \qquad (14)$$

It is seen in Figs. 6 and 7 that the formulas with the values of (14), shown graphically by the curve $B$, well represent the experimental plots. We have from Eq. (14)

$$k_2/k_1=8.5 \qquad (15)$$

as a experimental value, while we have obtained the theoretical value

$$k_2/k_1=4 \qquad (16)$$

as seen in Tab. I.

Now we shall consider the origin of this discrepancy between theory and experiment. It was found that it can be reasonably attributed to the nature of face-centred cubic lattice. In this lattice some of the nearest neighbors of one atom are also in nearest neighbor of one another. When, therefore, two B–B pairs enter into the neighboring bonds belonging to the same atom, the third B–B pair is necessarily produced, thus making the trigonal B–B–B group ($\varDelta$ B group) as shown in Fig. 9. It is easily proved that $\varDelta$B group has an energy $-(3/2)l\cos^2\varphi$, where $l$ is equal to that of Eq. (3) and $\varphi$ is the angle between magnetization and the normal of $\varDelta$B plane. Thus the $\varDelta$B group is equivalent to the atom pair having its bond direction parallel to ⟨111⟩ direction and will behave similarly to the atom pair in body-centred cubic lattice. Accordingly it may induce the magnetic anisotropy of body-centred cubic type. Then the magnetic anisotropy induced by B–B pair and $\varDelta$B group is given by

$$E_u=-\frac{ll'}{kT}\left\{\frac{N}{12}\sum_i\beta_i\gamma_i+\left(\frac{N_0}{3}+N'\right)\sum_{i>j}\beta_i\beta_j\gamma_i\gamma_j\right\} \tag{15}$$

where $N'$ is the total number of $\varDelta$B group and $N$ is that of B–B pairs which are not belonging to $\varDelta$B. Then

$$k_2/k_1=4+12\,N'/N\,. \tag{16}$$

In order to explain the experimental value 8.5, $N'=0.375\,N$, which may not be unreasonable value.

Now we shall consider the meaning of the variation of $\varDelta\theta$ in Fig. 8. For small value of $K_1$, $\varDelta\theta$ remains at a constant value which correspond to $k_2/k_1=8.5$. This means that the number of $\varDelta$ B group, $N$, decreases at first almost proportionally to the number of B–B pairs. It is seen, however, that when the alloy approaches to perfect order, $\varDelta\theta$ decreases gradually to about 10°, which is nearly equal to the value of N. T. Y curve (at 13.5°) in Fig. 7 and accordingly corresponds to $k_2/k_1=4$. This means that the number of $\varDelta$ B groups decreases more rapidly than that of B–B pairs. It will be reasonable, because the development of order would reject the presence of $\varDelta$ B group more severely than that of B–B pair, as being expected from the cooperative nature of the phenomenon. In short range ordered state, however, the cooperative effect is so weak that the rate of decrease of $\varDelta$ B group would not largely differ from that of B–B pairs.

Fig. 10 shows the variation of $K_1$ as a function of duration of the order treatment observed for the other specimen of Ni₃Fe.

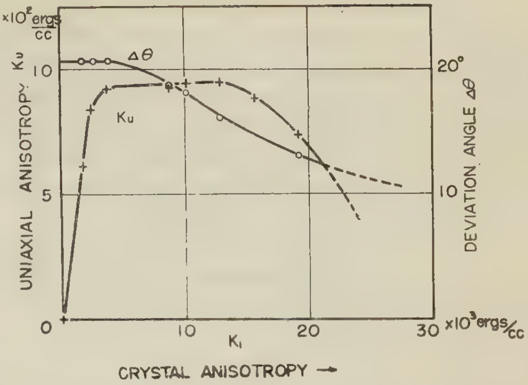

Fig. 8. $K_u$ and $\Delta\theta$ at $\theta_t=13.5°$ as a function of $K_1$. (Variation due to order formation.)

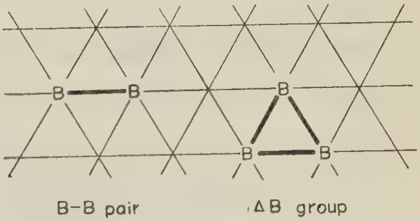

Fig. 9. Two types of the assembly of B atom in (111) plane of face-centred cubic lattice.

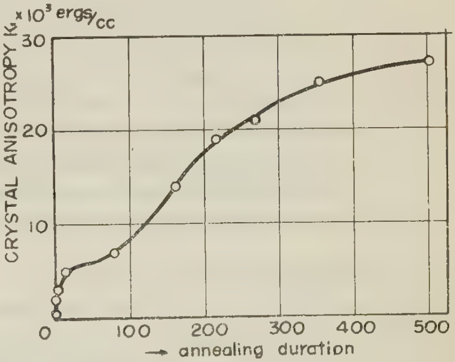

Fig. 10. Variation of $K_1$ with duration of order treatment (at from 490° to 430°C) for Ni₃Fe crystal.

It is interesting that the first increase of $K_1$ corresponds to the range where $\varDelta\theta$ remains unchanged.

It should be added that the influence of second nearest neighbor may not be important, because such pairs have the bond direction parallel to ⟨100⟩ and would induce the anisotropy of simple cubic type which increases $k_1$ instead of $k_2$ (Cf. Tab. I).

## § 6. Conclusions

It was shown that the characteristics of the magnetic anisotropy induced by magnetic annealing observed on $Ni_3Fe$ single crystal are well explained qualititavely by Néel-Taniguchi-Yamamoto's formula. Qualitative discrepancies between them can be interpreted by the nature of face-centred cubic lattice.

# The Forces Acting on Two Equal Circular Cylinders placed in a Uniform Stream at Low Values of Reynolds Number

By Hiroomi FUJIKAWA

*Junior College of Engineering, University of Osaka Prefecture*

(Received December 8, 1955)

The steady slow motion of a viscous fluid past two parallel circular cylinders of equal radius with their axes in one plane perpendicular to a uniform flow is discussed on the basis of Oseen's linearized equations of motion.

Expansion formulae in powers of Reynolds number $R$ for the forces acting on one of the cylinders are obtained correct to the order of $R$, the lowest order terms being $O(R^{-1})$.

After detailed numerical calculations, it is shown that the drag on one cylinder decreases as the distance between the two cylinders decreases and also that each cylinder experiences a repulsive force.

## §1. Introduction and Summary

The steady flow of a viscous fluid past an obstacle at small Reynolds numbers has been discussed so far by many authors on the basis of Oseen's linearized equations of motion. From these investigations it can be seen that the disturbance due to the obstacle spreads to a great distance at small Reynolds numbers. Therefore, it is expected in the case of flow past several obstacles that the interference effect would be very conspicuous.

In the present paper, the writer treats the steady slow motion of an incompressible viscous fluid past two parallel circular cylinders of equal radius with their axes in one plane perpendicular to a uniform stream. Expansion formulae in powers of Reynolds number for the forces acting on one of the cylinders are obtained up to the second term. Making use of these formulae, detailed numerical discussion is made for several cases when the distance between the axes of the two cylinders is equal to 10, 50, 100 and 500 times their diameter, the Reynolds number of the flow varying from 0 to 1.0.

Thus, it is found that, on increasing the distance between the two cylinders, the drag on one cylinder increases and approaches the value for a single cylinder in an unlimited stream. Also, it is found that each cylinder experiences a repulsive force in the direction perpendicular to the uniform stream.

## §2. Fundamental Equation and its Solutions

We consider two infinitely long parallel circular cylinders $C_1$, $C_2$, of equal radius $a$, set in a steady uniform stream of velocity $U$

of an incompressible viscous fluid in such a manner that their axes lie in a plane perpendicular to the uniform stream.

Let O$x$, O$y$ be the rectangular co-ordinate axes in the plane of fluid motion, the axis of $x$ being taken along the direction of the uniform stream and the origin coinciding with the centre of the cylinder $C_1$. The centre of the other cylinder $C_2$ is situated on the $y$-axis, its coordinates being denoted by $(0, -2h)$ (Fig. 1).

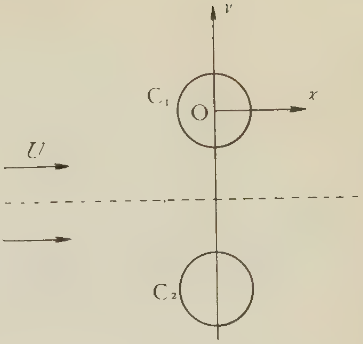

Fig. 1.

As is well known, the Navier-Stokes equations for the two-dimensional steady motion of an incompressible viscous fluid are written in a single equation as:

$$\left.\begin{aligned}\Delta\omega&=-\frac{1}{\nu}\frac{\partial(\Psi,\omega)}{\partial(x,y)}\,,\\ \omega&=-\Delta\Psi\,,\end{aligned}\right\} \tag{2.1}$$

where $\omega$ is the vorticity, $\Psi$ the stream function, $\nu$ the kinematic viscosity, and $\Delta$ stands for the operator $\partial^2/\partial x^2+\partial^2/\partial y^2$.

Now we may regard the flow under consideration as consisting of two parts, namely the uniform flow of the velocity $U$ and the perturbation due to the presence of the cylinders. Thus, denoting the perturbation stream function and the perturbation velocity components by $\psi$ and $u, v$ respectively, we may write

$$\Psi=Uy+\psi\,, \tag{2.2}$$

$$u=\partial\psi/\partial y\,,\qquad v=-\partial\psi/\partial x\,. \tag{2.3}$$

Inserting (2.2) into Eq. (2.1) and neglecting the second order terms in $\psi$, we arrive at Oseen's linearized equation of motion:

$$\Delta\left(\Delta-2k\frac{\partial}{\partial x}\right)\psi=0\,, \tag{2.4}$$

where

$$k=U/2\nu\,. \tag{2.5}$$

From (2.4), it will be seen that $\psi$ may be separated into two parts, namely harmonic and unharmonic parts:

$$\psi=\psi_h+\psi_u\,, \tag{2.6}$$

with

$$\Delta\psi_h=0\,, \tag{2.7}$$

and

$$\left(\Delta-2k\frac{\partial}{\partial x}\right)\psi_u=0\,. \tag{2.8}$$

For the case of a single circular cylinder placed in an unlimited uniform flow, the appropriate solutions of (2.7) and (2.8) which satisfy the boundary conditions at infinity have been given by Filon[1] in the forms;

$$\psi_h=\alpha_0\log r+a_0\theta+\sum_{n=1}^{\infty}r^{-n}(\alpha_n\cos n\theta+a_n\sin n\theta)\,, \tag{2.9}$$

$$\begin{aligned}k\psi_u=\beta_0e^{kx}K_0(kr)&+b_0\int_0^\theta kr\{K_1(kr)+K_0(kr)\cos\theta\}e^{kr\cos\theta}d\theta\\ &+e^{kx}\sum_{n=1}^{\infty}K_n(kr)(\beta_n\cos n\theta+b_n\sin n\theta)\,,\end{aligned} \tag{2.10}$$

where

$$x=r\cos\theta\,,\qquad y=r\sin\theta\,,$$

$a_n$, $\alpha_n$, $b_n$, $\beta_n$ are arbitrary real constants, and $K_n(kr)$ is the modified Bessel function of the second kind†. Also the condition that $\psi$ must be one-valued throughout the field of flow requires an additional condition

$$b_0/k=-a_0\,. \tag{2.11}$$

Let us here introduce the conjugate complex velocity

$$w=u-iv \tag{2.12}$$

for the perturbation flow, which is related to $\psi$ in the form:

---

† The definition of the modified Bessel function used here is identical with those in G. N. Watson's "*A Treatise on the Theory of Bessel Functions*" (Cambridge, 1922).

$$w=\psi_y+i\psi_x=2i\frac{\partial\psi}{\partial z},\qquad z=x+iy,\qquad \bar{z}=x-iy\,. \tag{2.13}$$

Then, after some calculations, it can be seen that

$$\left.\begin{aligned}
&w=w_h+w_u\,,\\
&w_h=\frac{A_0}{z}+\frac{A_1}{z^2}+\cdots\cdots\cdots\,,\\
&w_u=e^{kx}\Big\{\Big(B_0-\frac{1}{2}B_1\Big)K_0(kr)+\frac{1}{2}B_1K_1(kr)e^{i\theta}\\
&\qquad\qquad+\Big(\bar{B}_0-\frac{1}{2}\bar{B}_1\Big)K_1(kr)\,e^{-i\theta}+\frac{1}{2}\bar{B}_1K_2(kr)e^{-2i\theta}+\cdots\Big\}\,,
\end{aligned}\right\} \tag{2.14}$$

where

$$\left.\begin{aligned}
&A_0=a_0+i\alpha_0\,,\qquad A_1=a_1-i\alpha_1\,,\qquad \cdots\cdots\\
&B_0=b_0+i\beta_0\,,\qquad B_1=b_1+i\beta_1\,,\qquad \cdots\cdots\,.
\end{aligned}\right\} \tag{2.15}$$

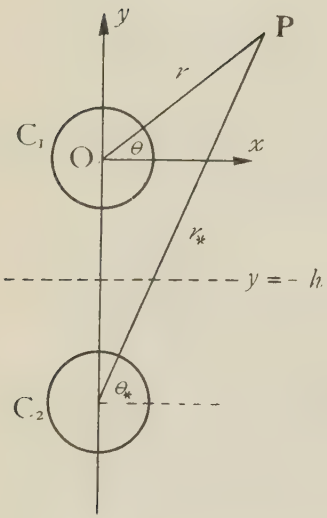

Fig. 2.

Now it may be observed from (2.9) and (2.10) that the perturbation flow due to the obstacle is composed of the harmonic and the unharmonic singularities (multiplets) situated at the origin. Therefore, in the present case in which the two circular cylinders are placed in the other-wise uniform stream, the perturbation flow may also be represented by the two systems of the fundamental singularities mentioned above, each being situated at the centre of the respective cylinder.

Thus, we may take the perturbation velocity $w$ in the form:

$$w=w_h^{(1)}+w_u^{(1)}+w_h^{(2)}+w_u^{(2)}\,, \tag{2.16}$$

with

$$\left.\begin{aligned}
&w_h^{(1)}=\frac{A_0}{z}+\frac{A_1}{z^2}+\cdots\cdots\,,\\
&w_u^{(1)}=e^{kx}\Big\{\Big(B_0-\frac{1}{2}B_1\Big)K_0(kr)+\frac{1}{2}B_1K_1(kr)e^{i\theta}\\
&\qquad\qquad+\Big(\bar{B}_0-\frac{1}{2}\bar{B}_1\Big)K_1(kr)e^{-i\theta}+\frac{1}{2}\bar{B}_1K_2(kr)e^{-2i\theta}+\cdots\cdots\Big\}\,,\\
&w_h^{(2)}=\frac{A_0{}^*}{z_*}+\frac{A_1{}^*}{z_*{}^2}+\cdots\cdots\,,\\
&w_u^{(2)}=e^{kx}\Big\{\Big(B_0{}^*-\frac{1}{2}B_1{}^*\Big)K_0(kr_*)+\frac{1}{2}B_1{}^*K_1(kr_*)e^{i\theta_*}\\
&\qquad\qquad+\Big(\bar{B}_0{}^*-\frac{1}{2}\bar{B}_1{}^*\Big)K_1(kr_*)\,e^{-i\theta_*}+\frac{1}{2}\bar{B}_1{}^*K_2(kr_*)e^{-2i\theta_*}+\cdots\cdots\Big\}\,,\\
&\text{where}\\
&\qquad\qquad z_*=r_*e^{i\theta_*}=z+2ih\,.
\end{aligned}\right\} \tag{2.17}$$

The flow field under consideration must be symmetric with respect to the straight streamline $y=-h$, i.e. $\mathfrak{I}(w)=0$ along $y=-h$. This condition yields immediately the following relations between the constants in (2.17):

$$\left.\begin{array}{lll} A_0^* = \overline{A}_0\,, & A_1^* = \overline{A}_1\,, & \cdots\cdots \\ B_0^* = \overline{B}_0\,, & B_1^* = \overline{B}_1\,, & \cdots\cdots\,. \end{array}\right\} \tag{2.18}$$

## § 3. Fulfilment of the Boundary Conditions on the Cylinders

We now proceed to consider the remaining boundary conditions, namely the conditions at the surfaces of the two cylinders. The flow is symmetric with respect to the streamline $y=-h$ and since the solution (2.16) together with (2.17) and (2.18) already satisfies this condition, it is sufficient to consider the fulfilment of the condition on one cylinder $C_1$ ($z=ae^{i\theta}$) only.

The resultant velocity $U+w$ must be zero on the surface of the cylinder, so that the required boundary condition is written as:

$$(w)_{r=a} = -U\,. \tag{3.1}$$

In order to apply this to $w$ as given by (2.16), we expand $w$ in a Fourier series in $\theta$ on the surface ($r=a$) of the cylinder $C_1$.

$w_h^{(1)}$ has already the required form:

$$(w_h^{(1)})_{r=a} = \frac{A_0}{a}\,e^{-i\theta} + \frac{A_1}{a^2}\,e^{-2i\theta} + \cdots\cdots\,. \tag{3.2}$$

Making use of the formula

$$e^{kx} = e^{kr\cos\theta} = \sum_{n=-\infty}^{\infty} I_n(kr)e^{in\theta}\,, \tag{3.3}$$

$w_u^{(1)}$ can be easily expanded in the form:

$$\begin{aligned} (w_u^{(1)})_{r-a} = {} & B_0I_0K_0 + \overline{B}_0I_1K_1 - \frac{1}{2}B_1(I_0K_0 - I_1K_1) - \frac{1}{2}\overline{B}_1(I_1K_1 - I_2K_2) \\ & + \left\{B_0I_1K_0 + \overline{B}_0I_0K_1 - \frac{1}{2}B_1(I_1K_0 - I_2K_1) - \frac{1}{2}\overline{B}_1(I_0K_1 - I_1K_2)\right\}e^{-i\theta} \\ & + \left\{B_0I_1K_0 + \overline{B}_0I_2K_1 + \frac{1}{2}B_1(I_0K_1 - I_1K_0) - \frac{1}{2}\overline{B}_1(I_2K_1 - I_3K_2)\right\}e^{i\theta} \\ & + \left\{B_0I_2K_0 + \overline{B}_0I_1K_1 - \frac{1}{2}B_1(I_2K_0 - I_3K_1) - \frac{1}{2}\overline{B}_1(I_1K_1 - I_0K_2)\right\}e^{-2i\theta} \\ & + \cdots\cdots\cdots\cdots\cdots\,, \end{aligned} \tag{3.4}$$

where the argument $ka$ of the modified Bessel functions $I_n$, $K_n$ has been omitted for simplicity.

Further, assuming that $h \gg a$, $w_h^{(2)}$ may be immediately expanded as:

$$\begin{aligned} (w_h^{(2)})_{r=a} = {} & \frac{1}{2ih}\overline{A}_0 + \frac{1}{(2ih)^2}\overline{A}_1 + \cdots\cdots - \left\{\frac{a}{(2ih)^2}\overline{A}_0 + \frac{2a}{(2ih)^3}\overline{A}_1 + \cdots\cdots\right\}e^{i\theta} \\ & + \cdots\cdots\cdots\cdots\cdots\,, \end{aligned} \tag{3.5}$$

where the condition (2.18) has been taken into account.

Finally, we proceed to obtain the expansion of $w_u^{(2)}$. Making use of the addition theorem[†] of the modified Bessel functions, we get

$$K_\sigma(kr_*)e^{i\sigma\theta_*} = \sum_{s=-\infty}^{\infty} i^{s+\sigma} I_s(kr) K_{s-\sigma}(2kh) e^{is\theta}\,. \tag{3.6}$$

Therefore, combining this with (3.3), we obtain the expansion

---

[†] See, for example, G. N. Watson, *A Treatise on the Theory of Bessel Functions* (Cambridge, 1922), § 11.3, p. 361.

$$\left.\begin{aligned} &[e^{kx}K_\sigma(kr_*)e^{i\sigma\theta_*}]_{r=a}=\sum_{n=-\infty}^{\infty}\lambda_{n,\sigma}e^{in\theta}\,,\\ &\lambda_{n,\sigma}=\sum_{s=-\infty}^{\infty}i^{s+\sigma}I_s(ka)I_{s-n}(ka)K_{s-\sigma}(2kh)\,,\\ &\sigma=0,\ \pm1,\ \pm2,\ \cdots\,. \end{aligned}\right\} \tag{3.7}$$

Obviously it follows

$$\lambda_{-n,-\sigma}=\overline{\lambda_{n,\sigma}}\,. \tag{3.8}$$

Using (3.7) together with (2.18), we finally obtain the expansion of the function $w_u^{(2)}$ in (2.17) in the following form:

$$[w_u^{(2)}]_{r=a}=\sum_{n=-\infty}^{\infty}\left\{\lambda_{n,0}\overline{B}_0+\frac{1}{2}(\lambda_{n,1}-\lambda_{n,0})\overline{B}_1+\lambda_{n,-1}B_0+\frac{1}{2}(\lambda_{n,-2}-\lambda_{n,-1})B_1+\cdots\right\}e^{in\theta}\,. \tag{3.9}$$

Substituting (3.2), (3.4), (3.5) and (3.9) into (2.16), we arrive at the Fourier expansion of the solution $w$ on the circular cylinder $r=a$.

According to the boundary condition (3.1), every coefficient of $e^{in\theta}$ ($n=0, \pm1, \pm2, \cdots$) in the expansion should vanish except for the constant term ($n=0$), which must be equal to $-U$. Thus, we obtain a doubly infinite set of linear algebraic equations for determining the constants $A_n$'s and $B_n$'s. Namely, for $n=0, -1, 1, -2, \cdots$, we have

$$\left.\begin{aligned} &(I_0K_0+\lambda_{0,-1})B_0+(I_1K_1+\lambda_{0,0})\overline{B}_0\\ &\quad+\frac{1}{2}(I_1K_1-I_0K_0+\lambda_{0,-2}-\lambda_{0,-1})B_1+\frac{1}{2}(I_2K_2-I_1K_1+\lambda_{0,1}-\lambda_{0,0})\overline{B}_1+\cdots\\ &\quad+\frac{1}{2ih}\overline{A}_0+\frac{1}{(2ih)^2}\overline{A}_1+\cdots\cdots=-U\,,\\ &(I_1K_0+\lambda_{-1,-1})B_0+(I_0K_1+\lambda_{-1,0})\overline{B}_0\\ &\quad+\frac{1}{2}(I_2K_1-I_1K_0+\lambda_{-1,-2}-\lambda_{-1,-1})B_1+\frac{1}{2}(I_1K_2-I_0K_1+\lambda_{-1,1}-\lambda_{-1,0})\overline{B}_1+\cdots\\ &\quad+\frac{A_0}{a}+\cdots\cdots=0\,,\\ &(I_1K_0+\lambda_{1,-1})B_0+(I_2K_1+\lambda_{1,0})\overline{B}_0\\ &\quad+\frac{1}{2}(I_0K_1-I_1K_0+\lambda_{1,-2}-\lambda_{1,-1})B_1+\frac{1}{2}(I_3K_2-I_2K_1+\lambda_{1,1}-\lambda_{1,0})\overline{B}_1+\cdots\\ &\quad-\frac{a}{(2ih)^2}\overline{A}_0-\frac{2a}{(2ih)^3}\overline{A}_1-\cdots\cdots=0\,,\\ &(I_2K_0+\lambda_{-2,-1})B_0+(I_1K_1+\lambda_{-2,0})\overline{B}_0\\ &\quad+\frac{1}{2}(I_3K_1-I_2K_0+\lambda_{-2,-2}-\lambda_{-2,-1})B_1+\frac{1}{2}(I_0K_2-I_1K_1+\lambda_{-2,1}-\lambda_{-2,0})\overline{B}_1+\cdots\\ &\quad+\frac{A_1}{a^2}+\cdots\cdots=0\,, \end{aligned}\right\} \tag{3.10}$$

where the argument $ka$ of the modified Bessel functions has been dropped for simplicity.

## § 4. Approximate Solution for the Case $ka \ll 1$, $(kh)^{-1}=O(1)$

The system of simultaneous equations (3.10) for determining constants $A_n$'s and $B_n$'s having been derived, we can obtain, the required solution satisfying all the boundary conditions. But, it is difficult to solve the equations (3.10) exactly. Since, however, we are mainly interested in the flow at small Reynolds numbers, i.e. the flow for which $ka$ takes small values, where the Oseen approximation is applicable, we next proceed to find out the approximate solution valid for such small values of $ka$.

Eliminating $A_n$'s from (3.10) and separating real and imaginary parts, we obtain the system of equations for determining $B_n=b_n+i\beta_n$:

$$\left.\begin{aligned}
&C_{11}b_0+C_{12}\beta_0+C_{13}(b_1/2)+C_{14}(\beta_1/2)+\cdots\cdots=-U\,,\\
&C_{i1}b_0+C_{i2}\beta_0+C_{i3}(b_1/2)+C_{i4}(\beta_1/2)+\cdots\cdots=0\\
&\qquad\qquad (i=2,\ 3,\ 4,\ \cdots)\,.
\end{aligned}\right\}\tag{4.1}$$

The coefficients $C_{ij}$ are given as follows:

$$\left.\begin{aligned}
C_{11}&=I_0K_0+I_1K_1+p_{0,\,0}+p_{0,\,-1}+(a/2h)(q_{-1,\,0}+q_{-1,\,-1})\\
&\qquad+(a/2h)^2(I_2K_0+I_1K_1+p_{-2,\,0}+p_{-2,\,-1})\,,\\
C_{12}&=-q_{0,\,-1}+(a/2h)(I_1K_0-I_0K_1-p_{-1,\,0}+p_{-1,\,-1})+(a/2h)^2(q_{-2,\,0}-q_{-2,\,-1})\,,\\
C_{13}&=I_2K_2-I_0K_0+p_{0,\,1}+p_{0,\,-2}+(a/2h)(q_{-1,\,1}+q_{-1,\,-2})\\
&\qquad+(a/2h)^2(I_3K_1-I_2K_0+I_0K_2-I_1K_1+p_{-2,\,1}+p_{-2,\,-2})\,,\\
C_{14}&=q_{0,\,1}-q_{0,\,-2}+(a/2h)(I_2K_1-I_1K_0-I_1K_2+I_0K_1-p_{-1,\,1}+p_{-1,\,-2})\\
&\qquad+(a/2h)^2(q_{-2,\,1}-q_{-2,\,-2})\,,\\
C_{21}&=q_{0,\,-1}+(1/2kh)-(a/2h)^2(q_{-2,\,0}+q_{-2,\,-1})\,,\\
C_{22}&=I_0K_0-I_1K_1-p_{0,\,0}+p_{0,\,-1}-(a/2h)^2(I_2K_0-I_1K_1-p_{-2,\,0}+p_{-2,\,-1})\,,\\
C_{23}&=q_{0,\,1}+q_{0,\,-2}-(a/2h)^2(q_{-2,\,1}+q_{-2,\,-2})\,,\\
C_{24}&=2I_1K_1-I_0K_0-I_2K_2-p_{0,\,1}+p_{0,\,-2}\\
&\qquad-(a/2h)^2(I_3K_1-I_2K_0-I_0K_2+I_1K_1-p_{-2,\,1}+p_{-2,\,-2})\,,\\
C_{31}&=I_1K_0+I_2K_1+p_{1,\,0}+p_{1,\,-1}-(1/2kh)^2ka+2(a/2h)^3(q_{-2,\,0}+q_{-2,\,-1})\,,\\
C_{32}&=q_{1,\,0}-q_{1,\,-1}+2(a/2h)^3(I_2K_0-I_1K_1-p_{-2,\,0}+p_{-2,\,-1})\,,\\
C_{33}&=I_0K_1-I_1K_0+I_3K_2-I_2K_1+p_{1,\,1}+p_{1,\,-2}+2(a/2h)^3(q_{-2,\,1}+q_{-2,\,-2})\,,\\
C_{34}&=q_{1,\,1}-q_{1,\,-2}+2(a/2h)^3(I_3K_1-I_2K_0-I_0K_2+I_1K_1-p_{-2,\,1}+p_{-2,\,-2})\,,\\
C_{41}&=q_{1,\,0}+q_{1,\,-1}+(a/2h)^2(q_{-1,\,0}+q_{-1,\,-1})+2(a/2h)^3(I_2K_0+I_1K_1+p_{-2,\,0}+p_{-2,\,-1})\,,\\
C_{42}&=I_1K_0-I_2K_1-p_{1,\,0}+p_{1,\,-1}+(a/2h)^2(I_1K_0-I_0K_1-p_{-1,\,0}+p_{-1,\,-1})\\
&\qquad+2(a/2h)^3(q_{-2,\,0}-q_{-2,\,-1})\,,\\
C_{43}&=q_{1,\,1}+q_{1,\,-2}+(a/2h)^2(q_{-1,\,1}+q_{-1,\,-2})\\
&\qquad+2(a/2h)^3(I_3K_1-I_2K_0+I_0K_2-I_1K_1+p_{-2,\,1}+p_{-2,\,-2})\,,\\
C_{44}&=I_0K_1-I_1K_0-I_3K_2+I_2K_1-p_{1,\,1}+p_{1,\,-2}\\
&\quad+(a/2h)^2(I_2K_1-I_1K_0-I_1K_2+I_0K_1-p_{-1,\,1}+p_{-1,\,-2})+2(a/2h)^3(q_{-2,\,1}-q_{-2,\,-2})\,,
\end{aligned}\right\}\tag{4.2}$$

where we have put

$$\left.\begin{aligned}
&\lambda_{n,\,0}=p_{n,\,0}+iq_{n,\,0}\,, &&\lambda_{n,\,-1}=p_{n,\,-1}+iq_{n,\,-1}\,,\\
&\lambda_{n,\,1}-\lambda_{n,\,0}=p_{n,\,1}+iq_{n,\,1}\,, &&\lambda_{n,\,-2}-\lambda_{n,\,-1}=p_{n,\,-2}+iq_{n,\,-2}\,,\ \cdots\cdots
\end{aligned}\right\}\tag{4.3}$$

$p_{n,\,\sigma}$ and $q_{n,\,\sigma}$ being all real.

In the first place, let us consider the case where $(kh)^{-1}=\mathrm{O}(1)$[†] and $ka\ll 1$. In this case the coefficients $C_{ij}$ given by (4.2) can be expanded as follows:

$$\left.\begin{aligned}
C_{11}&=H_*+\{(1/4)+2K_0+H_*+N\}(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{12}&=-M-2\{M-(1/kh)(1+H)\}(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{13}&=(3/4)-H_*+N-\{(1/6)+2(K_0+H_*)-(1/kh)(K_1-M)\}(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{14}&=-(1/2kh)(1+4H)(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{21}&=M-2K_1(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{22}&=H+\{(11/4)+2K_2+3H+N\}(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{23}&=2K_1+(5K_1-K_3)(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{24}&=(1/4)-H+N-\{(10/3)+(1/2k^2h^2)+4(K_2+H)\}(ka/2)^2+\mathrm{O}(k^4a^4)\,,\\
C_{31}&=-\{(1/4)-H_*+N\}(ka/2)+\{(1/3)+K_2+H_*\}(ka/2)^3+\mathrm{O}(k^5a^5)\,,\\
C_{32}&=2K_1(ka/2)+(1/2)\{5K_1-K_3-(2/k^3h^3)\}(ka/2)^3+\mathrm{O}(k^5a^5)\,,
\end{aligned}\right\}\tag{4.4}$$

---

[†] $4kh=2Uh/\nu$ is a Reynolds number referred to the distance $2h$ between the two cylinders.

$$\left.\begin{aligned}
C_{33}&=(1/2)(ka/2)^{-1}+2\{(5/12)-K_2-H_*\}(ka/2)\\
&\qquad -(1/2)\{(31/24)+4K_2-K_4+5H_*\}(ka/2)^3+O(k^5a^5)\ ,\\
C_{34}&=-(2N/kh)(ka/2)+(4/kh)\{K_2+(1/4k^2h^2)\}(ka/2)^3+O(k^5a^5)\ ,\\
C_{41}&=(1/kh)\{K_2+(2/kh)M\}(ka/2)^3+O(k^5a^5)\ ,\\
C_{42}&=\{(1/4)+H-N\}(ka/2)+2\{(13/12)+2K_2+H+N+(H/k^2h^2)\}(ka/2)^3+O(k^5a^5)\ ,\\
C_{43}&=(2N/kh)(ka/2)-(4/kh)\{K_0+(1/4k^2h^2)\}(ka/2)^3+O(k^5a^5)\ ,\\
C_{44}&=(1/2)(ka/2)^{-1}-2\{(5/12)+K_2+H\}(ka/2)\\
&\qquad -(1/2)[(185/24)-(3/kh)K_3+(1/k^2h^2)+(K_2+H)\{7+(4/k^2h^2)\}](ka/2)^3+O(k^5a^5)\ ,
\end{aligned}\right|$$

$$\left.\begin{aligned}
&\text{where}\quad H=S-1-K_0\ ,\quad H_*=S+K_0\ ,\quad M=(1/2kh)-K_1\ ,\quad N=(1/2k^2h^2)-K_2\ ,\\
&\text{with}\quad S=(1/2)-\gamma-\log(ka/2)\ ,
\end{aligned}\right\}\tag{4.5}$$
